1.1 GLOSSARY

(NS)	indicates nonstandard terminology
italics	definition or first usage
∇	gradient $(\partial/\partial x, \partial/\partial y, \partial/\partial z)$
prime, unprime	before and after, object and image space (not derivatives)
A	auxiliary function for ray tracing
A, A'	area, total field areas, object and image points
AB	directed distance from A to B
$\mathbf{a}$	unit axis vector, vectors
a_O, a_B, a_I	coefficients in characteristic function expansion
B	matrix element for symmetrical systems
B	auxiliary function for ray tracing
B, B'	arbitrary object and image points
$\mathbf{b}$	binormal unit vector of a ray path
$\mathcal{B}$	interspace (between) term in expansion
C	matrix element for conjugacy
$C(\mathcal{O}, \mathcal{B}, \mathcal{I})$	characteristic function
c	speed of light in vacuum
c	surface vertex curvature, spherical surface curvature
c_s	sagittal curvature
c_t	tangential curvature
D	auxiliary distance function for ray tracing
d	distance from origin to mirror
d	nominal focal distance
d, d'	arbitrary point to conjugate object, image points $d = AO$, $d' = A'O'$
d, d'	axial distances, distances along rays
d_H	hyperfocal distance

d_N	near focal distance
d_F	far focal distance
dA	differential area
ds	differential geometric path length
E	image irradiance
E_0	axial image irradiance
E, E'	entrance and exit pupil locations
e	eccentricity
e_x, e_y, e_z	coefficients for collineation
F	matrix element for front side
F, F'	front and rear focal points
FN	F-number
FN_m	F-number for magnification m
$F(\ )$	general function
$F(x, y, z)$	general surface function
f, f'	front and rear focal lengths $f = PF$, $f' = P'F'$
G	diffraction order
g, g'	focal lengths in tilted planes
h, h'	ray heights at objects and images, field heights, $\sqrt{x^2 + y^2}$
$\mathscr{H}$	hamiltonian
I, I'	incidence angles
$\mathbf{I}$	unit matrix
i, i'	paraxial incidence angles
$\mathscr{I}$	image space term in characteristic function expansion
L	surface x-direction cosine
L	paraxial invariant
l, l'	principal points to object and image axial points $l = PO$, $l' = P'O'$ axial distances from vertices of refracting surface $l = VO$, $l' = V'O'$
$\mathscr{L}$	lagrangian for heterogeneous media
M	lambertian emittance
M	surface z-direction cosine
m	transverse magnification
m_L	longitudinal magnification
m_α	angular magnification
m_E	paraxial pupil magnification
m_N	nodal point magnification $= n/n'$
m_P	pupil magnification in direction cosines
m_O	magnification at axial point
m_x, m_y, m_z	magnifications in the x, y, and z directions
N	surface z-direction cosine
N, N'	nodal points
NA, NA'	numerical aperture
n	refractive index

$\mathbf{n}$	normal unit vector of a ray path
O, O'	axial object and image points
$\mathcal{O}$	object space term in expansion
P	power (radiometric)
P, P'	principal points
$P(\alpha, \beta; x, y)$	pupil shape functions
$P'(\alpha', \beta'; x', y')$	
p	period of grating
$\mathbf{p}$	ray vector, optical direction cosine $\mathbf{p} = n\,\mathbf{r} = (p_x, p_y, p_z)$
p	pupil radius
p_x, p_y, p_z	optical direction cosines
$Q(\alpha, \beta; x, y)$	pupil shape functions relative to principal direction cosines
$Q'(\alpha', \beta'; x', y')$	
q	resolution parameter
q_i	coordinate for Lagrange equations
$\dot{q}_i$	derivative with respect to parameter
q, q'	auxiliary functions for collineation
$\mathbf{q}$	unit vector along grating lines
R	matrix element for rear side
r	radius of curvature, vertex radius of curvature
$\mathbf{r}$	ray unit direction vector $\mathbf{r} = (\alpha, \beta, \gamma)$
$\mathbf{S}$	surface normal $\mathbf{S} = (L, M, N)$
$S(x, y, x', y')$	point eikonal $V(x, y, z_0; x', y', z_{0'})$
s	geometric length
s	axial length
s, s'	distances associated with sagittal foci
$\mathscr{S}$	skew invariant
$T(\alpha, \beta; \alpha', \beta')$	angle characteristic function
t	thickness, vertex-to-vertex distance
t, t'	distances associated with tangential foci
t	time
$\mathbf{t}$	tangent unit vector of a ray path
U, U'	meridional ray angles relative to axis
u, u'	paraxial ray angles relative to axis
u_M	paraxial marginal ray angle
u_C	paraxial chief ray angle
u_1, u_2, u_3, u_4	homogeneous coordinates for collineation
V	optical path length
$V(\mathbf{x}; \mathbf{x}')$	point characteristic function
V, V'	vertex points

v	speed of light in medium
W_{LMN}	wavefront aberration term
W_x, W_y, W_z	wavefront aberration terms for reference shift
$W(\xi, \eta; x, y, z)$	wavefront aberration function
$W'(\alpha, \beta; x', y')$	angle-point characteristic function
$W(x, y; \alpha', \beta')$	point-angle characteristic function
$\mathbf{x} = (x, y, z)$	position vector
$\mathbf{x}(\sigma)$	parametric description of ray path
$\dot{\mathbf{x}}(\sigma)$	derivative with respect to parameter
$\ddot{\mathbf{x}}(\sigma)$	second derivative with respect to parameter
y	meridional ray height, paraxial ray height
y_M	paraxial marginal ray height
y_C	paraxial chief ray height
y_P, y'_P	paraxial ray height at the principal planes
z	axis of revolution
$z(\rho)$	surface sag
z_{sphere}	sag of a sphere
z_{conic}	sag of a conic
z, z'	focal point to object and image distances $z = FO, z' = F'O'$
α, β, γ	ray direction cosines
α, β, γ	entrance pupil directions
α', β', γ'	exit pupil direction cosines
α_0, β_0	principal direction of entrance pupil
α'_0, β'_0	principal direction of exit pupil
$\alpha_{\mathrm{max}}, \alpha_{\mathrm{min}}$	extreme pupil directions
$\beta_{\mathrm{max}}, \beta_{\mathrm{min}}$	extreme pupil directions
Γ	$n' \cos I' - n \cos I$
$\delta x, \delta y, \delta z$	reference point shifts
$\Delta\alpha, \Delta\beta$	angular aberrations
$\Delta x, \Delta y, \Delta z$	shifts
ε	surface shape parameter
$\varepsilon_x, \varepsilon_y$	transverse ray aberrations
ξ, η	pupil coordinates—not specific
θ	ray angle to surface normal marginal ray angle plane tilt angle

κ	conic parameter
κ	curvature of a ray path
λ	wavelength
ψ	aximuth angle field angle
ϕ	power, surface power azimuth
ρ	radius of curvature of a ray path distance from axis radial pupil coordinate
σ	ray path parameter general parameter for a curve
τ	reduced axial distances torsion of a ray path
$\tau(\alpha', \beta'; x', y')$	pupil transmittance function
ω, ω'	reduced angle $\omega = nu,\ \omega' = n'u'$
$d\omega$	differential solid angle

1.2 INTRODUCTION

The Subject

Geometrical optics is both the object of abstract study and a body of knowledge necessary for design and engineering. The subject of geometric optics is small, since so much can be derived from a single principle, that of Fermat, and large since the consequences are infinite and far from obvious. Geometric optics is deceptive in that much that seems simple is loaded with content and implications, as might be suggested by the fact that some of the most basic results required the likes of Newton and Gauss to discover them. Most of what appears complicated seems so because of obscuration with mathematical terminology and excessive abstraction. Since it is so old, geometric optics tends to be taken for granted and treated too casually by those who consider it to be "understood." One consequence is that what has been long known can be lost if it is not recirculated by successive generations of textbook authors, who are pressed to fit newer material in a fairly constant number of pages.

The Contents

The material in this chapter is intended to be that which is most fundamental, most general, and most useful to the greatest number of people. Some of this material is often thought to be more esoteric than practical, but this opinion is less related to its essence than to its typical presentation. There are no applications per se here, but everything is applicable, at least to understanding. An effort has been made to compensate here for what is lacking elsewhere and to correct some common errors. Many basic ideas and useful results have not found their way into textbooks, so are little known. Moreover, some basic principles are rarely stated explicitly. The contents are weighted toward the most common type of optical system, that with rotational symmetry consisting of mirrors and/or lens elements of homogeneous materials. There is a section on heterogeneous media, an application of which is gradient index optics discussed in another chapter. The treatment here is mostly monochromatic. The topics of caustics and anisotropic media are omitted, and there is little specifically about systems that are not figures of revolution. The section on aberrations is short and mostly descriptive, with no discussion of lens design, a vast field concerned with the practice of aberration control. Because of space limitations, there are too few diagrams.

Terminology

Because of the complicated history of geometric optics, its terminology is far from standardized. Geometric optics developed over centuries in many countries, and much of it has been rediscovered and renamed. Moreover, concepts have come into use without being named, and important terms are often used without formal definitions. This lack of standardization complicates communication between workers at different organizations, each of which tends to develop its own optical dialect. Accordingly, an attempt has been made here to provide precise definitions. Terms are italicized where defined or first used. Some needed nonstandard terms have been introduced, and these are likewise italicized, as well as indicated by ''NS'' for ''nonstandard.''

Notation

As with terminology, there is little standardization. And, as usual, the alphabet has too few letters to represent all the needed quantities. The choice here has been to use some of the same symbols more than once, rather than to encumber them with superscripts and subscripts. No symbol is used in a given section with more than one meaning. As a general practice nonprimed and primed quantities are used to indicate before and after, input and output, and object and image space.

References

No effort has been made to provide complete references, either technical or historical. (Such a list would fill the entire section.) The references were not chosen for priority, but for elucidation or interest, or because of their own references. Newer papers can be found by computer searches, so the older ones have been emphasized, especially since older work is receding from view beneath the current flood of papers. In geometric optics, nothing goes out of date, and much of what is included here has been known for a century or so—even if it has been subsequently forgotten.

Communication

Because of the confusion in terminology and notation, it is recommended that communication involving geometric optics be augmented with diagrams, graphs, equations, and numeric results, as appropriate. It also helps to provide diagrams showing both first order properties of systems, with object and image positions, pupil positions, and principal planes, as well as direction cosine space diagrams, as required, to show angular subtenses of pupils.

1.3 FUNDAMENTALS

What Is a Ray?

Geometric optics, which might better be called *ray optics,* is concerned with the light ray, an entity that does not exist. It is customary, therefore, to begin discussions of geometric optics with a theoretical justification for the use of the ray. The real justification is that, like other successful models in physics, rays are indispensable to our thinking, notwithstanding their shortcomings. The ray is a model that works well in some cases and not at all in others, and light is necessarily thought about in terms of rays, scalar waves, electromagnetic waves, and with quantum physics—depending on the class of phenomena under consideration.

Rays have been defined with both corpuscular and wave theory. In corpuscular theory, some definitions are (1) the path of a corpuscle and (2) the path of a photon. A difficulty here is that energy densities can become infinite. Other efforts have been made to define rays as quantities related to the wave theory, both scalar and electromagnetic. Some are (1) wavefront normals, (2) the Poynting vector, (3) a discontinuity in the electromagnetic field (Luneburg 1964,[1] Kline & Kay 1965[2]), (4) a descriptor of wave behavior in short wavelength or high frequency limit, (Born & Wolf 1980[3]) (5) quantum mechanically (Marcuse 1989[4]). One problem with these definitions is that there are many ordinary and simple cases where wavefronts and Poynting vectors become complicated and/or meaningless. For example, in the simple case of two coherent plane waves interfering, there is no well-defined wavefront in the overlap region. In addition, rays defined in what seems to be a reasonble way can have undesirable properties. For example, if rays are defined as normals to wavefronts, then, in the case of gaussian beams, rays bend in a vacuum.

An approach that avoids the difficulties of a physical definition is that of treating rays as mathematical entities. From definitions and postulates, a variety of results is found, which may be more or less useful and valid for light. Even with this approach, it is virtually impossible to think "purely geometrically"—unless rays are treated as objects of geometry, rather than optics. In fact, we often switch between ray thinking and wave thinking without noticing it, for instance in considering the dependence of refractive index on wavelength. Moreover, geometric optics makes use of quantities that must be calculated from other models, for example, the index of refraction. As usual, Rayleigh (Rayleigh 1884[5]) has put it well: "We shall, however, find it advisable not to exclude altogether the conceptions of the wave theory, for on certain most important and practical questions no conclusion can be drawn without the use of facts which are scarcely otherwise interpretable. Indeed it is not to be denied that the too rigid separation of optics into geometrical and physical has done a good deal of harm, much that is essential to a proper comprehension of the subject having fallen between the two stools."

The ray is inherently ill-defined, and attempts to refine a definition always break down. A definition that seems better in some ways is worse in others. Each definition provides some insight into the behavior of light, but does not give the full picture. There seems to be a problem associated with the uncertainty principle involved with attempts at definition, since what is really wanted from a ray is a specification of both position and direction, which is impossible by virtue of both classical wave properties and quantum behavior. So the approach taken here is to treat rays without precisely defining them, and there are few reminders hereafter that the predictions of ray optics are imperfect.

Refractive Index

For the purposes of this chapter, the optical characteristics of matter are completely specified by its refractive index. The *index of refraction* of a medium is defined in geometrical optics as

$$n = \frac{\text{speed of light in vacuum}}{\text{speed of light in medium}} = \frac{\mathrm{c}}{\mathrm{v}} \tag{1}$$

A *homogeneous medium* is one in which n is everywhere the same. In an *inhomogeneous* or *heterogeneous medium* the index varies with position. In an *isotropic medium* n is the same at each point for light traveling in all directions and with all polarizations, so the index is described by a scalar function of position. Anisotropic media are not treated here.

Care must be taken with equations using the symbol n, since it sometimes denotes the ratio of indices, sometimes with the implication that one of the two is unity. In many cases, the difference from unity of the index of air ($\simeq$1.0003) is important. Index varies with wavelength, but this dependence is not made explicit in this section, most of which is implicitly limited to monochromatic light. The output of a system in polychromatic light is the sum of outputs at the constituent wavelengths.

Systems Considered

The optical systems considered here are those in which spatial variations of surface features or refractive indices are large compared to the wavelength. In such systems ray identity is preserved; there is no "splitting" of one ray into many as occurs at a grating or scattering surface.

The term *lens* is used here to include a variety of systems. *Dioptric* or *refractive* systems employ only refraction. *Catoptric* or *reflective* systems employ only reflection. *Catadioptric* systems employ both refraction and reflection. No distinction is made here insofar as refraction and reflection can be treated in a common way. And the term lens may refer here to anything from a single surface to a system of arbitrary complexity.

Summary of the Behavior and Attributes of Rays

Rays propagate in straight lines in homogeneous media and have curved paths in heterogeneous media. Rays have positions, directions, and speeds. Between any pair of points on a given ray there is a geometrical path length and an optical path length. At smooth interfaces between media with different indices rays refract and reflect. Ray paths are reversible. Rays carry energy, and power per area is approximated by ray density.

Reversibility

Rays are reversible; a path can be taken in either direction, and reflection and refraction angles are the same in either direction. However, it is usually easier to think of light as traveling along rays in a particular direction, and, of course, in cases of real instruments there usually is such a direction. The solutions to some equations may have directional ambiguity.

Groups of Rays

Certain types of groups of rays are of particular importance. Rays that originate at a single point are called a *normal congruence* or *orthotomic system,* since as they propagate in isotropic media they are associated with perpendicular wavefronts. Such groups are also of interest in image formation, where their reconvergence to a point is important, as is the path length of the rays to a reference surface used for diffraction calculations. Important in radiometric considerations are groups of rays emanating from regions of a source over a range of angles. The changes of such groups as they propagate are constrained by conservation of brightness. Another group is that of two meridional paraxial rays, related by the two-ray invariant.

Invariance Properties

Individual rays and groups of rays may have *invariance properties*—relationships between the positions, directions, and path lengths—that remain constant as a ray or group of rays passes through an optical system (Welford 1986, chap. 6[6]). Some of these properties are completely general, e.g., the conservation of etendue and the perpendicularity of rays to wavefronts in isotropic media. Others arise from symmetries of the system, e.g., the skew invariant for rotationally symmetric systems. Other invariances hold in the paraxial limit. There are also differential invariance properties (Herzberger 1935,[7] Stavroudis 1972, chap. 13[8]). Some ray properties not ordinarily thought of in this way can be thought of as invariances. For example, Snell's law can be thought of as a refraction invariant $n \sin I$.

Description of Ray Paths

A *ray path* can be described parametrically as a locus of points $\mathbf{x}(\sigma)$, where σ is any monotonic parameter that labels points along the ray. The description of curved rays is elaborated in the section on heterogeneous media.

Real Rays and Virtual Rays

Since rays in homogeneous media are straight, they can be extrapolated infinitely from a given region. The term *real* refers to the portion of the ray that "really" exists, or the accessible part, and the term *virtual* refers to the extrapolated, or inaccessible, part.

Direction

At each position where the refractive index is continuous a ray has a unique direction. The direction is given by that of its unit *direction vector* **r**, whose cartesian components are direction cosines (α, β, γ), i.e.,

$$\mathbf{r} = (\alpha, \beta, \gamma)$$

where $|\mathbf{r}|^2 = \alpha^2 + \beta^2 + \gamma^2 = 1$. (2)

The three direction cosines are not independent, and one is often taken to depend implicitly on the other two. In this chapter it is usually γ, which is

$$\gamma(\alpha, \beta) = \sqrt{1 - \alpha^2 - \beta^2} \qquad (3)$$

Another vector with the same direction as $\mathbf{r}$ is

$$\mathbf{p} = n\mathbf{r} = (n\alpha, n\beta, n\gamma) = (p_x, p_y, p_z)$$

where $|\mathbf{p}|^2 = n^2$. (4)

Several names are used for this vector, including the *optical direction cosine* and the *ray vector.*

Geometric Path Length

Geometric path length is geometric distance measured along a ray between any two points. The differential unit of length is

$$ds = \sqrt{dx^2 + dy^2 + dz^2} \tag{5}$$

The path length between points $\mathbf{x}_1$ and $\mathbf{x}_2$ on a ray described parametrically by $\mathbf{x}(\sigma)$, with derivative $\dot{\mathbf{x}}(\sigma) = d\mathbf{x}(\sigma)/d\sigma$ is

$$s(\mathbf{x}_1; \mathbf{x}_2) = \int_{\mathbf{x}_1}^{\mathbf{x}_2} ds = \int_{\mathbf{x}_1}^{\mathbf{x}_2} \frac{ds}{d\sigma} d\sigma = \int_{\mathbf{x}_1}^{\mathbf{x}_2} \sqrt{|\dot{\mathbf{x}}(\sigma)|^2}\, d\sigma \tag{6}$$

Optical Path Length

The *optical path length* between two points $\mathbf{x}_1$ and $\mathbf{x}_2$ through which a ray passes is

$$\text{Optical path length} = V(\mathbf{x}_1; \mathbf{x}_2) = \int_{\mathbf{x}_1}^{\mathbf{x}_2} n(\mathbf{x})\, ds = \mathrm{c} \int \frac{ds}{\mathrm{v}} = \mathrm{c} \int d\mathrm{t} \tag{7}$$

The integral is taken along the ray path, which may traverse homogeneous and inhomogeneous media, and include any number of reflections and refractions. Path length can be defined for virtual rays. In some cases, path length should be considered positive definite, but in others it can be either positive or negative, depending on direction (Forbes & Stone 1993[9]). If $\mathbf{x}_0$, $\mathbf{x}_1$, and $\mathbf{x}_2$ are three points on the same ray, then

$$V(\mathbf{x}_0; \mathbf{x}_2) = V(\mathbf{x}_0; \mathbf{x}_1) + V(\mathbf{x}_1; \mathbf{x}_2) \tag{8}$$

Equivalently, the time required for light to travel between the two points is

$$\text{Time} = \frac{\text{optical path length}}{\mathrm{c}} = \frac{V}{\mathrm{c}} = \frac{1}{\mathrm{c}} \int_{\mathbf{x}_1}^{\mathbf{x}_2} n(\mathbf{x})\, ds = \int_{\mathbf{x}_1}^{\mathbf{x}_2} \frac{ds}{\mathrm{v}} \tag{9}$$

In homogeneous media, rays are straight lines, and the optical path length is $V = n \int ds =$ (index) × (distance between the points).

The optical path length integral has several interpretations, and much of geometrical optics involves the examination of its meanings. (1) With both points fixed, it is simply a scalar, the optical path length from one point to another. (2) With one point fixed, say $\mathbf{x}_0$, then treated as a function of $\mathbf{x}$, the surfaces $V(\mathbf{x}_0; \mathbf{x}) = \text{constant}$ are geometric wavefronts for light originating at $\mathbf{x}_0$. (3) Most generally, as a function of both arguments $V(\mathbf{x}_1; \mathbf{x}_2)$ is the *point characteristic function,* which contains all the information about the rays between the region containing $\mathbf{x}_1$ and that containing $\mathbf{x}_2$. There may not be a ray between all pairs of points.

Fermat's Principle

According to Fermat's principle (Magie 1963,[10] Fermat 1891,[11,12] Feynman 1963,[13] Rossi 1956,[14] Hecht 1987[15]) the optical path between two points through which a ray passes is an extremum. Light passing through these points along any other nearby path would take either more or less time. The principle applies to different *neighboring* paths. The optical path length of a ray may not be a global extremum. For example, the path lengths of rays through different facets of a Fresnel lens have no particular relationship. Fermat's principle applies to entire systems, as well as to any portion of a system, for example to any section of a ray. In a homogeneous medium, the extremum is a straight line or, if there are reflections, a series of straight line segments.

The extremum principle can be described mathematically as follows (Klein 1986[16]). With the end points fixed, if a nonphysical path differs from a physical one by an amount proportional to δ, the nonphysical optical path length differs from the actual one by a quantity proportional to δ^2 or to a higher order. If the order is three or higher, the first point is imaged at the second-to-first order. Roughly speaking, the higher the order, the better the image. A point is imaged stigmatically when a continuum of neighboring paths have the same length, so the equality holds to all orders. If they are sufficiently close, but vary slightly, the deviation from equality is a measure of the aberration of the imaging. An extension of Fermat's principle is given by Hopkins (H. Hopkins 1970[17]).

Ray and wave optics are related by the importance of path length in both (Walther 1967,[18] Walther 1969[19]). In wave optics, optical path length is proportional to phase change, and the extremum principle is associated with constructive interference. The more alike the path lengths are from an object point to its image, the less the differences in phase of the wave contributions, and the greater the magnitude of the net field. In imaging this connection is manifested in the relationship of the wavefront aberration and the eikonal.

Fermat's principle is a unifying principle of geometric optics that can be used to derive laws of reflection and refraction, and to find the equations that describe ray paths and geometric wavefronts in heterogeneous and homogeneous media. Fermat's is one of a number of variational principles based historically on the idea that nature is economical, a unifying principle of physics. The idea that the path length is an extremum could be used mathematically without interpreting the refractive index in terms of the speed of light.

Geometric Wavefronts

For rays originating at a single point, a *geometric wavefront* is a surface that is a locus of constant optical path length from the source. If the source point is located at $\mathbf{x}_0$ and light leaves at time t_0, then the wavefront at time t is given by

$$V(\mathbf{x}_0; \mathbf{x}) = \mathrm{c}(\mathrm{t} - \mathrm{t}_0) \tag{10}$$

The function $V(\mathbf{x}; \mathbf{x}_0)$, as a function of $\mathbf{x}$, satisfies the *eikonal equation*

$$\begin{aligned} n(\mathbf{x})^2 &= \left(\frac{\partial V}{\partial x}\right)^2 + \left(\frac{\partial V}{\partial y}\right)^2 + \left(\frac{\partial V}{\partial z}\right)^2 \\ &= |\nabla V(\mathbf{x}; \mathbf{x}_0)|^2 \end{aligned} \tag{11}$$

This equation can also be written in relativistic form, with a four-dimensional gradient as $0 = \sum (\partial V/\partial x_i)^2$ (Landau & Lifshitz 1951, sec. 7.1[20]).

For constant refractive index, the eikonal equation has some simple solutions, one of which is $V = n[\alpha(x - x_0) + \beta(y - y_0) + \gamma(z - z_0)]$, corresponding to a parallel bundle of rays with directions (α, β, γ). Another is $V = n[(x - x_0)^2 + (y - y_0)^2 + (z - z_0)^2]^{1/2}$, describing rays traveling radially from a point (x_0, y_0, z_0).

In isotropic media, rays and wavefronts are everywhere perpendicular, a condition referred to as *orthotomic.* According to the *Malus-Dupin principle*, if a group of rays emanating fron a single point is reflected and/or refracted any number of times, the perpendicularity of rays to wavefronts is maintained. The direction of a ray from $\mathbf{x}_0$ at $\mathbf{x}$ is that of the gradient of $V(\mathbf{x}_0; \mathbf{x})$

$$\mathbf{p} = n\mathbf{r} = \nabla V$$

or

$$n\alpha = \frac{\partial V}{\partial x} \qquad n\beta = \frac{\partial V}{\partial y} \qquad n\gamma = \frac{\partial V}{\partial z} \tag{12}$$

In a homogeneous medium, all wavefronts can be found from any one wavefront by a construction. Wavefront normals, i.e., rays, are projected from the known wavefront, and loci of points equidistant therefrom are other wavefronts. This gives wavefronts in both directions, that is, both subsequent and previous wavefronts. (A single wavefront contains no directional information.) The construction also gives virtual wavefronts, those which would occur or would have occurred if the medium extended infinitely. This construction is related to that of Huygens for wave optics. At each point on a wavefront there are two principal curvatures, so there are two foci along each ray and two caustic surfaces (Stavroudis 1972,[8] Kneisly 1964[21]).

The geometric wavefront is analogous to the surface of constant phase in wave optics, and the eikonal equation can be obtained from the wave equation in the limit of small wavelength (Born & Wolf 1980,[3] Marcuse 1989[4]). A way in which wave optics differs from ray optics is that the phase fronts can be modified by phase changes that occur on reflection, transmission, or in passing through foci.

Fields of Rays

In many cases the optical direction cosine vectors $\mathbf{p}$ form a field, where the optical path length is the potential, and the geometric wavefronts are equipotential surfaces. The potential changes with position according to

$$dV = n\alpha\, dx + n\beta\, dy + n\gamma\, dz = n\mathbf{r} \cdot d\mathbf{x} = \mathbf{p} \cdot d\mathbf{x} \tag{13}$$

If $d\mathbf{x}$ is in the direction of a ray, then $dV/dx = n,$ the maximum rate of change. If $d\mathbf{x}$ is perpendicular to a ray, then $dV/dx = 0$. The potential difference between any two wavefronts is

$$V_2 - V_1 = \int_{\mathbf{x}_1}^{\mathbf{x}_2} dV \tag{14}$$

where $\mathbf{x}_1$ and $\mathbf{x}_2$ are any two points on the respective wavefronts, and the integrand is independent of the path. Other relationships for rays originating at a single point are

$$0 = \nabla \times \mathbf{p} = \nabla \times (n\mathbf{r}) \qquad \text{and} \qquad 0 = \oint \mathbf{p} \cdot d\mathbf{x} \tag{15}$$

where the integral is about a closed path (Born & Wolf 1980[3]). These follow since $\mathbf{p}$ is a gradient, Eq. (13). In regions where rays are folded onto themselves by refraction or reflections, **p** and V are not single-valued, so there is not a field.

1.4 CHARACTERISTIC FUNCTIONS

Introduction

Characteristic functions contain all the information about the path lengths between pairs of points, which may either be in a contiguous region or physically separated, e.g., on the two sides of a lens. These functions were first considered by Hamilton (Hamilton 1931[22]), so their study is referred to as *hamiltonian optics.* They were rediscovered in somewhat different form by Bruns (Bruns 1895,[23] Schwarzschild 1905[24]) and referred to as eikonals, leading to a confusing set of names for the various functions. The subject is discussed in a number of books (Czapski-Eppenstein 1924,[25] Steward 1928,[26] Herzberger 1931,[27] Synge 1937,[28] Caratheodory 1937,[29] Rayleigh 1908,[30] Pegis 1961,[31] Luneburg 1964,[32] Brouwer and Walther 1967,[33] Buchdahl 1970,[34] Born & Wolf 1980,[35] Herzberger 1958[36]).

Four parameters are required to specify a ray. For example, an input ray is defined in the $z = 0$ plane by coordinates (x, y) and direction (α, β). So four functions of four variables specify how an incident ray emerges from a system. In an output plane $z' = 0$, the ray has coordinates $x' = x'(x, y, \alpha, \beta)$, $y' = y'(x, y, \alpha, \beta)$, and directions $\alpha' = \alpha'(x, y, \alpha, \beta)$, $\beta' = \beta'(x, y, \alpha, \beta)$. Because of Fermat's principle, these four functions are not independent, and the geometrical optics properties of a system can be fully characterized by a single function (Luneburg 1964, sec. 19[32]).

For any given system, there is a variety of characteristic functions related by Legendre transformations, with different combinations of spatial and angular variables (Buchdahl 1970[34]). The different functions are suited for different types of analysis. *Mixed* characteristic functions have both spatial and angular arguments. Those functions that are of most general use are discussed below. The others may be useful in special circumstances. If the regions have constant refractive indices, the volumes over which the characteristic functions are defined can be extended virtually from physically accessible to inaccessible regions.

From any of its characteristic functions, all the properties of a system involving ray paths can be found, for example, ray positions, directions, and geometric wavefronts. An important use of characteristic functions is demonstrating general principles and fundamental limitations. Much of this can be done by using the general properties, e.g., symmetry under rotation. (Unfortunately, it is not always known how closely the impossible can be approached.)

Point Characteristic Function

The *point characteristic function* is the optical path integral $V(\mathbf{x}; \mathbf{x}') = V(x, y, z; x', y', z')$ taken as a function of both points **x** and **x**$'$. At point **x** where the index is n,

$$-n\alpha = \frac{\partial V}{\partial x} \qquad -n\beta = \frac{\partial V}{\partial y} \qquad -n\gamma = \frac{\partial V}{\partial z} \qquad \text{or} \qquad -\mathbf{p} = \nabla V \tag{16}$$

Similarly, at $\mathbf{x}'$, where the index is n',

$$n'\alpha' = \frac{\partial V}{\partial x'} \qquad n'\beta' = \frac{\partial V}{\partial y'} \qquad n'\gamma' = \frac{\partial V}{\partial z'} \qquad \text{or} \qquad \mathbf{p}' = \nabla' V \tag{17}$$

It follows from the above equations and Eq. (4) that the point characteristic satisfies two conditions:

$$n^2 = |\nabla V|^2 \qquad \text{and} \qquad n'^2 = |\nabla' V|^2 \tag{18}$$

Therefore, the point characteristic is not an arbitrary function of six variables. The total differential of V is

$$dV(\mathbf{x}; \mathbf{x}') = \mathbf{p}' \cdot \mathrm{d}\mathbf{x}' - \mathbf{p} \cdot d\mathbf{x} \tag{19}$$

"This expression can be said to contain all the basic laws of optics" (Herzberger 1958[36]).

Point Eikonal

If reference planes in object and image space are fixed, for which we use z_0 and z_0', then the *point eikonal* is $S(x, y; x', y') = V(x, y, z_0; x', y', z_0')$. This is the optical path length between pairs of points on the two planes. The function is not useful if the planes are conjugate, since more than one ray through a pair of points can have the same path length. The function is arbitrary, except for the requirement (Herzberger 1936[38]) that

$$\frac{\partial^2 S}{\partial x\, \partial x'} \frac{\partial^2 S}{\partial y\, \partial y'} - \frac{\partial^2 S}{\partial x\, \partial y'} \frac{\partial^2 S}{\partial x'\, \partial y} \neq 0 \tag{20}$$

The partial derivatives of the point eikonal are

$$-n\alpha = \frac{\partial S}{\partial x} \qquad -n\beta = \frac{\partial S}{\partial y} \qquad \text{and} \qquad n'\alpha' = \frac{\partial S}{\partial x'} \qquad n'\beta' = \frac{\partial S}{\partial y'} \tag{21}$$

The relative merits of the point characteristic function and point eikonal have been debated. (Herzberger 1936,[38] Herzberger 1937,[39] Synge 1937[40]).

Angle Characteristic

The *angle characteristic function* $T(\alpha, \beta; \alpha', \beta')$, also called the *eikonal,* is related to the point characteristic by

$$\begin{aligned} T(\alpha, \beta; \alpha', \beta') = V(x, y, z; x', y', z') + n(\alpha x + \beta y + \gamma z) \\ - n'(\alpha' x' + \beta' y' + \gamma' z') \end{aligned} \tag{22}$$

Here the input plane z and output plane z' are fixed and are implicit parameters of T.

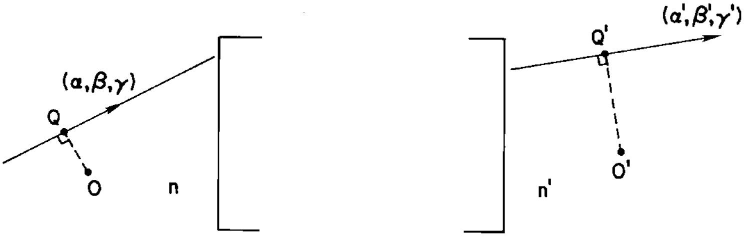

FIGURE 1 Geometrical interpretation of the angle characteristic function for constant object and image space indices. There is, in general, a single ray with directions (α, β, γ) in object space and $(\alpha', \beta', \gamma')$ in image space. Point O is the coordinate origin in object space, and O' is that in image space. From the origins, perpendiculars to the ray are constructed, which intersect the ray at Q and Q'. The angle characteristic function $T(\alpha, \beta; \alpha', \beta')$ is the path length from Q to Q'.

This equation is really shorthand for a Legendre transformation to coordinates $p_x = \partial V / \partial x$, etc. In principle, the expressions of Eq. (16) are used to solve for x and y in terms of α and β, and likewise Eq. (17) gives x' and y' in terms of α' and β', so

$$\begin{aligned} T(\alpha, \beta; \alpha', \beta') = V(x(\alpha, \beta), y(\alpha, \beta), z; x'(\alpha', \beta'), y'(\alpha', \beta'), z') \\ + n[\alpha x(\alpha, \beta) + \beta y(\alpha, \beta) + \sqrt{1-\alpha^2-\beta^2}\, z] \\ - n'[\alpha' x'(\alpha', \beta') + \beta' y'(\alpha', \beta') + \sqrt{1-\alpha'^2-\beta'^2}\, z'] \end{aligned} \tag{23}$$

The angle characteristic is an arbitrary function of four variables that completely specify the directions of rays in two regions. This function is not useful if parallel incoming rays give rise to parallel outgoing rays, as is the case with afocal systems, since the relationship between incoming and outgoing directions is not unique. The partial derivatives of the angular characteristic function are

$$\frac{\partial T}{\partial \alpha} = n\left(x - \frac{\alpha}{\gamma} z\right) \qquad \frac{\partial T}{\partial \beta} = n\left(y - \frac{\beta}{\gamma} z\right) \tag{24}$$

$$\frac{\partial T}{\partial \alpha'} = -n'\left(x' - \frac{\alpha'}{\gamma'} z'\right) \qquad \frac{\partial T}{\partial \beta'} = -n'\left(y' - \frac{\beta'}{\gamma'} z'\right) \tag{25}$$

These expressions are simplified if the reference planes are taken to be $z = 0$ and $z' = 0$. The geometrical interpretation of T is that it is the path length between the intersection point of rays with perpendicular planes through the coordinate origins in the two spaces, as shown in Fig. 1 for the case of constant n and n'. If the indices are heterogeneous, the construction applies to the tangents to the rays. Of all the characteristic functions, T is most easily found for single surfaces and most easily concatenated for series of surfaces.

Point-Angle Characteristic

The *point-angle characteristic function* is a mixed function defined by

$$\begin{aligned} W(x, y, z; \alpha', \beta') &= V(x, y, z; x', y', z') - n'(\alpha' x' + \beta' y' + \gamma' z') \\ &= T(\alpha, \beta; \alpha', \beta') - n(\alpha x + \beta y + \gamma z) \end{aligned} \tag{26}$$

As with Eq. (22), this equation is to be understood as shorthand for a Legendre transformation. The partial derivatives with respect to the spatial variables are related by equations like those of Eq. (16), so $n^2 = |\nabla W|^2$, and the derivatives with respect to the angular variables are like those of Eq. (25). This function is useful for examining transverse ray aberrations for a given object point, since $\partial W/\partial\alpha'$, $\partial W/\partial\beta'$ give the intersection points (x', y') in plane z for rays originating at (x, y) in plane z.

Angle-Point Characteristic

The *angle-point characteristic function* is

$$\begin{aligned} W'(\alpha, \beta; x', y', z') &= V(x, y, z; x', y', z') + n(\alpha x + \beta y + \gamma z) \\ &= T(\alpha, \beta; \alpha', \beta') - n'(\alpha' x' + \beta' y' + \gamma' z) \end{aligned} \tag{27}$$

Again, this is shorthand for the Legendre transformation. This function satisfies relationships like those of Eq. (17) and satisfies $n'^2 = |\nabla' W'|^2$. Derivatives with respect to spatial variables are like those of Eq. (21). It is useful when input angles are given, and output angles are to be found.

Expansions About an Arbitrary Ray

If two points on a ray that are not conjugate are taken as coordinate origins, and the z axes of the coordinate systems are taken to lie along the rays, then the expansion to second order of the point eikonal about these points is

$$\begin{aligned} S(x_1, y_1; x_2, y_2) &= v + a_1 x_1^2 + b_1 x_1 y_1 + c_1 y_1^2 + a_2 x_2^2 + b_2 x_2 y_2 + c_2 y_2^2 \\ &\quad + d x_1 x_2 + e y_1 y_2 + f x_1 x_2 + g y_1 x_2 \end{aligned} \tag{28}$$

The other characteristic functions have similar expansions. These expansions have three types of terms, those associated with the input space, the output space, and "interspace" terms. From the coefficients, information about imaging along a known ray is obtained. This subject is treated in the references for the section "Images About Known Rays."

Expansions About the Axis

For rotationally symmetric systems, the building blocks for an expansion about the axis are

$$\text{Object space term:} \quad \mathcal{O} = x^2 + y^2 \quad \text{or} \quad \alpha^2 + \beta^2 \tag{29}$$

$$\text{Image space term:} \quad \mathcal{I} = x'^2 + y'^2 \quad \text{or} \quad \alpha'^2 + \beta'^2 \tag{30}$$

$$\begin{aligned} \text{Interspace term:} \quad \mathcal{B} = xx' + yy' \quad \text{or} \quad \alpha\alpha' + \beta\beta' \quad \text{or} \quad x\alpha' + y\beta' \\ \text{or} \quad \alpha x' + \beta y' \end{aligned} \tag{31}$$

(Here $\mathcal{B}$ = "between.") The interspace term combines the variables included in $\mathcal{O}$ and $\mathcal{I}$. The general form can be written as a series

$$C(\mathcal{O}, \mathcal{B}, \mathcal{I}) = \sum_{L,M,N} a_{LMN} \mathcal{O}^L \mathcal{B}^M \mathcal{I}^N \tag{32}$$

To second order, the expansion is

$$\begin{aligned} C(\mathcal{O}, \mathcal{B}, \mathcal{I}) &= a_0 + a_{100}\mathcal{O} + a_{010}\mathcal{B} + a_{001}\mathcal{I} + a_{200}\mathcal{O}^2 + a_{020}\mathcal{B}^2 + a_{002}\mathcal{I}^2 \\ &\quad + a_{110}\mathcal{O}\mathcal{B} + a_{101}\mathcal{O}\mathcal{I} + a_{011}\mathcal{B}\mathcal{I} + \cdots \end{aligned} \tag{33}$$

The constant term is the optical path length between coordinate origins in the two spaces. It is often unimportant, but it does matter if two systems are used in parallel, as in an interferometer. The three first-order terms give the paraxial approximation. For imaging systems, the second-order terms are associated with third-order ray aberrations, and so on (Rayleigh 1908[30]). It is also possible to expand the characteristic functions in terms of three linear combinations of $\mathscr{O}$, $\mathscr{B}$, and $\mathscr{I}$. These combinations can be chosen so that the characteristic function of an aberration-free system depends on only one of the three terms, and the other two describe the aberrations (Steward 1928,[26] Smith 1945,[37] Pegis 1961[31]).

Paraxial Forms for Rotationally Symmetric Systems

These functions contain one each of the object space, image space, and interspace terms, with coefficients a_O, a_I, and a_B. The coefficients of the object and image space terms depend on the input and output plane locations. That of the interspace term depends on the system power. Point eikonal:

$$S(x', y'; x, y) = a + a_O(x^2 + y^2) + a_B(xx' + yy') + a_I(x'^2 + y'^2) \tag{34}$$

Angle characteristic:

$$T(\alpha', \beta'; \alpha, \beta) = a + a_O(\alpha^2 + \beta^2) + a_B(\alpha\alpha' + \beta\beta') + a_I(\alpha'^2 + \beta'^2) \tag{35}$$

Point-angle characteristic:

$$W(x, y; \alpha', \beta') = a + a_O(x^2 + y^2) + a_B(x\alpha' + y\beta') + a_I(\alpha'^2 + \beta'^2) \tag{36}$$

Angle-point characteristic:

$$W'(\alpha, \beta, x', y') = a + a_O(\alpha^2 + \beta^2) + a_B(\alpha x' + \beta y') + a_I(x'^2 + y'^2) \tag{37}$$

The coefficients in these expressions are different. The familiar properties of paraxial and gaussian optics can be found from these functions by taking the appropriate partial derivatives.

Some Ideal Characteristic Functions

For a system that satisfies certain conditions, the form of a characteristic function can sometimes be found. Thereafter, some of its properties can be determined. Some examples of characteristic functions follow, in each of which expression the function F is arbitrary.

For maxwellian perfect imaging (defined below) by a rotationally symmetric system between planes at $z = 0$ and $z' = 0$ related by transverse magnification m, the point characteristic function, defined for $z' \neq 0$, is

$$V(x', y', z'; x, y) = F(x^2 + y^2) + [(x' - mx)^2 + (y' - my)^2 + z'^2]^{1/2} \tag{38}$$

Expanding the expression above for small x, x', y, y' give the paraxial form, Eq. (34). The form of the point-angle characteristic is

$$W(x, y; \alpha',\beta') = F(x^2 + y^2) - m(n'\alpha'x + n'\beta'y) \tag{39}$$

The form of the angle-point characteristic is

$$W'(\alpha, \beta; x', y') = F(x'^2 + y'^2) + \frac{1}{m}(n\alpha x' + n\beta y') \tag{40}$$

The functions F are determined if the imaging is also stigmatic at one additional point, for example, at the center of the pupil (Steward 1928,[26] T. Smith 1945,[37] Buchdahl 1970,[34] Velzel 1991[41]). The angular characteristic function has the form

$$T(\alpha, \beta; \alpha', \beta') = F((n\alpha - mn'\alpha')^2 + (n\beta - mn'\beta')^2) \tag{41}$$

where F is any function.

For a lens of power ϕ that stigmatically images objects at infinity in a plane, and does so in either direction,

$$S(x, y; x', y') = -\phi(xx' + yy') \qquad \text{and} \qquad T(\alpha, \beta; \alpha', \beta') = \frac{nn'}{\phi}(\alpha\alpha' + \beta\beta') \tag{42}$$

Partially differentiating with respect to the appropriate variables shows that for such a system, the heights of point images in the rear focal plane are proportional to the sines of the incident angles, rather than the tangents.

1.5 RAYS IN HETEROGENEOUS MEDIA

Introduction

This section provides equations for describing and determining the curved ray paths in a heterogeneous or inhomogeneous medium, one whose refractive index varies with position. It is assumed here that $n(\mathbf{x})$ and the other relevant functions are continuous and have continuous derivatives to whatever order is needed. Various aspects of this subject are discussed in a number of books and papers (Heath 1895,[42] Herman 1900,[43] Synge 1937,[44] Luneburg 1964,[45] Stavroudis 1972,[46] Ghatak 1978,[47] Born & Wolf 1980,[48] Marcuse 1989[49]). This material is often discussed in the literature on gradient index lenses (Marchand 1973,[50] Marchand 1978,[51] Sharma, Kumar, & Ghatak 1982,[52] Moore 1992,[53] Moore 1994[54]) and in discussions of microwave lenses (Brown 1953,[55] Cornbleet 1976,[56] Cornbleet 1983,[57] Cornbleet 1984[58]).

Differential Geometry of Space Curves

A curved ray path is a space curve, which can be described by a standard parametric description, $\mathbf{x}(\sigma) = (x(\sigma), y(\sigma), z(\sigma))$, where σ is an arbitrary parameter (Blaschke 1945,[59] Kreyszig 1991,[60] Stoker 1969,[61] Struik 1990,[62] Stavroudis 1972[46]).

Different parameters may be used according to the situation. The path length s along the ray is sometimes used, as is the axial position z. Some equations change form according to the parameter, and those involving derivatives are simplest when the parameter is s. Derivatives with respect to the parameter are denoted by dots, so $\dot{\mathbf{x}}(\sigma) = d\mathbf{x}(\sigma)/d\sigma = (\dot{x}(\sigma), \dot{y}(\sigma), \dot{z}(\sigma))$. A parameter other than s is a function of s, so $d\mathbf{x}(\sigma)/ds = (d\mathbf{x}/d\sigma)(d\sigma/ds)$.

Associated with space curves are three mutually perpendicular unit vectors, the tangent vector **t**, the principal normal **n**, and the binormal **b**, as well as two scalars, the curvature and the torsion. The direction of a ray is that of its unit *tangent vector*

$$\mathbf{t} = \frac{\dot{\mathbf{x}}(\sigma)}{|\dot{\mathbf{x}}(\sigma)|} = \dot{\mathbf{x}}(s) = (\alpha, \beta, \gamma) \tag{43}$$

The tangent vector **t** is the same as the direction vector **r** used elsewhere in this chapter. The rate of change of the tangent vector with respect to path length is

$$\kappa\mathbf{n} = \dot{\mathbf{t}}(s) = \ddot{\mathbf{x}}(s) = \left(\frac{d\alpha}{dx}, \frac{d\beta}{ds}, \frac{d\gamma}{ds}\right) \tag{44}$$

The *normal vector* is the unit vector in this direction

$$\mathbf{n} = \frac{\ddot{\mathbf{x}}(s)}{|\ddot{\mathbf{x}}(s)|} \tag{45}$$

The vectors **t** and **n** define the *osculating plane*. The *curvature* $\kappa = |\ddot{\mathbf{x}}(s)|$ is the rate of change of direction of **t** in the osculating plane.

$$\kappa^2 = \frac{|\dot{\mathbf{x}}(\sigma) \times \ddot{\mathbf{x}}(\sigma)|^2}{|\dot{\mathbf{x}}(\sigma)|^6} = |\ddot{\mathbf{x}}(s)|^2 = \left(\frac{d\alpha}{ds}\right)^2 + \left(\frac{d\beta}{ds}\right)^2 + \left(\frac{d\gamma}{ds}\right)^2 \tag{46}$$

The radius of curvature is $\rho = 1/\kappa$. Perpendicular to the osculating plane is the unit *binormal vector*

$$\mathbf{b} = \mathbf{t} \times \mathbf{n} = \frac{\dot{\mathbf{x}}(s) \times \ddot{\mathbf{x}}(s)}{|\ddot{\mathbf{x}}(s)|} \tag{47}$$

The *torsion* is the rate of change of the normal to the osculating plane

$$\tau = \mathbf{b}(s) \cdot \frac{d\mathbf{n}(s)}{ds} = \frac{(\dot{\mathbf{x}}(\sigma) \times \ddot{\mathbf{x}}(\sigma)) \cdot \dddot{\mathbf{x}}(\sigma)}{|\dot{\mathbf{x}}(\sigma) \times \ddot{\mathbf{x}}(\sigma)|^2} = \frac{(\dot{\mathbf{x}}(s) \times \ddot{\mathbf{x}}(s)) \cdot \dddot{\mathbf{x}}(s)}{|\ddot{\mathbf{x}}(s)|^2} \tag{48}$$

The quantity $1/\tau$ is the *radius of torsion*. For a plane curve, $\tau = 0$ and **b** is constant. The rates of change of **t**, **n**, and **b** are given by the Frenet equations:

$$\dot{\mathbf{t}}(s) = \kappa\mathbf{n} \qquad \dot{\mathbf{n}}(s) = -\kappa\mathbf{t} + \tau\mathbf{b} \qquad \dot{\mathbf{b}}(s) = -\tau\mathbf{n} \tag{49}$$

In some books, $1/\kappa$ and $1/\tau$ are used for what are denoted here by κ and τ.

Differential Geometry Equations Specific to Rays

From the general space curve equations above and the differential equations below specific to rays, the following equations for rays are obtained. Note that n here is the refractive index, unrelated to **n**. The tangent and normal vectors are related by Eq. (59), which can be written

$$\nabla \log n = \kappa\mathbf{n} + (\nabla \log n \cdot \mathbf{t})\mathbf{t} \tag{50}$$

The osculating plane always contains the vector ∇n. Taking the dot product with **n** in the above equation gives

$$\kappa = \frac{\partial \log n}{\partial N} = \mathbf{n} \cdot \nabla \log n = \mathbf{b} \cdot (\dot{\mathbf{x}} \times \nabla \log n) \tag{51}$$

The partial derivative $\partial/\partial N$ is in the direction of the principal normal, so rays bend toward regions of higher refractive index. Other relations (Stavroudis 1972[46]) are

$$\mathbf{n} = \rho\dot{\mathbf{x}}(s) \times (\nabla \log n \times \dot{\mathbf{x}}(s)) \tag{52}$$

$$\mathbf{b} = \rho\dot{\mathbf{x}}(s) \times \nabla \log n \qquad \text{and} \qquad 0 = \mathbf{b} \cdot \nabla n \tag{53}$$

$$\tau = \frac{(\dot{\mathbf{x}}(s) \times \nabla n) \cdot \nabla \dot{n}}{|\nabla n \times \dot{\mathbf{x}}(s)|^2} \tag{54}$$

Variational Integral

Written in terms of parameter σ, the optical path length integral, Eq. (7) is

$$V = \int n\,ds = \int \left(n\frac{ds}{d\sigma}\right) d\sigma = \int \mathscr{L}\,d\sigma \tag{55}$$

The solution for ray paths involves the calculus of variations in a way analogous to that used in classical mechanics, where the time integral of the lagrangian $\mathscr{L}$ is an extremum (Goldstein 1980[63]). If $\mathscr{L}$ has no explicit dependence on σ, the mechanical analogue to the optics case is that of no explicit time dependence.

Differential Equations for Rays

General Differential Equations. Because the optical path length integral is an extremum, the integrand $\mathscr{L}$ satisfies the Euler equations (Stavroudis 1972[46]). For an arbitrary coordinate system, with coordinates q_1, q_2, q_3 and the derivatives with respect to the parameter $\dot{q}_i = dq_i/d\sigma$, the differential equations for the path are

$$0 = \frac{d}{d\sigma}\frac{\partial \mathscr{L}}{\partial \dot{q}_i} - \frac{\partial \mathscr{L}}{\partial q_i} = \frac{d}{d\sigma}\left(n\frac{\partial}{\partial \dot{q}_i}\frac{ds}{d\sigma}\right) - \frac{\partial}{\partial q_i}\left(n\frac{ds}{d\sigma}\right) \qquad i = 1, 2, 3 \tag{56}$$

Cartesian Coordinates with Unspecified Parameter. In cartesian coordinates $ds/d\sigma = (\dot{x}^2 + \dot{y}^2 + \dot{z}^2)^{1/2}$, so the x equation is

$$0 = \frac{d}{d\sigma}\left(n\frac{\partial}{\partial \dot{x}}\frac{ds}{d\sigma}\right) - \frac{ds}{d\sigma}\frac{\partial n}{\partial x} = \frac{d}{d\sigma}\left[\frac{n\dot{x}}{(\dot{x}^2 + \dot{y}^2 + \dot{z}^2)^{1/2}}\right] - (\dot{x}^2 + \dot{y}^2 + \dot{z}^2)^{1/2}\frac{\partial n}{\partial x} \tag{57}$$

Similar equations hold for y and z.

Cartesian Coordinates with Parameter $\sigma = s$. With $\sigma = s$, so $ds/d\sigma = 1$, an expression, sometimes called the *ray equation,* is obtained (Synge 1937[28]).

$$\nabla n = \frac{d}{ds}\left(n\frac{d\mathbf{x}(s)}{ds}\right) = n\frac{d^2\mathbf{x}(s)}{ds^2} + \frac{dn(\mathbf{x}(s))}{ds}\frac{d\mathbf{x}(s)}{ds} \tag{58}$$

Using $dn/ds = \nabla n \cdot \dot{\mathbf{x}}$, the ray equation can also be written

$$\nabla n = n\ddot{\mathbf{x}} + (\nabla n \cdot \dot{\mathbf{x}})\dot{\mathbf{x}} \qquad \text{or} \qquad \nabla \log n = \ddot{\mathbf{x}} + (\nabla \log n \cdot \dot{\mathbf{x}})\dot{\mathbf{x}} \tag{59}$$

Only two of the component equations are independent, since $|\dot{\mathbf{x}}| = 1$.

Cartesian Coordinates with Parameter $\sigma = \int ds/n$. The parameter $\sigma = \int ds/n$, for which $ds/d\sigma = n$ and $n^2 = \dot{x}^2 + \dot{y}^2 + \dot{z}^2$, gives (Synge 1937[44])

$$\frac{d^2\mathbf{x}}{d\sigma^2} = \nabla(\tfrac{1}{2}n^2) \tag{60}$$

This equation is analogous to Newton's law of motion for a particle, $\mathbf{F} = m\, d^2\mathbf{x}/dt^2$, so the ray paths are like the paths of particles in a field with a potential proportional to $n^2(\mathbf{x})$. This analogy describes paths, but not speeds, since light travels slower where n is greater, whereas the particles would have greater speeds (Arnaud 1979,[64] Evans & Rosenquist 1986[65]).

Euler Equations for Parameter $\sigma = z$. If $\sigma = z$, then $ds/d\sigma = (\dot{x}^2 + \dot{y}^2 + 1)^{1/2}$ and $\mathscr{L} = \mathscr{L}(x, y; \dot{x}, \dot{y}; z)$. This gives (Luneburg 1964,[45] Marcuse 1989[49])

$$0 = \frac{d}{dz}\left(n\frac{\partial}{\partial \dot{x}}\frac{ds}{dz}\right) - \frac{ds}{dz}\frac{\partial n}{\partial x} = \frac{d}{dz}\left[\frac{n\dot{x}}{(1 + \dot{x}^2 + \dot{y}^2)^{1/2}}\right] - (1 + \dot{x}^2 + \dot{y}^2)^{1/2}\frac{\partial n}{\partial x} \tag{61}$$

with a similar equation for y. The equations can also be written (Moore 1975,[66] Marchand 1978, app. A[51]) as

$$n\ddot{x} = (1 + \dot{x}^2 + \dot{y}^2)\left(\frac{\partial n}{\partial x} - \frac{\partial n}{\partial z}\dot{x}\right) \qquad n\ddot{y} = (1 + \dot{x}^2 + \dot{y}^2)\left(\frac{\partial n}{\partial y} - \frac{\partial n}{\partial z}\dot{y}\right) \tag{62}$$

This parameter is particularly useful when n is rotationally symmetric about the z axis.

Hamilton's Equations with Cartesian Coordinates for Parameter $\sigma = z$. A set of Hamilton's equations can also be written in cartesian coordinates using z as the parameter. (Luneburg 1964,[45] Marcuse 1989[49]) The canonical momenta in cartesian coordinates are the optical direction cosines

$$p_x = \frac{\partial \mathscr{L}}{\partial \dot{x}} = n\alpha \qquad p_y = \frac{\partial \mathscr{L}}{\partial \dot{y}} = n\beta \tag{63}$$

The hamiltonian is

$$\mathscr{H}(x, y, ; p_x, p_y; z) = \dot{x}p_x + \dot{y}p_y - \mathscr{L} = -\sqrt{n^2(x, y, z) - (p_x^2 + p_y^2)} \tag{64}$$

Hamilton's equations are

$$\frac{dx}{dz} = \frac{\partial \mathscr{H}}{\partial p_x} \qquad \frac{dy}{dz} = \frac{\partial \mathscr{H}}{\partial p_y} \qquad \frac{dp_x}{dz} = -\frac{\partial \mathscr{H}}{\partial x} \qquad \frac{dp_y}{dz} = -\frac{\partial \mathscr{H}}{\partial y} \tag{65}$$

It is not possible to write a set of Hamilton's equations using an arbitrary parameter and three canonical momenta, since they are not independent (Forbes 1991[67]). Another equation is

$$\frac{\partial \mathscr{H}}{\partial z} = \frac{d\mathscr{H}}{dz} = \frac{1}{\gamma}\frac{\partial n}{\partial z} \tag{66}$$

Paraxial Form of Hamilton's Equations for $\sigma = z$. In the paraxial limit, if n_0 is the average index, the above set of equations gives (Marcuse 1989[49])

$$\frac{d^2x(z)}{dz^2} = \frac{1}{n_0}\frac{\partial n}{\partial x} \qquad \frac{d^2y(z)}{dz^2} = \frac{1}{n_0}\frac{\partial n}{\partial y} \tag{67}$$

Other Forms. A variety of additional differential equations can be obtained with various parameters (Forbes 1991[67]). Time cannot be used as a parameter (Landau & Lifshitz 1951[68]). The equations can also be expressed in a variety of coordinate systems (Buchdahl 1973,[69] Cornbleet 1976,[56] Cornbleet 1978,[70] Cornbleet 1979,[71] Cornbleet 1984[58]).

Refractive Index Symmetries

When the refractive index has symmetry or does not vary with one or more of the spatial variables, the above equations may simplify and take special forms. If, in some coordinate system, n does not vary with a coordinate q_i, so $\partial n/\partial q_i = 0$, and if, in addition, $\partial/\partial q_i(ds/d\sigma) = 0$, then

$$\frac{\partial \mathscr{L}}{\partial q_i} = 0 \qquad \text{and} \qquad \frac{\partial \mathscr{L}}{\partial \dot{q}} = n\frac{\partial}{\partial \dot{q}}\left(\frac{ds}{d\sigma}\right) = \text{constant} \tag{68}$$

There is an associated invariance of the ray path (Synge 1937,[44] Cornbleet 1976,[56] 1984,[58] Marcuse 1989[49]). (This is analogous to the case in mechanics where a potential does not vary with some coordinate.) A more esoteric approach to symmetries involves Noether's theorem (Blaker 1974,[72] Joyce 1975[73]). There are a number of special cases.

If the index is rotationally symmetric about the z axis, $n = n(x^2 + y^2, z)$, then $\partial\mathscr{L}/\partial\phi = 0$, where ϕ is the azimuth angle, and the constant of motion is analogous to that of the z component of angular momentum in mechanics for a potential with rotational symmetry. The constant quantity is the *skew invariant,* discussed elsewhere.

If the refractive index is a function of radius, $n = n(r)$, there are two constants of motion. The ray paths lie in planes through the center ($r = 0$) and have constant angular motion about an axis through the center that is perpendicular to this plane, so $\mathbf{x} \times \mathbf{p}$ is constant. If the plane is in the x-y plane, then $n(\alpha y - \beta x)$ is constant. This is analogous to motion of a particle in a central force field. Two of the best-known examples are the Maxwell fisheye (Maxwell 1854,[74] Born & Wolf 1980[48]) for which $n(r) \propto (1 + r^2)^{-1}$, and the Luneburg lens (Luneburg 1964,[45] Morgan 1958[75]), for which $n(r) = \sqrt{2 - r^2}$ for $r \leq 1$ and $n = 1$ for $r > 1$.

If n does not vary with z, then $\mathscr{H} = n\gamma$ is constant for a ray as a function of z, according to Eq. (66).

If the medium is layered, so the index varies in only the z direction, then $n\alpha$ and $n\beta$ are constant. If θ is the angle relative to the z axis, then $n(z)\sin\theta(z)$ is constant, giving Snell's law as a special case.

The homogeneous medium, where $\partial n/\partial x = \partial n/\partial y = \partial n/\partial z = 0$, is a special case in which there are three constants of motion, $n\alpha$, $n\beta$, and $n\gamma$, so rays travel in straight lines.

1.6 CONSERVATION OF ÉTENDUE

If a bundle of rays intersects a constant z plane in a small region of size $dx\,dy$ and has a small range of angles $d\alpha\,d\beta$, then as the light propagates through a lossless system, the following quantity remains constant:

$$n^2\,dx\,dy\,d\alpha\,d\beta = n^2\,dA\,d\alpha\,d\beta = n^2\,dA\cos\theta\,d\omega = dx\,dy\,dp_x\,dp_y \tag{69}$$

Here $dA = dx\,dy$ is the differential area, $d\omega$ is the solid angle, and θ is measured relative to the normal to the plane. The integral of this quantity

$$\int n^2\,dx\,dy\,d\alpha\,d\beta = \int n^2\,dA\,d\alpha\,d\beta = \int n^2\,dA\cos\theta\,d\omega = \int dx\,dy\,dp_x\,dp_y \tag{70}$$

is the *étendue,* and is also conserved. For lambertian radiation of radiance L_e, the total power transferred is $P = \int L_e n^2\,d\alpha\,d\beta\,dx\,dy$. The étendue and related quantities are known by a variety of names (Steel 1974[76]), including *generalized Lagrange invariant, luminosity, light-gathering power, light grasp, throughput, acceptance, optical extent,* and *area-solid-angle-product.* The angle term is not actually a solid angle, but is weighted. It does approach a solid angle in the limit of small extent. In addition, the integrations can be over area, giving $n^2\,d\alpha\,d\beta \int dA$, or over angle, giving $n^2\,dA \int d\alpha\,d\beta$. A related quantity is the geometrical vector flux (Winston 1979[77]), with components $(\int dp_y\,dp_z, \int dp_x\,dp_z, \int dp_x\,dp_y)$. In some cases these quantities include a brightness factor, and in others they are purely geometrical. The étendue is related to the information capacity of a system (Gabor 1961[78]).

As special case, if the initial and final planes are conjugate with transverse magnification $m = dx'/dx = dy'/dy$, then

$$n^2\,d\alpha\,d\beta = n'^2 m^2\,d\alpha'\,d\beta' \tag{71}$$

Consequently, the angular extents of the entrance and exit pupil in direction cosine coordinates are related by

$$n^2 \int_{\text{entrance pupil}} d\alpha\,d\beta = n'^2 m^2 \int_{\text{exit pupil}} d\alpha'\,d\beta' \tag{72}$$

See also the discussion of image irradiance in the section on apertures and pupils.

This conservation law is general; it does not depend on index homogeneity or on axial symmetry. It can be proven in a variety of ways, one of which is with characteristic functions (Welford & Winston 1978,[79] Welford 1986,[80] Welford & Winston 1989[81]). Phase space arguments involving Liouville's theorem can also be applied (di Francia 1950,[82] Winston 1970,[83] Jannson & Winston 1986,[84] Marcuse 1989[85]). Another type of proof involves thermodynamics, using conservation of radiance (or brightness) or the principal of detailed balance (Clausius 1864,[86] Clausius 1879,[87] Helmholtz 1874,[88] Liebes 1969[89]). Conversely, the thermodynamic principle can be proven from the geometric optics one (Nicodemus 1963,[90] Boyd 1983,[91] Klein 1986[92]). In the paraxial limit for systems of revolution the conservation of etendue between object and image planes is related to the two-ray paraxial invariant, Eq. (152). Some historical aspects are discussed by Rayleigh (Rayleigh 1886[93]) and Southall (Southall 1910[94]).

1.7 SKEW INVARIANT

In a rotationally symmetric system, whose indices may be constant or varying, a *skew ray* is one that does not lie in a plane containing the axis. The *skewness* of such a ray is

$$\mathcal{S} = n(\alpha y - \beta x) = n\alpha y - n\beta x = p_x y - p_y x \tag{73}$$

As a skew ray propagates through the system, this quantity, known as the *skew invariant,* does not change (T. Smith 1921,[95] H. Hopkins 1947,[96] Marshall 1952,[97] Buchdahl 1954, sec. 4,[98] M. Herzberger 1958,[99] Welford 1968,[100] Stavroudis 1972, p. 208,[101] Welford 1974, sec. 5.4,[102] Welford 1986, sec. 6.4[103] Welford & Winston 1989, p. 228[104]). For a meridional ray, one lying in a plane containing the axis, $\mathcal{S} = 0$. The skewness can be written in vector form as

$$\mathcal{S} = \mathbf{a} \cdot (\mathbf{x} \times \mathbf{p}) \tag{74}$$

where **a** is a unit vector along the axis, **x** is the position on a ray, and **p** is the optical cosine and vector at that position.

This invariance is analogous to the conservation of the axial component of angular momentum in a cylindrical force field, and it can be proven in several ways. One is by performing the rotation operations on α, β, x, and y (as discussed in the section on heterogeneous media). Another is by means of characteristic functions. It can also be demonstrated that $\mathcal{S}$ is not changed by refraction or reflection by surfaces with radial gradients. The invariance holds also for diffractive optics that are figures of rotation.

A special case of the invariant relates the intersection points of a skew ray with a given meridian. If a ray with directions (α, β) in a space of index n intersects the $x = 0$ meridian with height y, then at another intersection with this meridian in a space with index n', its height y' and direction cosine α' are related by

$$n\alpha y = n'\alpha' y' \tag{75}$$

The points where rays intersect the same meridian are known as *diapoints* and the ratio y'/y as the *diamagnification* (Herzberger 1958[99]).

1.8 REFRACTION AND REFLECTION AT INTERFACES BETWEEN HOMOGENEOUS MEDIA

Introduction

The initial ray direction is specified by the unit vector $\mathbf{r} = (\alpha, \beta, \gamma)$. After refraction or reflection the direction is $\mathbf{r}' = (\alpha', \beta', \gamma')$. At the point where the ray intersects the surface, its normal has direction $\mathbf{S} = (L, M, N)$.

The *angle of incidence* I is the angle between a ray and the surface normal at the intersection point. This angle and the corresponding outgoing angle I' are given by

$$\begin{aligned} |\cos I| &= |\mathbf{r} \cdot \mathbf{S}| = |\alpha L + \beta M + \gamma N| \\ |\cos I'| &= |\mathbf{r}' \cdot \mathbf{S}| = |\alpha' L + \beta' M + \gamma' N| \end{aligned} \tag{76}$$

In addition

$$|\sin I| = |\mathbf{r} \times \mathbf{S}| \qquad |\sin I'| = |\mathbf{r}' \times \mathbf{S}| \tag{77}$$

The signs of these expressions depend on which way the surface normal vector is directed. The surface normal and the ray direction define the *plane of incidence,* which is perpendicular to the vector cross product $\mathbf{S} \times \mathbf{r} = (M\gamma - N\beta, N\alpha - L\gamma, L\beta - M\alpha)$. After refraction or reflection, the outgoing ray is in the same plane. This symmetry is related to the fact that optical path length is an extremum.

The laws of reflection and refraction can be derived from Fermat's principle, as is done in many books. At a planar interface, the reflection and refraction directions are derived from Maxwell's equations using the boundary conditions. For scalar waves at a plane interface, the directions are related to the fact that the number of oscillation cycles is the same for incident and outgoing waves.

Refraction

At an interface between two homogeneous and isotropic media, described by indices n and n', the incidence angle I and the outgoing angle I' are related by *Snell's law* (Magie 1963[105]):

$$n' \sin I' = n \sin I \tag{78}$$

If $\sin I' > 1$, there is total internal reflection. Another relationship is

$$n' \cos I' = \sqrt{n'^2 - n^2 \sin^2 I} = \sqrt{n'^2 - n^2 - n^2 \cos^2 I} \tag{79}$$

Snell's law can be expressed in a number of ways, one of which is

$$n[\mathbf{r} + (\mathbf{r} \cdot \mathbf{S})\mathbf{S}] = n'[\mathbf{r}' + (\mathbf{r}' \cdot \mathbf{S})\mathbf{S}] \tag{80}$$

Taking the cross product of both sides with $\mathbf{S}$ gives another form

$$n'(\mathbf{S} \times \mathbf{r}') = n(\mathbf{S} \times \mathbf{r}) \tag{81}$$

A quantity that appears frequently in geometrical optics (but which has no common name or symbol) is

$$\Gamma = n' \cos I' - n \cos I \tag{82}$$

It can be written several ways

$$\Gamma = (n\mathbf{r} - n'\mathbf{r}') \cdot \mathbf{S} = -n \cos I + \sqrt{n'^2 - n^2 \sin^2 I} = -n \cos I + \sqrt{n'^2 - n^2 + n^2 \cos^2 I} \tag{83}$$

In terms of Γ, Snell's law is

$$n'\mathbf{r}' = n\mathbf{r} + \Gamma\mathbf{S} \tag{84}$$

or

$$n'\alpha' = n\alpha + L\Gamma \qquad n'\beta' = n\beta + M\Gamma \qquad n'\gamma' = n\gamma + N\Gamma \tag{85}$$

The outgoing direction is expressed explicitly as a function of incident direction by

$$n'\mathbf{r}' = n\mathbf{r} + \mathbf{S}[n\mathbf{r} \cdot \mathbf{S} - \sqrt{n'^2 - n^2 + (n\mathbf{r} \cdot \mathbf{S})^2}] \tag{86}$$

If the surface normal is in the z direction, the equations simplify to

$$n'\alpha' = n\alpha \qquad n'\beta' = n\beta \qquad n'\gamma' = \sqrt{n'^2 - n^2 + n^2\gamma^2} \tag{87}$$

If $\beta = 0$, this reduces to $n'\alpha' = n\alpha$, the familiar form of Snell's law, written with direction cosines, with $n'\gamma' = (n'^2 - n^2\alpha^2)^{1/2}$, corresponding to Eq. (79). Another relation is

$$\frac{n'\alpha' - n\alpha}{L} = \frac{n'\beta' - n\beta}{M} = \frac{n'\gamma' - n\gamma}{N} = \Gamma \tag{88}$$

All of the above expressions can be formally simplified by using $\mathbf{p} = n\mathbf{r}$ and $\mathbf{p}' = n'\mathbf{r}'$. For a succession of refractions by parallel surfaces,

$$n_1 \sin I_1 = n_2 \sin I_2 = n_3 \sin I_3 = \cdots \tag{89}$$

so the angles within any two media are related by their indices alone, regardless of the intervening layers. Refractive indices vary with wavelength, so the angles of refraction do likewise.

Reflection

The reflection equations can be derived from those for refraction by setting the index of the final medium equal to the negative of that of the incident medium, i.e., $n' = -n$, which gives $\Gamma = -2n \cos I$. The angles of incidence and reflection are equal

$$I' = I \tag{90}$$

The incident and reflected ray directions are related by

$$\mathbf{S} \times \mathbf{r}' = -\mathbf{S} \times \mathbf{r} \tag{91}$$

Another expression is

$$\mathbf{r}' = \mathbf{r} - (2\mathbf{S} \cdot \mathbf{r})\mathbf{S} = \mathbf{r} - (2 \cos I)\mathbf{S} \tag{92}$$

The components are

$$\alpha' = \alpha - 2L \cos I \qquad \beta' = \beta - 2M \cos I \qquad \gamma' = \gamma - 2N \cos I \tag{93}$$

This relationship can be written in terms of dyadics (Silberstein 1918[106]) as $\mathbf{r}' = (\mathbf{I} - \mathbf{SS}) \cdot \mathbf{r}$. This is equivalent to the matrix form (T. Smith 1928,[107] Luneburg 1964,[108] R. E. Hopkins 1965,[109] Levi 1968,[110] Tongshu 1991[111])

$$\begin{pmatrix} \alpha' \\ \beta' \\ \gamma' \end{pmatrix} = \begin{pmatrix} 1-2L^2 & -2LM & -2LN \\ -2LM & 1-2M^2 & -2MN \\ -2LN & -2MN & 1-2N^2 \end{pmatrix} \begin{pmatrix} \alpha \\ \beta \\ \gamma \end{pmatrix} \tag{94}$$

Each column of this matrix is a set of direction cosines and is orthogonal to the others, and likewise for the rows. The matrix associated with a sequence of reflections from plane surfaces is calculated by multiplying the matrices for each reflection. Another relationship is

$$\frac{\alpha' - \alpha}{L} = \frac{\beta' - \beta}{M} = \frac{\gamma' - \gamma}{N} \tag{95}$$

If the surface normal is in the z direction, so $(L, M, N) = (0, 0, 1)$, then

$$\alpha' = \alpha \qquad \beta' = \beta \qquad \gamma' = -\gamma \tag{96}$$

Reflection by a Plane Mirror—Positions of Image Points

If light from a point (x, y, z) is reflected by a plane mirror whose distance from the coordinate origin is d, and whose surface normal has direction (L, M, N), the image point coordinates (x', y', z') are given by

$$\begin{pmatrix} x' \\ y' \\ z' \\ 1 \end{pmatrix} = \begin{pmatrix} 1-2L^2 & -2LM & -2LN & 2dL \\ -2LM & 1-2M^2 & -2MN & 2dM \\ -2LN & -2MN & 1-2N^2 & 2dN \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} \tag{97}$$

This transformation involves both rotation and translation, with only the former effect applying if $d = 0$. It is an affine type of collinear transformation, discussed in the section on collineation. The effect of a series of reflections by plane mirrors is found by a product of such matrices. The transformation can also be formulated in terms of quaternions (Wagner 1951,[112] Levi 1968, p. 367[110]).

Diffractive Elements

The changes in directions produced by gratings or diffractive elements can be handled in an ad hoc geometrical way (Spencer & Murty 1962,[113] di Francia 1950[114])

$$n'\mathbf{r}'_G \times \mathbf{S} = n\mathbf{r} \times \mathbf{S} + G\frac{\lambda}{\mathrm{p}}\mathbf{q} \tag{98}$$

Here λ is the vacuum wavelength, p is the grating period, $\mathbf{q}$ is a unit vector tangent to the surface and parallel to the rulings, and G is the diffraction order. Equations (81) and (91) are special cases of this equation for the 0th order.

1.9 IMAGING

Introduction

Image formation is the principal use of lenses. Moreover, lenses form images even if this is not their intended purpose. This section provides definitions, and discusses basic concepts and limitations. The purposes of the geometric analysis of imaging include the following: (1) discovering the nominal relationship between an object and its image, principally the size, shape, and location of the image, which is usually done with paraxial optics; (2) determining the deviations from the nominal image, i.e., the aberrations; (3) estimating image irradiance; (4) understanding fundamental limitations—what is inherently possible and impossible; (5) supplying information for diffraction calculations, usually optical path lengths.

Images and Types of Images

A definition of image (Webster 1934[115]) is: "The optical counterpart of an object produced by a lens, mirror, or other optical system. It is a geometrical system made up of foci corresponding to the parts of the object." The point-by-point correspondence is the key, since a given object can have a variety of different images.

Image irradiance can be found only approximately from geometric optics, the degree of accuracy of the predictions varying from case to case. In many instances wave optics is required, and for objects that are not self-luminous, an analysis involving partial coherence is also needed.

The term *image* is used in a variety of ways, so clarification is useful. The light from an object produces a three-dimensional distribution in image space. The *aerial image* is the distribution on a mathematical surface, often that of best focus, the locus of points of the images of object points. An aerial image is never the final goal; ultimately, the light is to be captured. The *receiving surface* (NS) is that on which the light falls, the distribution of which there can be called the *received image* (NS). This distinction is important in considerations of defocus, which is a relationship, not an absolute. The record thereby produced is the *recorded image* (NS). The recorded image varies with the position of the receiving surface, which is usually intended to correspond with the aerial image surface. In this section, "image" means aerial image, unless otherwise stated.

Object Space and Image Space

The object is said to exist in *object space*; the image, in *image space.* Each space is infinite, with a physically accessible region called *real,* and an inaccessible region, referred to as *virtual.* The two spaces may overlap physically, as with reflective systems. Corresponding quantities and locations associated with the object and image spaces are typically denoted by the same symbol, with a prime indicating image space. Positions are specified by a coordinate system (x, y, z) in object space and (x', y', z') in image space. The refractive indices of the object and image spaces are n and n'.

Image of a Point

An *object point* is thought of as emitting rays in all directions, some of which are captured by the lens, whose internal action converges the rays, more or less, to an *image point,* the term "point" being used even if the ray convergence is imperfect. Object and image points are said to be *conjugate.* Since geometric optics is reversible, if A' is the image of $A,$ then A is the image of A'.

Mapping Object Space to Image Space

If every point were imaged stigmatically, then the entire object space would be mapped into the image space according to a transformation

$$x' = x'(x, y, z) \qquad y' = y'(x, y, z) \qquad z' = z'(x, y, z) \tag{99}$$

The mapping is reciprocal, so the equations can be inverted. If n and n' are constant, then the mapping is a collinear transformation, discussed below.

Images of Extended Objects

An *extended object* can be thought of as a collection of points, a subset of the entire space, and its stigmatic image is the set of conjugate image points. A surface described by $0 = F(x, y, z)$ has an image surface

$$0 = F'(x', y', z') = F(x(x', y', z'), y(x', y', z'), z(x', y', z')) \tag{100}$$

A curve described parametrically by $\mathbf{x}(\sigma) = (x(\sigma), y(\sigma), z(\sigma))$ has an image curve

$$\mathbf{x}'(\sigma) = (x'(x(\sigma), y(\sigma), z(\sigma)), y'(x(\sigma), y(\sigma), z(\sigma)), z'(x(\sigma), y(\sigma), z(\sigma))) \tag{101}$$

Rotationally Symmetric Lenses

Rotationally symmetric lenses have an *axis,* which is a ray path (unless there is an obstruction). All planes through the axis, the *meridians* or *meridional planes,* are planes with respect to which there is bilateral symmetry. An *axial object point* is conjugate to an *axial image point.* An axial image point is located with a single ray in addition to the axial one. Off-axis object and image points are in the same meridian, and may be on the same or opposite sides of the axis. The *object height* is the distance of a point from the axis, and the *image height* is that for its image. It is possible to have rotational symmetry without bilateral symmetry, as in a system made of crystalline quartz (Buchdahl 1970[116]), but such systems are not discussed here. For stigmatic imaging by a lens rotationally symmetric about the z axis, Eq. (99) gives

$$x' = x'(x, z) \qquad y' = y'(y, z) \qquad z' = z'(z) \tag{102}$$

Planes Perpendicular to the Axis

The arrangement most often of interest is that of planar object and receiving surfaces, both perpendicular to the lens axis. When the terms *object plane* and *image plane* are used here without further elaboration, this is the meaning. (This arrangement is more common for manufactured systems with flat detectors, than for natural systems, for instance, eyes, with their curved retinas.)

Magnifications

The term *magnification* is used in a general way to denote the ratio of conjugate object and image dimensions, for example, heights, distances, areas, volumes, and angles. A single number is inadequate when object and image shapes are not geometrically similar. The term magnification implies an increase, but this is not the case in general.

Transverse Magnification

With object and image planes perpendicular to the axis, the relative scale factor of length is the *transverse magnification* or *lateral magnification,* denoted by m, and usually referred to simply as ''the magnification.'' The transverse magnification is the ratio of image height to object height, $m = h'/h$. It can also be written in differential form, e.g., $m = dx'/dx$ or $m = \Delta x'/\Delta x$. The transverse magnification is signed, and it can have any value from $-\infty$ to $+\infty$. Areas in such planes are scaled by m^2. A lens may contain plane mirrors that affect the image parity or it may be accompanied by external plane mirrors that reorient images and change their parity, but these changes are independent of the magnification at which the lens works.

Longitudinal Magnification

Along the rotational axis, the *longitudinal magnification,* m_L, also called *axial magnification,* is the ratio of image length to object length in the limit of small lengths, i.e., $m_L = dz'/dz$.

Visual Magnification

With visual instruments, the perceived size of the image depends on its angular subtense. *Visual magnification* is the ratio of the angular subtense of an image relative to that of the object viewed directly. Other terms are used for this quantity, including ''magnification,'' ''power,'' and ''magnifying power.'' For objects whose positions can be controlled, there is arbitrariness in the subtense without the instrument, which is greatest when the object is located at the near-point of the observer. This distance varies from person to person, but for purposes of standardization the distance is taken to be 250 mm. For instruments that view distant objects there is no arbitrariness of subtense with direct viewing.

Ideal Imaging and Disappointments in Imaging

Terms such as *perfect imaging* and *ideal imaging* are used in various ways. The ideal varies with the circumstances, and there are applications in which imaging is not the purpose, for instance, energy collection and Fourier transformation. The term *desired imaging* might be more appropriate in cases where that which is desired is fundamentally impossible. Some deviations from what is desired are called *aberrations,* whether their avoidance is possible or not. Any ideal that can be approximated must agree in its paraxial limit ideal with what a lens actually does in its paraxial limit.

Maxwellian Ideal for Single-Plane Imaging

The most common meaning of perfect imaging is that elucidated by Maxwell (Maxwell 1858[117]), and referred to here as *maxwellian ideal* or *maxwellian perfection.* This ideal is fundamentally possible. The three conditions for such imaging of points in a plane perpendicular to the lens axis are: (1) Each point is imaged stigmatically. (2) The images of all the points in a plane lie on a plane that is likewise perpendicular to the axis, so the field is flat, or free from field curvature. (3) The ratio of image heights to object heights is the same for all points in the plane. That is, transverse magnification is constant, or there is no distortion.

The Volume Imaging Ideal

A more demanding ideal is that points everywhere in regions of constant index be imaged stigmatically and that the imaging of every plane be flat and free from distortion. For planes perpendicular to the lens axis, such imaging is described mathematically by the collinear transformation, discussed below. It is inherently impossible for a lens to function in this way, but the mathematical apparatus of collineation is useful in obtaining approximate results.

Paraxial, First-Order, and Gaussian Optics

The terms "paraxial," "first order," and "gaussian" are often used interchangeably, and their consideration is merged with that of collineation. The distinction is often not made, probably because these descriptions agree in result, although differing in approach. One of the few discussions is that of Southall (Southall 1910[118]). A *paraxial* analysis has to do with the limiting case in which the distances of rays from the axis approach zero, as do the angles of the rays relative to the axis. The term *first order* refers to the associated mathematical approximation in which the positions and directions of such rays are computed with terms to the first order only in height and angle. *Gaussian* refers to certain results of the paraxial optics, where lenses are black boxes whose properties are summarized by the existence and locations of cardinal points. In the limit of small heights and angles, the equations of collineation are identical to those of paraxial optics. Each of these is discussed in greater detail below.

Fundamental Limitations

There are fundamental geometrical limitations on optical systems, relating to the fact that a given ray passes through many points and a given point lies on many rays. So the images of points on the same line or plane, or on different planes, are not independent. A set of rays intersecting at several points in object space cannot be made to satisfy arbitrary requirements in image space. Such limitations are best studied by the methods of hamiltonian optics.

Stigmatic Imaging

If all rays from an object point converge precisely to an image point, the imaging of this point is said to be *stigmatic*. The optical path lengths of all rays between two such points is identical. A stigmatic image point is located by the intersection of any two rays that pass through the points. An *absolute instrument* is one which images all points stigmatically (Born & Wolf 1980[119]). For such imaging

$$n\,\delta x = n'\,\delta x' \qquad n\,\delta y = n'\,\delta y' \qquad n\,\delta z = n'\,\delta z' \tag{103}$$

where conjugate length elements are δx and $\delta x'$, δy and $\delta y'$, δz and $\delta z'$.

Path Lengths and Conjugate Points

All the rays from an object point to its stigmatic image point have the same optical path length. For focal lenses, the paths lengths for different pairs of conjugate points in a plane perpendicular to the axis are different, except for points on circles centered on the axis. For afocal lenses path lengths are nominally the same for all points in planes perpendicular to the axis. For afocal lenses with transverse magnification $\pm n/n'$, path lengths can be the same for all points. In general, the path lengths between different points on an object and image surface are equal only if the shape of the image surface is that of a wavefront that has propagated from a wavefront whose shape is that of the object surface.

The Cosine Condition

The *cosine condition* relates object space and image space ray angles, if the imaging is stigmatic over some area (T. Smith 1922,[120] Steward 1928,[121] Buchdahl 1970[116]). Let the x-y plane lie in the object surface and the x'-y' plane in the conjugate surface (Fig. 2). Two

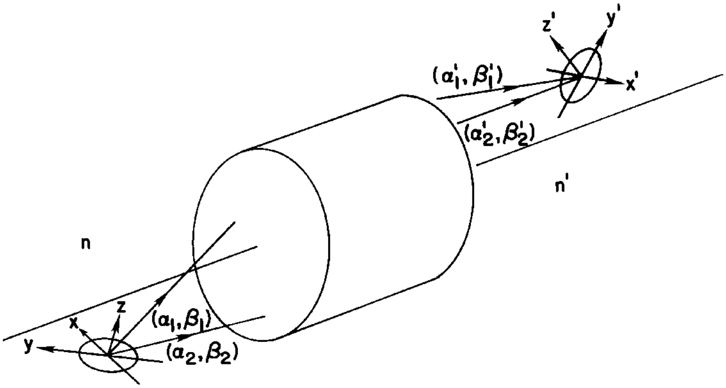

FIGURE 2 The cosine condition. A small area in object space about the origin in the x-y plane is imaged to the region around the origin of the x'-y' plane in image space. A pair of rays from the origin with direction cosines (α_1, β_1) and (α_2, β_2) arrive with (α_1', β_1') and (α_2', β_2'). The direction cosines and the transverse magnification in the planes are related by Eq. (104).

rays leaving a point in the object region have direction cosines (α_1, β_1) and (α_2, β_2), and the rays on the image side have (α_1', β_1') and (α_2', β_2'). If the imaging is stigmatic, with local transverse magnification m on the surface, then

$$m = \frac{n(\alpha_1 - \alpha_2)}{n'(\alpha_1' - \alpha_2')} = \frac{n(\beta_1 - \beta_2)}{n'(\beta_1' - \beta_2')} \tag{104}$$

In the limit as $\alpha_1 \to \alpha_2$ and $\beta_1 \to \beta_2$, the cosine condition gives

$$m = \frac{n\, d\alpha}{n'\, d\alpha'} = \frac{n\, d\beta}{n'\, d\beta'} \tag{105}$$

This condition also holds in the more general case of *isoplanatic* imaging, where there is aberration that is locally constant across the region in question (Welford 1976,[122] Welford 1986, sec. 94[123]).

The Abbe Sine Condition

The *sine condition* or *Abbe sine condition* (Abbe 1879,[124] Born & Wolf 1980[119]) is a special case of the cosine condition for object and image planes perpendicular to the axis in regions about the axis. For a plane with transverse magnification m, let θ be the angle relative to the axis made by a ray from an axial object point, and θ' be that in image space. If the lens is free of coma

$$m = \frac{n \sin\theta}{n' \sin\theta'} = \frac{n\alpha}{n'\alpha'} = \frac{n\beta}{n'\beta'} \tag{106}$$

for all θ and θ'. There are signs associated with θ and θ', so that $m > 0$ if they have the same sign, and $m < 0$ if the signs are opposite. This equation is sometimes written with m replaced by the ratio of paraxial angles. There is sometimes the implication that θ and θ' refer only to the extreme angles passing through the lens, when in fact the sine condition dictates that the ratio of the sines is the constant for all angles. For an object at infinity, the sine condition is

$$\sin\theta' = -\frac{y}{f'} \qquad \text{or} \qquad n'\beta' = -y\phi \tag{107}$$

where y is the height of a ray parallel to the axis, ϕ is the power of the lens, and f' is the rear focal length. These relationships hold to a good approximation in most lenses, since small deviations are associated with large aberrations. A deviation from this relationship is called *offense against the sine condition,* and is associated with coma (Conrady 1992,[125] H. Hopkins 1946,[126] T. Smith 1948,[127] H. Hopkins 1950,[128] Welford 1986[123]). The sine condition does not apply where there are discontinuities in ray behavior, for example, in devices like Fresnel lenses, or to diffraction-based devices like zone plates.

The Herschel Condition

The *Herschel condition* is a relationship that holds if the imaging is stigmatic for nearby points along the axis (Herschel 1821,[129] H. Hopkins 1946,[130] Born & Wolf 1980[119]). The two equivalent relations are

$$m = \frac{n \sin(\frac{1}{2}\theta)}{n' \sin(\frac{1}{2}\theta')} \qquad \text{and} \qquad m_L = \frac{n \sin^2(\frac{1}{2}\theta)}{n' \sin^2(\frac{1}{2}\theta')} = \frac{n(1-\gamma)}{n'(1-\gamma')} \tag{108}$$

The Herschel condition is inconsistent with the sine condition unless $m \pm n/n'$. So, in general, stigmatic imaging in one plane precludes that in others.

Sine and Herschel Conditions for Afocal Systems

For afocal systems the sine condition and Herschel condition are identical. For rays entering parallel to the axis at y and leaving at y' they are

$$m = \frac{y'}{y} \tag{109}$$

That is, the ratio of incoming and outgoing heights is independent of the incoming height. (H. Hopkins,[128] Chap. III "The Sine Condition and Herschel's Condition.")

Stigmatic Imaging Possibilities

For object and image spaces with constant refractive indices, stigmatic imaging is only possible for the entire spaces for afocal lenses with identical transverse and longitudinal magnifications $m = \pm n/n'$ and $|m_L| = |m|$. Such lenses re-create not only the intersection points, but the wavefronts, since the corresponding optical path lengths are the same in both spaces, Eq. (103). For other lenses with constant object and image space indices, the maxwellian ideal can be met for only a single surface. In addition, a single point elsewhere can be imaged stigmatically (T. Smith 1948,[127] Velzel 1991[131]). Nonplanar surfaces can be imaged stigmatically, a well-known example being the imaging of spherical surfaces by a spherical refracting surface, for a particular magnification (Born & Wolf 1980, sec. 4.2.3[119]). For systems with spherical symmetry, it is possible that two nonplanar surfaces be stigmatically imaged (T. Smith 1927[132]). In addition, various systems with heterogeneous indices can image stigmatically over a volume.

1.10 DESCRIPTION OF SYSTEMS OF REVOLUTION

Introduction

This section is concerned with the optical description of lens and mirror systems that are figures of revolution.[133–145] From a mechanical viewpoint, optical systems are comprised of lenses and mirrors. From the point of view of the light, the system is regions of media with different indices, separated by interfaces of various shapes. This section is limited to homogeneous isotropic media. It is further restricted to reflecting and refracting surfaces that are nominally smooth, and to surfaces that are figures of revolution arranged so their axes are collinear, so the entire system is a figure of revolution about the *lens axis.* (The often-used term "optical axis" is also used in crystallography. Moreover, the axis is often mechanical as well as "optical.") The lens axis is the z axis of an orthogonal coordinate system, with the x-y plane perpendicular. The distance from a point to the axis is $\rho = \sqrt{x^2 + y^2}$. Along the axis, the positive direction is from left to right.

Terminology

A *meridian* or *meridional plane* contains the axis, all such planes being equivalent. Meridional planes are planes of bilateral symmetry if the indices are homogeneous and isotropic. Some optical systems are comprised of pieces of surfaces of revolution, in which case it is still useful to discuss the behavior about the axis.

Reflection, Unfolded Diagrams

Light passes through refractive systems more or less in the same direction relative to the axis. In reflective and catadioptric systems, the light may change directions. (It may not, in the case of grazing incidence optics.) In order to consider all types of systems in a unified way, pictorially and algebraically, reflections can often be "unfolded," i.e., represented pictorially as transmission, with mirrors replaced by hypothetical lenses with the same properties, Figs. 3 and 18. Some structures must be taken into account several times in unfolding. For example, a hole may block light at one point along a ray and transmit it at another. (In some considerations, unfolding can be misleading—for instance, those involving stray light.)

Description of Surfaces

A *surface* is an interface between media with different refractive indices—either refracting or reflecting. The surface is the optical element, produced by a lens, which is a mechanical element. Surfaces can be described mathematically in many ways. (For example, conics can be described as loci of points with certain relationships.) In optical instruments, the entire surface is rarely used, and the axial region is usually special, so the description usually begins there and works out. The *vertex* of a figure of revolution intersects with

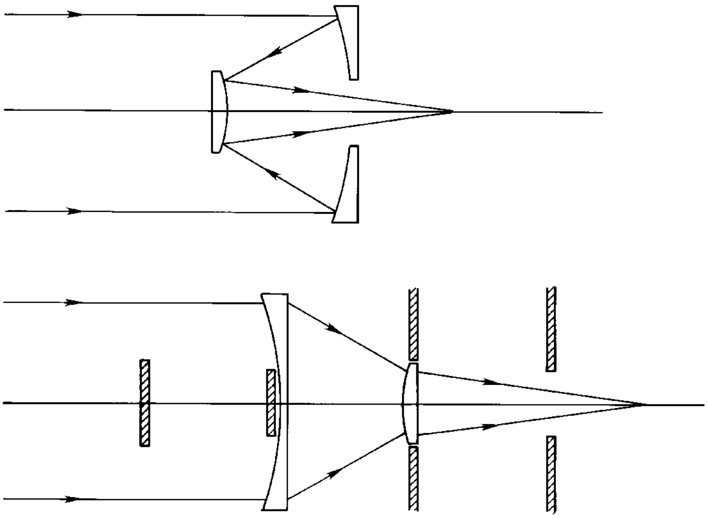

FIGURE 3 Example of an unfolded diagram. The two-mirror system above has an unfolded representation below. The reflective surfaces are replaced by thin lens equivalents. Their obstructions and the finite openings are accounted for by dummy elements.

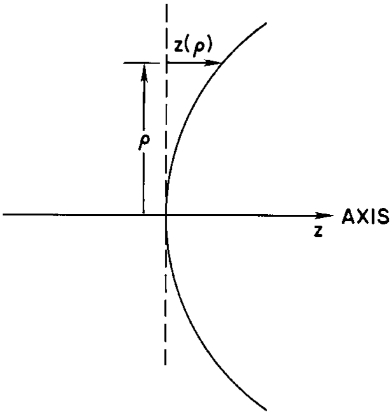

FIGURE 4 Description of a surface of revolution. The distance from the axis is ρ, and the sag $z(\rho)$ is the distance from the vertex tangent plane to the surface.

the axis, and is a local extremum. The plane perpendicular to the axis and tangent to the vertex will be referred to as the *vertex plane* (NS). A surface can be described by its *sag*, the directed distance $z(\rho)$ from the vertex plane to the surface, Fig. 4. The vertex is usually taken to have $z(0) = 0$. The *vertex curvature* or *paraxial curvature* c and radius of curvature r are given by

$$c = \frac{1}{r} = \left.\frac{\partial^2 z(\rho)}{\partial \rho^2}\right|_{\rho=0} \tag{110}$$

For an arbitrary surface, this curvature is identical to that of the sphere which is a best fit on axis. The sign convention for curvature and radius is that c and r are positive if the center of curvature is to the right of the vertex, as in the case shown in Fig. 4. In general, the curvature is mathematically more foolproof than radius, since curvature can be zero, but it is never infinite, whereas radius is never zero, but may be infinite.

Spherical Surfaces

The spherical surface is the most common in optics, since it is most naturally produced. Spherical is the default, and is assumed when no other mention is made. Aspheres are thought of as deviating from spheres, rather than spheres as special cases of more general forms. The equation for a sphere with radius r, curvature c, and a vertex at $z = 0$ is

$$\rho^2 + (z - r)^2 = r^2 \tag{111}$$

The sag is given by

$$z(\rho) = r - \sqrt{r^2 - \rho^2} = r(1 - \sqrt{1 - c^2\rho^2}) = \frac{c\rho^2}{1 + \sqrt{1 - c^2\rho^2}} \tag{112}$$

The Taylor expansion is

$$z(\rho) = \tfrac{1}{2}c\rho^2 + \tfrac{1}{8}c^3\rho^4 + \tfrac{1}{16}c^5\rho^6 + \tfrac{5}{128}c^7\rho^8 + \tfrac{7}{256}c^9\rho^{10} + \cdots \tag{113}$$

At the point (x, y, z) on the surface of the sphere, the surface normal has direction cosines

$$(L, M, N) = \left(\frac{x}{r}, \frac{y}{r}, \frac{z-r}{r}\right) = (cx, cy, cz - 1) \tag{114}$$

Conics of Rotation

The general form of a conic of rotation about the z axis is

$$z(\rho) = \frac{r}{\varepsilon}(1 - \sqrt{1 - \varepsilon c^2 \rho^2}) = \frac{c\rho^2}{1 + \sqrt{1 - \varepsilon c^2 \rho^2}} \tag{115}$$

The value of ε determines the type of conic, as given in the table below. It is common in optics to use κ, the *conic parameter* or *conic constant,* related by

$$\kappa = \varepsilon - 1 \qquad \text{or} \qquad \varepsilon = 1 + \kappa \tag{116}$$

Another parameter used to describe conics is the *eccentricity* e, used in the polar coordinate form for conics about their focus: $r(\theta) = a/(1 + e \cos \theta)$ where $e^2 = -\kappa$. In the case of paraboloids, the first form of Eq. (115) breaks down. A cone can be approximated by a hyperbola with $\kappa = -\sec^2 \theta$, where θ is the cone half angle.

Conic Type and Value of Parameter

Parameter	ε	κ	e
Oblate ellipsoid	$\varepsilon > 1$	$\kappa > 0$	—
Sphere	$\varepsilon = 1$	$\kappa = 0$	0
Prolate ellipsoid	$0 < \varepsilon < 1$	$-1 < \kappa < 0$	$0 < e < 1$
Paraboloid	$\varepsilon = 0$	$\kappa = -1$	$e = 1$
Hyperboloid	$\varepsilon < 0$	$\kappa < -1$	$e > 1$

The Taylor expansion for the sag is

$$z(\rho) = \tfrac{1}{2}c\rho^2 + \tfrac{1}{8}\varepsilon c^3\rho^4 + \tfrac{1}{16}\varepsilon^2 c^5 \rho^6 + \tfrac{5}{128}\varepsilon^3 c^7 \rho^8 + \tfrac{7}{256}\varepsilon^5 c^9 \rho^{10} + \cdots \tag{117}$$

The surface normals are

$$(L, M, N) = [1 - 2c(\varepsilon - 1)z + c^2\varepsilon(\varepsilon - 1)z^2]^{-1/2}(cx, cy, cz - 1) \tag{118}$$

The sagittal and tangential curvatures are

$$c_s = \frac{c}{[1 + (1 - \varepsilon)c^2\rho^2]^{1/2}} \qquad c_t = \frac{c}{[1 + (1 - \varepsilon)c^2\rho^2]^{3/2}} \tag{119}$$

General Asphere of Revolution

For an arbitrary figure of revolution all of whose derivatives are continuous, the Taylor expansion is

$$z(\rho) = \tfrac{1}{2}c\rho^2 + q_4\rho^4 + q_6\rho^6 + \cdots \tag{120}$$

An asphere is often treated as a sphere that matches at the vertex and a deviation therefrom:

$$z(\rho) = z_{\text{sphere}}(\rho) + a_4\rho^4 + a_6\rho^6 + \cdots \tag{121}$$

Alternatively, nonconic aspheres can be treated as conics and a deviation therefrom:

$$z(\rho) = z_{\text{conic}}(\rho) + b_4\rho^4 + b_6\rho^6 + \cdots \tag{122}$$

The expansion coefficients are different in each case. Additional information on the coefficients is given by Malacara (Malacara 1992[144]) and Brueggemann (Brueggemann 1968[135]). The sagittal and tangential curvatures are given in general by

$$c_s = \frac{\dot{z}(\rho)}{\rho[1 + \dot{z}(\rho)^2]^{1/2}} \qquad c_t = \frac{\ddot{z}(\rho)}{[1 + \dot{z}(\rho)^2]^{3/2}} \tag{123}$$

Here $\dot{z}(\rho) = dz(\rho)/d\rho$ and $\ddot{z}(\rho) = d^2z(\rho)/d\rho^2$.

1.11 TRACING RAYS IN CENTERED SYSTEMS OF SPHERICAL SURFACES

Introduction

Ray tracing is the process of calculating the paths of rays through optical systems. Two operations are involved, propagation from one surface to the next and refraction or reflection at the surfaces. Exact equations can be written for spherical surfaces and conics of revolution with homogeneous media (Spencer & Murty 1962,[146] Welford 1974, chap. 4,[147] Kingslake 1978,[148] Kinglake 1983,[149] Slyusarev 1984,[150] Klein & Furtak 1986, sec. 3.1,[151] Welford 1986, chap. 4,[152] W. J. Smith 1992, chap. 10[153]). Conics are discussed by Welford (Welford 1986, sec. 4.7[152]). For general aspheres, the intersection position is found by iterating (Nussbaum & Phillips, p. 95,[154] W. J. Smith 1992, sec. 10.5[153]). Nonsymmetric systems are discussed by Welford (Welford 1986, chap. 5[152]).

Description and Classification of Rays in a Lens

For optical systems with rotational symmetry, rays are typically described in terms of the axial parameter z. A ray crosses each constant z plane at a point (x, y) with direction cosines (α, β, γ), where γ is not independent. Thus a ray is described by $(x(z), y(z))$ and $(\alpha(z), \beta(z))$.

For systems that are figures of revolution, *meridional rays* are those lying in a meridional plane, a plane that includes the axis, and other rays are *skew rays.* The *axial ray* corresponds to the axis of revolution. Rays are also classified according to their proximity to the axis. *Paraxial rays* are those in the limit of having small angles and small distances from the axis. Nonparaxial rays are sometimes referred to as *finite rays* or *real rays. Ray fans* are groups of rays lying in a plane. A *tangential fan* lies in a meridian, and intersects at a *tangential focus.* A *sagittal fan* lies in a plane perpendicular to a meridian, and intersects at a *sagittal focus.*

Transfer

In propagating through a homogeneous medium, a ray originating at (x_1, y_1, z_1) with directions (α, β, γ) intersects a z_2 plane at

$$x_2 = x_1 + \frac{\alpha}{\gamma}(z_2 - z_1) \qquad \text{and} \qquad y_2 = y_1 + \frac{\beta}{\gamma}(z_2 - z_1) \tag{124}$$

Intersection Points

Let the intersection points of the ray with the vertex plane at $z = 0$ be $(x_0, y_0, 0)$, Fig. 5. Define auxiliary functions

$$A(x_0, y_0; \alpha, \beta; c) = \gamma - c(\alpha x_0 + \beta y_0) \qquad \text{and} \qquad B(x_0, y_0, c) = c^2(x_0^2 + y_0^2) \tag{125}$$

The distance D along the ray from this point to the surface is given by

$$cD = A - \sqrt{A^2 - B} = \frac{B}{A + \sqrt{A^2 - B}} \tag{126}$$

The intersection point has the coordinates

$$x = x_0 + \alpha D \qquad y = y_0 + \beta D \qquad z = \gamma D \tag{127}$$

The incidence angle I at the intersection point is given by

$$\cos I = \sqrt{A^2 - B} \tag{128}$$

so

$$\Gamma = -n\sqrt{A^2 - B} + \sqrt{n'^2 - n^2 + n^2(A^2 - B)} \tag{129}$$

Mathematically, double intersection points are possible, so they must be checked for. If

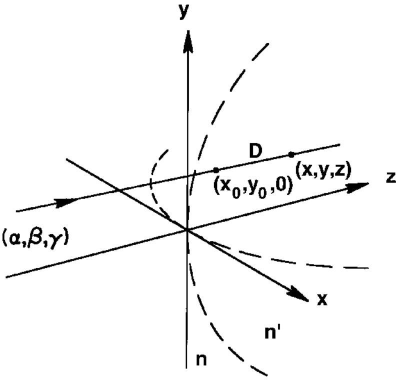

FIGURE 5 Intersection points. A ray with direction cosines (α, β, γ) intersects the vertex tangent plane at $(x_0, y_0, 0)$ and the optical surface at (x, y, z). The distance between these points is D, given by Eq. (126).

the ray misses the surface, then $A^2 < B$. If there is total internal reflection, the second square root in Eq. (129) is imaginary.

Refraction and Reflection by Spherical Surfaces

Rays refract or reflect at surfaces with reference to the local normal at the intersection point. The surface normal given by Eq. (114) is substituted in the general form for refraction, Eq. (85), to give

$$n'\alpha' = n\alpha - \Gamma cx \qquad n'\beta' = n\beta - \Gamma cy \qquad n'\gamma' = ny - \Gamma(1 - cz) \tag{130}$$

For reflection, the above equations are used, with $n' = -n$, so $\Gamma = 2n \cos I = 2n\sqrt{A^2 - B}$.

Meridianal Rays

The meridian is customarily taken to be that for which $x = 0$, so the direction cosines are $(0, \beta, \gamma)$. Let U be the angle between the axis and the ray, so $\beta = \sin U$ and $\gamma = \cos U$. The transfer equation, Eq. (124) becomes

$$y_2 = y_1 + \tan U(z_2 - z_1) \tag{131}$$

The second equation of Eq. (130) can be written

$$n' \sin U' - n \sin U = -cy(n' \cos I' - n \cos I) \tag{132}$$

If the directed distance from the vertex to the intersection point of the incident ray with the axis is l, the outgoing angle is

$$U' = U + \arcsin\left[(lc - 1)\sin U\right] - \arcsin\left[\frac{n}{n'}(lc - 1)\sin U\right] \tag{133}$$

The directed distance l' from the vertex to the axial intersection of the refracted ray is given by

$$cl' = 1 + (cl - 1)\frac{n}{n'}\frac{\sin U}{\sin U'} \tag{134}$$

For reflection, setting $n' = -n$ gives

$$U' = U + 2\arcsin\left[(lc - 1)\sin U\right] \tag{135}$$

1.12 PARAXIAL OPTICS OF SYSTEMS OF REVOLUTION

Introduction

The term *paraxial* is used in different ways. In one, paraxial rays are those whose distances from the axis and whose angles relative to the axis are small. This leaves questions of how small is small enough and how this varies from system to system. The other interpretation of the term, which is used here, is that paraxial rays represent a limiting case in which the distances from the axis and angles relative to the axis vanish. *Paraxial optics* then describes the behavior of systems in this limit. The ray-tracing equations in the paraxial limit are linear in angle and in distance from the axis, hence the term *first-order optics,* which is often considered equivalent to paraxial. (There are no 0th-order terms since the expansion is taken about the axis, so a ray with an initial height and angle of zero, i.e., a ray along the axis, has the same outgoing height and angle.) The linearity of the paraxial equations makes them simple and understandable, as well as expressible in matrix form. Paraxial ray tracing is discussed to some extent by almost every book that treats geometrical optics.

Paraxial ray tracing is done to determine the gaussian properties of lenses, to locate image positions and magnifications, and to locate pupils and determine their sizes. Another use of paraxial ray tracing, not discussed here, is the computation of third-order aberrations (W. Smith 1992[155]).

Paraxial imaging is perfect in the sense that it agrees with the Maxwell ideal and with that of collineation. Point images everywhere are stigmatic, fields are flat, and there is no distortion. Aberration is often thought of as the difference between the behavior of finite rays and that of paraxial rays. If this approach is taken, then in the process of lens design, finite rays are made to agree, insofar as possible, with the paraxial ones, which cannot be similarly changed. In the paraxial limit, surfaces are described by their vertex curvatures, so conics, aspheres, and spheres are indistinguishable, the difference being in the fourth power and above. Consequently, aberrations can be altered by changing the surface asphericity without changing paraxial properties. A paraxial treatment can be done even if a system is missing the axial region, as in the case with central obstructions and off-axis sections of figures of revolution.

This section is concerned with systems of mirrors and lenses with rotational symmetry and homogeneous refractive indices. In this case, it suffices to work in a single meridian. Generalizations are found in the sections in this chapter on images about known rays and rays in heterogeneous media. Other generalizations involve expansions about given rays in systems that are not rotationally symmetric.

The Paraxial Limit

The lens axis is the z axis, and rays in the $x = 0$ meridian are considered. Ray heights are y, and angles relative to the axis are u. In the paraxial limit, the quantities u, $\tan u$, and $\sin u = \beta$ are indistinguishable. The z-direction cosine is $\gamma = \cos u \simeq 1$. Since the ray angles and heights are small, incidence angles are likewise, so $i \simeq \sin i$, $\cos I \simeq 1$, $\cos I' \simeq 1$, and $\Gamma = n' \cos I' - n \cos I \simeq n' - n$.

Transfer

In traversing a distance t between two planes, the height of a meridional ray changes from y to y' according to Eq. (124), $y' = y + t\beta/\gamma$. In the paraxial limit, this equation becomes

$$y' = y + tu \tag{136}$$

If a ray travels from one curved surface to the next, the distance t equals the vertex separation to first order, since the correction for the surface sag is of second order in height and angle. This term is given above in Eq. (127).

Refraction

The paraxial form of Snell's law, Eq. (78), is

$$n'i' = ni \tag{137}$$

Reflection

The law of reflection is the same for paraxial as for finite rays,

$$i' = -i \tag{138}$$

Angle of Incidence at a Surface

A ray with an angle u, which intersects a surface of curvature c at height y, makes an angle i with the local surface normal of the surface given by

$$i = u + yc \tag{139}$$

This equation is easily remembered from two special cases. When $y = 0$, the intersection is at the vertex, so $i = u$. When $u = -cy$, the ray is directed through the center of curvature, so $i = 0$.

Refraction at a Surface

The above equation combined with that for Snell's law gives

$$n'u' = nu - yc(n' - n) \tag{140}$$

This equation can also be obtained from the exact equation, $n'\beta' = n\beta - \Gamma cy$, Eq. (125). In the paraxial limit, $\Gamma = n' - n$, and the intersection height y is that in the vertex plane.

Reflection at a Surface

The relationship between incident and outgoing angles at a reflecting surface is found by combining Eqs. (138) and (139), to be

$$u' = -u - 2cy \tag{141}$$

Refraction and Reflection United—Surface Power

Reflection and refraction can be treated the same way mathematically by thinking of reflection as refraction with $n' = -n$, in which case Eq. (140) gives Eq. (141). A reflecting surface can be represented graphically as a thin convex-plano or concave-plano thin lens with index $-n$, where n is the index of the medium, Fig. 18. For both refraction and reflection,

$$n'u' = nu - y\phi \tag{142}$$

where the surface *power* ϕ is

$$\phi = c(n' - n) \tag{143}$$

If the surface is approached from the opposite direction, then n and n' are switched, as is the sign of c, so ϕ is the same in both directions. Thus ϕ is a scalar property of the interface, which can be positive, negative, or zero. The power is zero if $n' = n$ or $c = 0$. If $n' = n$, the surface is "invisible," and the rays are not bent. If $c = 0$, the rays are bent. For a planar refracting surface $n'u' = nu$, and a planar reflecting surface gives $u' = -u$.

Principal Focal Lengths of a Surface

A ray approaching a surface parallel to the axis ($u = 0$) with a height y has an outgoing angle given by

$$n'u' = -y\phi \tag{144}$$

This ray intercepts the axis at the *rear focal point,* whose directed distance from the vertex is $f' = y/u' = n'/\phi$. This directed distance is the *rear focal length.* Similarly, a ray entering from the right with $u' = 0$ intercepts the axis at the *front focal point,* a directed distance from the vertex of $f = y/u = -n/\phi$, the *front focal length.* Thus, a surface has a single power and two focal lengths, among which the following relationships hold:

$$f' = \frac{n}{\phi} \qquad f = -\frac{n}{\phi} \qquad \phi = -\frac{n}{f} = \frac{n'}{f'} \qquad \frac{f'}{f} = -\frac{n'}{n} \tag{145}$$

For a refracting surface, the signs of f' and f are opposite. For a reflecting surface $f' = f$.

Axial Object and Image Locations for a Single Surface

A ray from an axial point a directed distance l from the vertex of a surface that makes an angle u with the axis intersects the surface at height $y = -l/u$. After refraction or reflection, the ray angle is u', and the ray intersects the axis at a distance $l' = -y/u'$ from the vertex, Fig. 6. Substituting for u and u' in Eq. (142), the relationship between axial object and image distances is

$$\frac{n'}{l'} = \frac{n}{l} + \phi \tag{146}$$

This can also be written

$$n\left(\frac{1}{r} - \frac{1}{l}\right) = n'\left(\frac{1}{r} - \frac{1}{l'}\right) \tag{147}$$

This is a special case of the equations below for imaging about a given ray. The transverse magnification is $m = l'/l$.

Paraxial Ray Tracing

Paraxial rays are traced through an arbitrary lens by a sequence of transfers between surfaces and power operations at surfaces. Each transfer changes height but not angle, and each power operation changes angle but not height. An image can be found by applying Eq. (136) and Eq. (142) successively. Alternatively, matrix methods described below can be used.

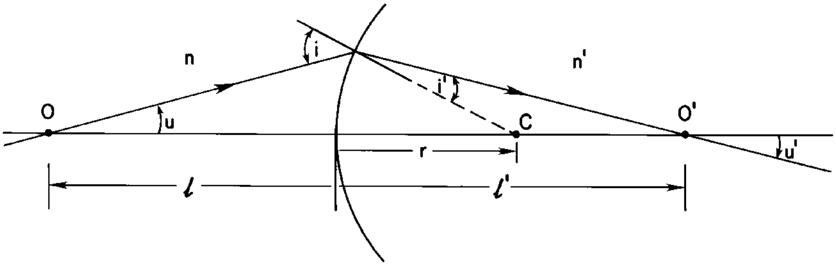

FIGURE 6 Refraction at a single spherical surface with center C and radius r. Axial object point O is imaged at O'.

Linearity of Paraxial Optics

For both the transfer and power operations, the outgoing heights and angles depend linearly on the incoming heights and angles. So a system described by a sequence of such operations is also linear. Therefore, a ray that enters with height y and angle u leaves with $y'(y, u)$ and $u'(y, u)$ given by

$$y' = \left(\frac{\partial y'}{\partial y}\right) y + \left(\frac{\partial y'}{\partial u}\right) u \qquad \text{and} \qquad u' = \left(\frac{\partial u'}{\partial y}\right) y + \left(\frac{\partial u'}{\partial u}\right) u \tag{148}$$

These equations can also be thought of as the first terms of Taylor expansions of exact expressions for $y'(y, u)$ and $u'(y, u)$. These partial derivatives depend on the structure of the system, and they can be determined by tracing two rays through the system. The partial derivatives, other than $\partial u'/\partial y$, also depend on the axial locations of the input and output surfaces. The changes with respect to these locations are treated easily by matrix methods.

The Two-Ray Paraxial Invariant

The various rays that pass through a lens are not acted upon independently, so there are several invariants that involve groups of rays. Consider two meridional paraxial rays that pass through a lens. At a given plane, where the medium has an index n, one ray has height y_1 and angle u_1, and the other has y_2 and u_2. The quantity

$$L = ny_1u_2 - ny_2u_1 = n(y_1u_2 - y_2u_1) \tag{149}$$

which we refer to as the *paraxial invariant* (NS), is unchanged as the rays pass through the system. Applying Eq. (136) and Eq. (142) to the above expression shows that this quantity does not change upon transfer or upon refraction and reflection. The invariant is also related to the general skew invariant, Eq. (73), since a paraxial skew ray can be decomposed into two meridional rays.

Another version of the invariance relationship is as follows. Two objects with heights y_1 and y_2 are separated axially by d_{12}. If their image heights are y_1' and y_2', and the image separation is d_{12}', then

$$n\frac{y_1 y_2}{d_{12}} = n'\frac{y_1' y_2'}{d_{12}'} \tag{150}$$

An additional version of the invariance relationship is

$$\left(\frac{\partial y'}{\partial y}\right)\left(\frac{\partial u'}{\partial u}\right) - \left(\frac{\partial y'}{\partial u}\right)\left(\frac{\partial u'}{\partial y}\right) = \frac{n}{n'} \tag{151}$$

where the partial derivatives, Eq. (148), describe the action of any system.

The invariant applies *regardless* of the system. Thus, for example, if the lens changes, as with a zoom system, so that both of the outgoing rays change, their invariant remains. The invariant arises from basic physical principles that are manifested in a variety of ways, for example, as conservation of brightness and Liouville's theorem, discussed above in the section on conservation of etendue. This invariance shows that there are fundamental limits on what optical systems can do. Given the paraxial heights and angles of two input rays, only three of the four output heights and angles can be chosen arbitrarily. Likewise, only three of the four partial derivatives above can be freely chosen. The invariant is not useful if it vanishes identically. This occurs if the two rays are scaled versions of one another, which happens if both $u_1 = 0$ and $u_2 = 0$ for some z, or if both rays pass through the same axial object point, in which case $y_1 = 0$ and $y_2 = 0$. The invariant also vanishes if one of the rays lies along the axis, so that $y_1 = 0$ and $u_1 = 0$.

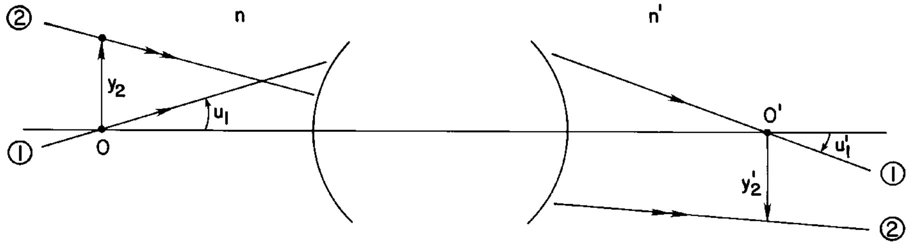

FIGURE 7 An object and image plane with ray 1 through the axial points and ray 2 through off-axis points. The location and magnification of an image plane can be found by tracing a ray from the axial object point O to axial image point O'. The magnification is given by Eq. (153). In the case pictured, u_1 and u_1' have opposite signs, so the transverse magnification is negative.

Image Location and Magnification

To locate an image plane, any ray originating at the axial object point can be traced through the system to determine where it again intersects the axis, Fig. 7. The magnification for these conjugates can be found in two ways. One is to trace an arbitrary ray from any off-axis point in the object plane. The ratio of its height in the image plane to that in the object plane is the transverse magnification.

Alternately, the magnification can be found from the initial and final angles of the ray through the axial points. Let ray 1 leave the axial object point, so $y_1 = 0$. Let ray 2 originate in the object plane some distance from the axis. At the object plane $L = ny_2u_1$, and at the image plane $y_2' = 0$, so $L = n'y_2'u_1'$. Therefore,

$$L = ny_2u_1 = n'y_2'u_1' \tag{152}$$

So the magnification is

$$m = \frac{y_2'}{y_2} = \frac{nu_1}{n'u_1'} \tag{153}$$

The relative signs of u and u' determine that of the magnification. Equation (153) is a paraxial form of the sine condition Eq. (106). Squaring this equation gives $L^2 = n^2y_2^2u_1^2$, which is proportional to a paraxial form of the etendue. These matters are discussed further in the sections on conservation of etendue and on apertures. The quantity ny_2u_1 is sometimes referred to as *the* invariant, but it is not the most general form.

Three-Ray Rule

A further consequence of the paraxial invariant and of the linearity of paraxial optics, is that once the paths of two paraxial meridional rays has been found, that of any third ray is determined. Its heights and angles are a linear combination of those of the other two rays. Given three rays, each pair has an invariant: $L_{12} = n(y_1u_2 - y_2u_1)$, $L_{23} = n(y_2u_3 - y_3u_2)$, and $L_{31} = n(y_3u_1 - y_1u_3)$. Therefore, in every plane

$$y_3 = -\frac{L_{23}}{L_{12}}y_1 + \frac{L_{31}}{L_{12}}y_2 \quad \text{and} \quad u_3 = -\frac{L_{23}}{L_{12}}u_1 + \frac{L_{31}}{L_{12}}u_2 \tag{154}$$

This assumes that no pair of the three rays are simply scaled versions of one another, i.e. that both $L_{23} \neq 0$ and $L_{31} \neq 0$.

Switching Axial Object and Viewing Positions

If an axial object and axial viewing position are switched, the apparent size of the image is unchanged. Put more precisely, let an object lie in a plane intersecting the axial point A and let its image be viewed from an axial point B' in image space that is not conjugate to

A. If the object and viewing positions are switched, so the eye is at *A* and the object plane is at *B′*, the subtense of the object as seen by the eye is unchanged. (Rayleigh 1886,[156] Southall 1910,[157] Herzberg 1935,[158] Brouwer 1967[159]).

1.13 IMAGES ABOUT KNOWN RAYS

Given a ray, referred to here as the *central ray* (also "base ray"), other rays from a point on the central ray making a small angle with respect to it are focused at or near other points on the central ray. These foci can be determined if the path of a central ray is known, as well as the indices of the media through which it passes, and the principal curvatures at the surfaces where it intersects. Here indices are constant. At each intersection point with an optical surface, the wavefront has two principal curvatures, as does the surface. After refraction or reflection, the wavefront has two different principal curvatures. Accordingly, if a single point is imaged, there are two astigmatic focal lines at some orientation. These foci are perpendicular, but they do not necessarily lie in planes perpendicular to that of the central ray. The imaging of a small extended region is generally skewed, so, for example, a small square in a plane perpendicular to the central ray can be imaged as a rectangle, parallelogram, or trapezoid.

This is a generalization of paraxial optics, in which the central ray is the axis of a system of revolution. While not difficult conceptually, the general case of an arbitrary central ray and an arbitrary optical system is algebraically complicated. This case can also be analyzed with a hamiltonian optics approach, using an expansion of a characteristic function about the central ray, like that of Eq. (28). The subject is sometimes referred to as *parabasal optics,* and the central ray as the *base ray.* This subject has been discussed by numerous authors[160–186] under various names, e.g., "narrow beams," "narrow pencils," "first order."

The following is limited to the case of meridional central rays and surfaces that are figures of revolution. The surface, at the point of intersection, has two principal curvatures c_s and c_t. [See Eqs. (119), (123).] For spherical surfaces, $c_s = c_t = c,$ and for planar surfaces $c = 0$. There is a focus for the sagittal fan and one for the tangential one, Fig. 8, the two

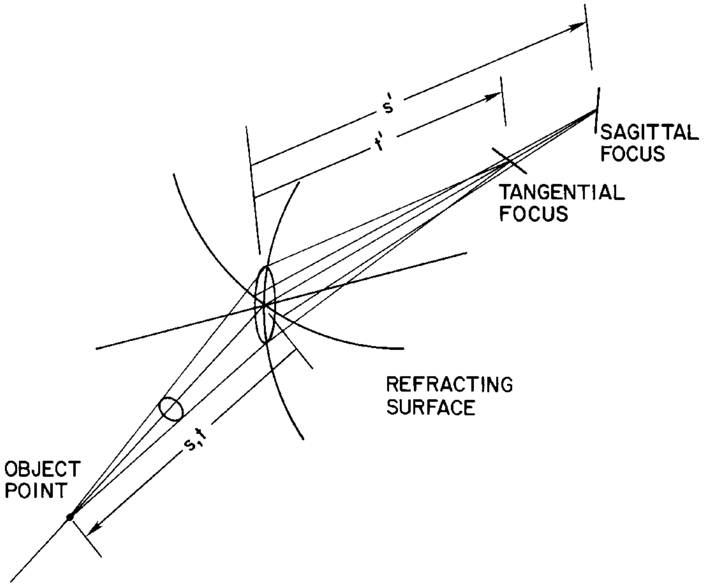

FIGURE 8 Astigmatic imaging of a point by a single refracting surface. The distance from the surface to the object point along the central ray of the bundle is $s = t$. The distances from the surface to the sagittal focus is s', and that to the tangential focus is t', as given by Eq. (155).

foci coinciding if the imaging is stigmatic. After one or more surfaces are encountered, the separated foci are the sources for subsequent imaging. Let s and t be the directed distances from the intersection point of the central ray and the surface to the object point, and s' and t' be the distances from intersection point to the foci. The separation $|s'-t'|$ is known as the *astigmatic difference.*

For refraction

$$\frac{n'}{s'}=\frac{n}{s}+c_s\Gamma \qquad \text{and} \qquad \frac{n'\cos^2 I'}{t'}=\frac{n\cos^2 I}{t}+c_t\Gamma \tag{155}$$

where $\Gamma = n'\cos I' - n\cos I$, Eq. (82). The sagittal equation is simpler, providing a mnemonic for remembering which equation is which: "S" = sagittal = simpler. If the surface is spherical, and the ray fan makes an arbitrary angle of ψ with the meridian, then (H. Hopkins 1950[175])

$$\frac{n'}{d'}(1-\cos^2\psi\sin^2 I')=\frac{n}{d}(1-\cos^2\psi\sin^2 I)+c\Gamma \tag{156}$$

where d and d' are the distances along the central ray from the surface to the object and image points. For normal incidence at a spherical surface $\Gamma = n'-n$, so both equations become

$$\frac{n'}{d'}=\frac{n}{d}+c(n'-n) \tag{157}$$

This also applies to surfaces of revolution if the central ray lies along the axis. This equation is identical to the paraxial equation, Eq. (146).

The corresponding relations for reflection are obtained by setting $n' = -n$ and $I' = I$ in the refraction equations, giving

$$\frac{1}{s'}=-\frac{1}{s}+2c_s\cos I \qquad \text{and} \qquad \frac{1}{t'}=-\frac{1}{t}+\frac{2c_t}{\cos I} \tag{158}$$

For stigmatic imaging between the foci of reflective conics, $s = t$ is the distance from one focus to a point on the surface, and $s' = t'$ is that from the surface to the other focus. Therefore, $c_t = c_s\cos^2 I$. The reflection analogue to Eq. (156), for a spherical surface is

$$\frac{1}{d'}=-\frac{1}{d}+\frac{2c\cos I}{1-\cos^2\psi\sin^2 I} \tag{159}$$

These equations are known by several names, including *Coddington's equations, Young's astigmatic formulae,* and the *s-* and *t-trace formulae.*

1.14 GAUSSIAN LENS PROPERTIES

Introduction

The meaning of the term *gaussian optics* is not universally agreed upon, and it is often taken to be indistinguishable from paraxial optics or first-order optics, as well as collineation. Here the term is considered to apply to those aspects of paraxial optics discovered by Gauss (Gauss 1840[187]), who recognized that all rotationally symmetric systems of lens elements can be described paraxially by certain system properties. In particular, lenses can be treated as black boxes described by two axial length parameters and the locations of special points, called *cardinal points,* also called *Gauss points.* Once a lens is so characterized, knowledge of its actual makeup is unnecessary for many purposes, and repeated ray traces need not be performed. For example, given the object location, the image location and magnification are determined from the gaussian parameters. From the gaussian description of two or more lenses, that of a coaxial combination can be found. Another consequence of Gauss's discovery is that there is an infinity of specific embodiments for any external prescription.

The lenses considered in this section are figures of revolution with uniform object space and image space indices n and n'. All quantities discussed in this section are paraxial, so the prefix "paraxial" is not repeated. For the purposes of this section, no distinction is made between real and virtual rays. Those in each space are considered to extend infinitely, and intersection points may be either accessible or inaccessible. The quantities used in this section are found in Table 1.

Power, Focal Lenses, and Afocal Lenses

A paraxial ray entering a lens parallel to the axis height y leaves with some angle u', Fig. 9. Likewise, a ray entering from the opposite side with height y' leaves with angle u. The *power* of the lens is defined by

$$\phi = -n'\frac{u'}{y} = n\frac{u}{y'} \tag{160}$$

The outgoing ray can have any angle, and the power can be positive, negative, or zero. If $u' = 0$, then $\phi = 0$ and the lens is *afocal* or *telescopic.* Lenses for which $\phi \neq 0$ are referred to here as *focal,* although the term "nonafocal" is more common. Afocal lenses are fundamentally different from focal ones, and are treated separately below. Power is the same in both directions, i.e. whether the ray enters from left to right or from right to left. The lens in Fig. 9 has $\phi > 0$, and that in Fig. 10 has $\phi < 0$. Diagrams such as Fig. 11 show the location of the principal focal point, but not the sign of the power; two rays enter and two leave, but there is no indication of which is which. (Note that some negative lenses have accessible rear focal points.) Another expression for power involves two rays at arbitrary angles and heights. If two incident rays have (y_1, u_1) and (y_2, u_2), and a nonzero invariant $L = n(y_1u_2 - y_2u_1)$, and the outgoing ray angles are u'_1 and u'_2, then

$$\phi = -\frac{nn'}{L}(u'_1u_2 - u'_2u_1) \tag{161}$$

Focal Lenses

Focal lenses are those for which $\phi \neq 0$. Their cardinal points are the principal focal points, the principal points, and the nodal points. These points may be located anywhere on axis relative to the physical lens system. If they are inside a lens, then the intersection points referred to below are virtual. The cardinal points are pairs consisting of a member in object space and one in image space. The one in object space is often referred to as *front,* and the one in image space as *rear,* but this terminology may be misleading, since the points can be any sequence along the axis.

Principal Focal Points. Rays entering a lens parallel to its axis cross the axis at the *principal focal points* or *focal points.* Rays parallel to the axis in object space intersect the axis at the *rear focal point F'* in image space and those parallel in image space intersect at the *front focal point F* in object space, Fig. 9. The *principal focal planes* or *focal planes* are the planes perpendicular to the axis at the focal points. The terms *focal point* and *focal plane* are often used to refer to the images of any point or plane. In this chapter, *image point* is used for other points where rays are focused and *image plane* for other planes.

Principal Planes. The *principal planes* are the conjugate planes for which the transverse

TABLE 1 Gaussian Notation and Definitions

By convention, in the diagrams the object space is to the left of the lens, image space is to the right, and rays go left to right. Object space quantities are unprimed, and image space quantities are primed, and quantities or positions that correspond in some way have same symbol, primed and unprimed. This correspondence can have several forms, e.g., the same type of thing or conjugate. The term *front* refers to object space, or left side, and *rear* to image space, or right side. A ‘‘front’’ entity may actually be behind a ‘‘rear’’ one. For example, a negative singlet has its object space focal point behind lens.

Scalars

n and n' object and image space refractive indices
ϕ power
m transverse magnification
m_N nodal point magnification $= n/n'$
m_L longitudinal magnification
m_α angular magnification
u and u' paraxial ray angles (the positive direction is counterclockwise from the axis)
y and y' paraxial ray heights
y_P paraxial ray height at the principal planes $= y'_P$

Axial points

Cardinal points:
Focal points F and F', not conjugate
Principal points P and P', conjugate $m = +1$
Nodal points N and N', conjugate $m_N = n/n'$
Other points:
Axial object and image points O and O', conjugate
Arbitrary object and image points A and A', B and B'
Vertices V and V', not conjugate, in general

Directed axial distances

These distances here are between axial points and are directed.
Their signs are positive if from left to right and vice versa.
Types of distances: entirely in object or image space, between spaces
Principal focal lengths: $f = PF$ and $f' = P'F'$
Principal points to object and image axial points: $l = PO$ and $l' = P'O'$
Front and rear focal points to object and image axial points: $z = FO$ and $z' = F'O'$
Relations: $l = f + z$ and $l' = f' + z'$
Arbitrary point to conjugate object and image points: $d = AO$ and $d' = A'O'$

Distances between object space and image space points involve distances within both spaces, as well as a distance *between* the spaces, e.g., PP', FF', VV', and OO'. The distances between spaces depend on the particular structure of the lens. They can be found by paraxial ray tracing.

magnification is unity, Fig. 12. The intersections of the principal planes and the axis are the *principal points,* denoted by P and P'. The *rear principal plane* is the locus of intersections between $u = 0$ rays incident from the left and their outgoing portions, Fig. 9. Likewise, the *front principal plane* is the intersection so formed with the rays for which $u' = 0$. A ray intersecting the first principal plane with height y_P and angle u leaves the second principal plane with height $y' = y_P$ and an angle given by

$$n'u' = nu - y_P\phi \qquad (162)$$

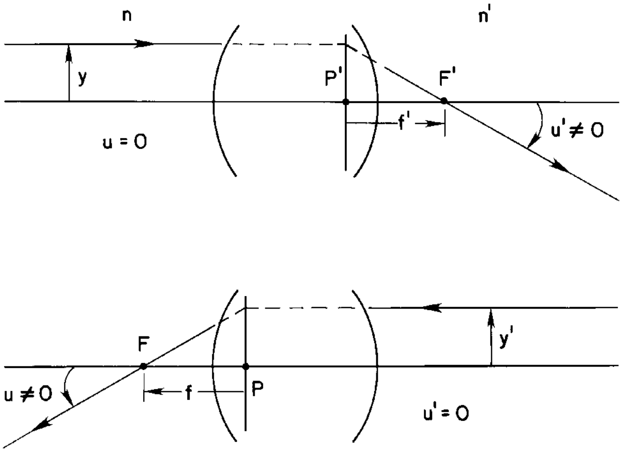

FIGURE 9 Diagrams for determining power, focal points, and focal lengths. Rays parallel to the axis in one space cross the axis in the other space at the focal points. The principal planes are at the intersections of entering and leaving rays. The power is given by Eq. (159). The lens in this diagram has positive power, a positive rear focal length, and a negative front focal length.

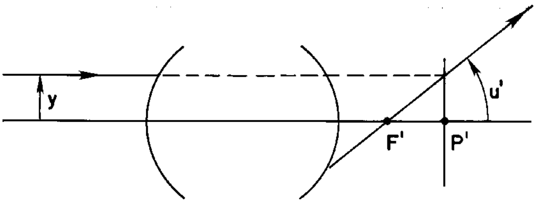

FIGURE 10 A lens with negative power and negative rear focal length. An incoming ray parallel to the axis with a positive height leaves the lens with a positive angle. The rear focal plane precedes the rear principal plane.

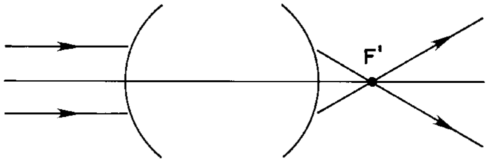

FIGURE 11 An ambiguous diagram. Two rays that enter a lens parallel to its axis converge at the rear focal point *F'*. Without specifying which ray is which, the sign of the power is not known.

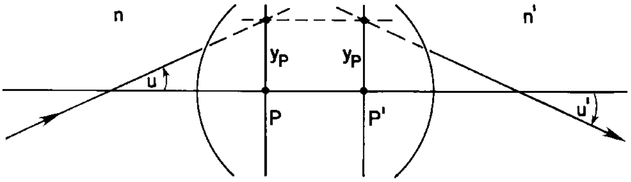

FIGURE 12 Principal planes as effective ray-bending surfaces. Incoming and outgoing paraxial rays intersect the object and image space principal planes at the same height y_P. The angles are related by Eq. (161).

The lens behaves as if the incoming ray intercepts the front principal plane, is transferred to the second with its height unchanged, and is bent at the second by an amount proportional to its height and to the power of lens. The power of the lens determines the amount of bending. For rays passing through the principal points, $y_p = 0$, so $u'/u = n/n'$.

Principal Focal Lengths. The *focal lengths,* also called *effective focal lengths,* are the directed distances from the principal points to the focal points. The front and rear focal lengths are

$$PF = f = -\frac{n}{\phi} \qquad \text{and} \qquad P'F' = f' = \frac{n'}{\phi} \tag{163}$$

The two focal lengths are related by

$$\phi = -\frac{n}{f} = \frac{n'}{f'} \qquad \text{and} \qquad \frac{f}{f'} = -\frac{n}{n'} \tag{164}$$

This ratio is required by the paraxial invariant (Kingslake 1965, p. 214[188]). If $n = n'$, then $f' = -f$. If $n = n' = 1$, then

$$f' = -f = \frac{1}{\phi} \tag{165}$$

The focal lengths are the axial scaling factors for the lens, so axial distances in all equations can be scaled to them.

Nodal Points. The *nodal points* are points of unit angular magnification. A paraxial ray entering the *object space nodal point N* leaves the *image space point N'* at the same angle, Fig. 13. The planes containing the nodal points are called *nodal planes.* A *nodal ray* is one that passes through the nodal points. Such a ray must cross the axis, and the point where it does so physically is sometimes called the *lens center.* In general, this point has no special properties. (Gauss suggested an alternate "lens center," the point midway between the

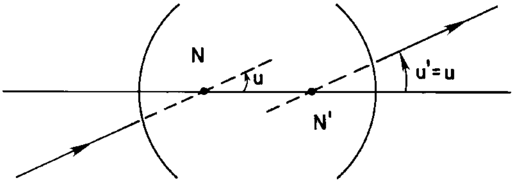

FIGURE 13 Nodal points. A paraxial ray through the object space nodal point N passes through image space nodal point N' with the same angle.

principal points. Rotating a lens front to rear about this point would leave object and image positions and magnifications unchanged.)

If the refractive indices of the object space and image space are the same, the nodal points correspond to the principal points. If not, both nodal points are shifted according to

$$PN = P'N' = \frac{n' - n}{\phi} = f + f' \tag{166}$$

The distances from the nodal points to the focal points are

$$N'F' = -f \qquad \text{and} \qquad NF = -f' \tag{167}$$

The nodal points are conjugate, and the transverse magnification of the nodal planes is

$$m_{\mathrm{N}} = \frac{n}{n'} \tag{168}$$

These equations can be recalled by the simple example of the single refracting surface, for which both nodal points correspond to the center of curvature.

Conjugate Equations. For an object plane perpendicular to the axis at point O, there is an image plane perpendicular to the axis at O', in which the transverse magnification is m. Note that specifying magnification implies both object and image positions. There is a variety of *conjugate equations* (NS) that relate their positions and magnifications. The equations differ in which object space and image space reference points are used from which to measure the directed distances to the object and image. These equations can be written in several ways, as given below, and with reference to Fig. 14. Axial distances can be scaled to the focal lengths, or the distances can be scaled to the indices, with a common power term remaining.

The simplest conjugate equation is *Newton's equation*, for which the reference points are the focal points and the lengths therefrom are $z = FO$ and $z' = F'O'$. The equation can be written in several forms:

$$zz' = ff' \qquad \text{or} \qquad \frac{z'}{f'}\frac{z}{f} = 1 \qquad \text{or} \qquad \frac{z'}{n'}\frac{z}{n} = \frac{1}{\phi^2} \tag{169}$$

More generally, if A and A' are any pair of axial conjugate points, as are B and B', then

$$FA \times F'A' = FB \times F'B' \tag{170}$$

Another form is that for which the reference points are the principal points and the

If the reference points are arbitrary conjugates with magnification m_A and the axial distances are $d = AO$ and $d' = A'O'$, then

$$m_A \frac{n'}{d'} = \frac{1}{m_A} \frac{n}{d} + \phi \qquad \text{or} \qquad \frac{d'}{f'} = \frac{m_A^2 \dfrac{d}{f}}{1 - m_A \dfrac{d}{f}} \tag{172}$$

This equation also relates the curvatures of a wavefront at conjugate points. For a point source at A the radius of the wavefront at O is d, so at O' the radius is d'.

If the reference points are the nodal points, $m_A = m_N = n/n'$, and the axial distances are $d = NO$ and $d' = N'O'$, then

$$1 = \frac{f}{d'} + \frac{f'}{d} \qquad \text{or} \qquad \frac{n}{d'} = \frac{n'}{d} + \phi \tag{173}$$

The most general equation relating conjugate points is obtained when both reference points are arbitrary. Let the reference point in object space be a point A, at which the magnification is m_A, and that in image space be B', associated with magnification m'_B. If $d = AO$ and $d' = B'O'$, then

$$\frac{1}{\phi}\left(1 - \frac{m'_B}{m_A}\right) = \frac{1}{m_A} d - m'_B\, d' + \phi\, d\, d' \qquad \text{or}$$

$$d' = \frac{\dfrac{1}{m_A} d + \left(\dfrac{m'_B}{m_A} - 1\right)\dfrac{1}{\phi}}{\phi\, d - m'_B} \tag{174}$$

All the other conjugate equations are special cases of this one with the appropriate choice of m_A and m'_B.

If the reference point in object space is the focal point, and that in image space is the principal plane, then $m_A = \infty$ and $m'_B = 1$, giving

$$\frac{n'}{z'\phi} = \frac{l\phi}{n} + 1 \qquad \text{or} \qquad \frac{f'}{z'} = \frac{l}{f} + 1 \tag{175}$$

Likewise, if the object space reference point is P and the image space reference is F', then

$$\frac{n'}{l'\phi} = \frac{z\phi}{n} + 1 \qquad \text{or} \qquad \frac{f'}{l'} = \frac{z}{f} + 1 \tag{176}$$

A relationship between distances to the object and image from the principal points and those from the focal points is

$$1 = \frac{z'}{l'} + \frac{z}{l} = \frac{F'O'}{P'O'} + \frac{FO}{PO} \tag{177}$$

Transverse Magnification. In planes perpendicular to the axis, the *transverse magnification,* usually referred to simply as the *magnification,* is

$$m = \frac{x'}{x} = \frac{y'}{y} = \frac{dx'}{dx} = \frac{dy'}{dy} \tag{178}$$

There are several equations for magnification as a function of object position or image position, or as a relationship between the two. Newton's equations are

$$m = -\frac{f}{z} = -\frac{z'}{f'} = \frac{f}{f - l} = \frac{f' - l'}{f'} \tag{179}$$

Other relationships are

$$m = \frac{n}{n'}\frac{l'}{l} = -\frac{f}{f'}\frac{l'}{l} = \frac{z'}{l'}\frac{l}{z} \tag{180}$$

If $n = n'$, then $m = l'/l$. Another form, with respect to conjugate planes of magnification m_A is

$$mm_A = \frac{n}{d}\frac{d'}{n'} = \frac{f}{d}\frac{d'}{f'} \tag{181}$$

If d and d' are distances from the nodal points, $m = d'/d$. The change of magnification with respect to object or image positions with conjugacy maintained is

$$\frac{dm}{dz'} = -\frac{1}{f'} = \frac{m}{z'} \qquad \text{and} \qquad \frac{dm}{dz} = \frac{f}{z^2} = \frac{m^2}{f} = \frac{m}{z} \tag{182}$$

Images of Distant Objects. If an object at a great distance from the lens subtends an angle ψ from the axis at the lens, then its paraxial linear extent is $y = z\psi$. The image height is

$$y' = my = \frac{-f}{z}y = -f\psi = \frac{n}{n'}f'\psi \qquad \text{and} \qquad \frac{dy'}{d\psi} = \frac{n}{n'}f' \tag{183}$$

If a distant object moves perpendicularly to the axis, then its image moves in the opposite direction if $f' > 0$ and in the same direction if $f' < 0$, so long as n and n' have the same sign.

Distance Between Object and Image. The directed distance from an axial object point to its image contains three terms, one in object space, one in image space, and one relating the two spaces. The first two depend on the magnification and focal lengths. The interspace term depends on the particular structure of the lens, and is found by paraxial ray tracing. The most commonly used interspace distance is PP', since it equals zero for a thin lens, but the equations using FF' are simpler. Newton's equations give $z = -f/m$ and $z' = -mf'$, so the object-to-image distance is

$$OO' = FF' - z + z' = FF' - f'm + \frac{f}{m} = FF' - \frac{1}{\phi}\left(n'm + \frac{n}{m}\right) \tag{184}$$

This is the basic equation from which all others are derived. If the reference points are the principal points, then

$$OO' = PP' + f'(1-m) - f\left(1 - \frac{1}{m}\right) = PP' + \frac{1}{\phi}\left[n'(1-m) + n\left(1 - \frac{1}{m}\right)\right] \tag{185}$$

If the object-to-image distance is given, the magnification is

$$m = \frac{1}{2n'}(-q \pm \sqrt{q^2 - 4nn'})$$

where $q = \phi(OO' - PP') - n - n'$. (186)

There are two magnifications for which OO' is the same. The magnitude of their product is n/n'. The derivative of the object-to-image distance with respect to the magnification is

$$\frac{d}{dm}OO' = -f' - \frac{f}{m^2} = -f' - \frac{z^2}{f} = \frac{1}{\phi}\left(\frac{n}{m^2} - n'\right) \tag{187}$$

Extrema occur at $m \pm \sqrt{n/n'}$, giving $m = \pm 1$ if $n = n'$. The extrema are

$$OO' - FF' = \pm \frac{2}{\phi} \sqrt{nn'} = \pm 2\sqrt{-ff'} \tag{188}$$

or

$$OO' - PP' = \frac{1}{\phi}(n + n' \pm 2\sqrt{nn'}) = f' - f \pm 2\sqrt{-ff'} \tag{189}$$

For the common case of $n' = n$, the object-to-image distance is

$$OO' = PP' + f'\left(2 - m - \frac{1}{m}\right) \tag{190}$$

OO' is the same for magnifications m and $1/m$. For a lens with $f' > 0$, the extremum object-to-image distances are $OO' - PP' = 4f'$ with $m = -1$ and $OO' - PP' = 0$ for $m = +1$. If the object-to-image distance and the focal length are given, then the magnification is

$$m = -\tfrac{1}{2}s \pm \sqrt{\tfrac{1}{4}s^2 - 1}$$

where $s = \frac{1}{f'}(OO' - PP') - 2.$ (191)

The two values of m are reciprocal.

Axial Separations and Longitudinal Magnification. Two axial points A and B are imaged at A' and B' with magnifications m_A and m_B. Newton's equations give the object separation

$$\Delta z = z_A - z_B = \frac{m_A m_B}{m_B - m_A} f \tag{192}$$

The separation of their images is

$$\Delta z' = z'_A - z'_B = (m_B - m_A) f' \tag{193}$$

The ratio of the image and object separations is

$$\frac{\Delta z'}{\Delta z} = \frac{z'_A - z'_B}{z_A - z_B} = \frac{A'B'}{AB} = \frac{n'}{n} m_A m_B = -\frac{f'}{f} m_A m_B \tag{194}$$

If m_A and m_B have different signs, then the direction of $A'B'$ is opposite that of AB. This occurs when A and B are on opposite sides of the front focal point. In the limit as the separation between A and B vanishes, m_A and m_B both approach the same magnification m. The *longitudinal magnification* m_L is the ratio of axial separations in the limit of small separations

$$m_L = \underset{A \to B}{LIMIT} \frac{A'B'}{AB} = \frac{dz'}{dz} = \frac{n'}{n} m^2 = -\frac{z'}{z} \tag{195}$$

This quantity is also called the *axial magnification.* Since m^2 is always positive, as an object moves axially in a given direction, its image moves in a constant direction. There is a discontinuity in image position when the object crosses the focal point, but the direction of motion stays the same. At the nodal points, the transverse and longitudinal magnifications are equal.

Angular Magnification. The ratio of the outgoing to incoming ray angles, u'/u is sometimes called the *angular magnification* m_α. If the ray passes through conjugate axial points with magnification m, then the angular magnification is

$$m_\alpha = \frac{u'}{u} = \frac{n}{n'}\frac{1}{m} \tag{196}$$

If the ray leaves an object point with height y in a plane for which the magnification is m, the outgoing ray angle is given by

$$n'u' = \frac{1}{m} nu - y\phi = \frac{1}{m}(nu - y'\phi) \tag{197}$$

The ratio u'/u is not constant unless $y = 0$ or $\phi = 0$.

Relationship Between Magnifications. The transverse, angular, and longitudinal magnifications are related by

$$m_\alpha m_L = m \tag{198}$$

This relationship is connected to the paraxial invariant and also holds for afocal lenses.

Reduced Coordinates. Many relationships are formally simplified by using reduced axial distances $\tau = z/n$ and $\tau' = z'/n'$ and reduced angles $\omega = nu$, $\omega' = n'u'$, which are paraxial optical direction cosines. For example, the angular magnification is $\omega'/\omega = 1/m$, and the longitudinal magnification is $d\tau'/d\tau = m^2$.

Mechanical Distances. The cardinal points can be located anywhere on axis relative to the physical structure of the lens. The *vertex* of a lens is its extreme physical point on axis. The object space vertex is denoted by V and the image space vertex by V'. The two vertices are not, in general, conjugate. The *front focal distance FV* is that from the vertex to the front focal point, and the *rear focal distance V'F'* is that from the rear vertex to the rear focal point. Likewise, the *front working distance OV* is the distance from the object to the vertex, and the *rear working distance V'O'* is that from the vertex to the image. These lengths have no significance to the gaussian description of a lens. For example, a lens of a given focal length can have any focal distance and vice versa. For a *telephoto* lens the focal length is greater than the focal distance, and for a *retrofocus* lens the focal distance is greater than the focal length.

Afocal Lenses

An *afocal* or *telescopic* lens (Wetherell 1987,[189] Wetherell 1994,[190] Goodman 1988[191]) is one for which $\phi = 0$. A ray entering with $u = 0$ leaves with $u' = 0$, Fig. 15. There are no

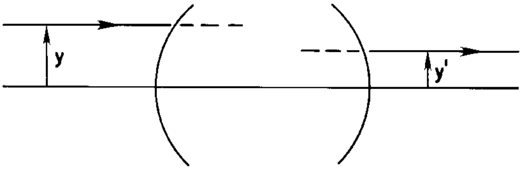

FIGURE 15 Afocal lens. Paraxial rays entering parallel to the axis leave parallel, in general at a different height. The ratio of the heights is the transverse magnification, which is constant.

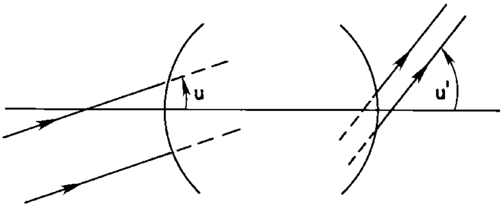

FIGURE 16 Afocal lens. Groups of paraxial rays entering parallel leave parallel, in general at a different angle. The ratio of the angles is the angular magnification, which is constant.

principal focal points or focal lengths. In general, the $u = 0$ ray leaves at a different height than that at which it enters. The ratio y'/y is the same for all such rays, so the transverse magnification m is constant. Likewise, the longitudinal magnification is constant, equaling $m_L = (n'/n)m^2$, as is the angular magnification $u'/u = m_\alpha = n/(n'm)$. A parallel bundle of rays entering at angle u leaves as a parallel bundle at $u' = m_\alpha u$, Fig. 16. Summarizing:

$$m = \text{const} \qquad m_L = \frac{n'}{n} m^2 = \text{const} \qquad m_\alpha = \frac{n}{n'} \frac{1}{m} = \text{const} \qquad m = m_L m_\alpha \tag{199}$$

Any two of these magnifications provide the two scaling factors that describe the system. If $m = n/n'$, then $m_L = m$ and $m_\alpha = 1$, so image space is a scaled version of object space.

Afocal lenses differ fundamentally from focal lenses. Objects at infinity are imaged by afocal lenses at infinity, and objects at finite distances are imaged at finite distances. An afocal lens has no cardinal points and the focal length is undefined. Afocal lenses have no principal planes. If $m \neq 1$ there are no unit magnification conjugates, and if $m = 1$ there is only unit magnification. Likewise, there are no nodal points; the angular magnification is either always unity or always differs from unity. It is sometimes stated or implied that an afocal lens is a focal one with an infinite focal length, but this description is dubious. For example, the above equations relating magnification and conjugate positions to focal length are meaningless for afocal lenses, and they cannot be made useful by substituting $f = \infty$. The equations for the afocal lenses can be obtained from those for focal lenses with a limiting process, but for most purposes this approach is not helpful.

If the positions for a single axial conjugate pair A and A' are known, other pairs are located from the property of constant longitudinal magnification. If O and O' are another pair of conjugates, then

$$A'O' = m_L AO \tag{200}$$

As a function of distance AO, the object-to-image distance OO' is

$$OO' = AA' + (m_L - 1)AO \tag{201}$$

where AA' is the separation between the initially known conjugates. If $m_L = 1$, the object-to-image distance is constant. Otherwise, it can take any value. For all afocal lenses, except those for which $m_L = 1$, there is a position, sometimes called the *center,* at which $OO' = 0$, so the object and image planes coincide.

A principal use of afocal lenses is in viewing distant objects, as with binoculars. An object of height h a great distance d from the lens subtends an angle $\psi \simeq h/d$. The image height is $h' = mh$, and the image distance is approximately $d' = m^2 d$. So the image subtends an angle $\psi' \simeq m\psi = \psi/m_\alpha$. Thus a telescope used visually produces an image which is actually smaller, but which is closer by a greater factor, so the subtense increases.

Determination of Gaussian Parameters

If a lens prescription is given, its gaussian properties can be obtained by paraxially tracing any two meridional rays whose invariant is not zero. A common choice for focal lenses is the rays with $u = 0$ and $u' = 0$, which give F, P, F', and P'. If a lens is known to be afocal, a single ray not parallel to the axis suffices, since such a ray gives a pair of conjugates and the angular magnification. If it is not known that the lens is afocal, two rays show that it is, as well as giving the required information about conjugates. Alternately, a matrix representation of the lens can be determined, from which the cardinal points are found, as described in the matrix section. The gaussian properties can also be determined experimentally in a number of ways.

Basic Systems

Single Refracting Surface. Media of indices n and n' are separated by a surface of curvature c and radius r. The power is $\phi = (n' - n)c$. The principal points coincide at the vertex. The nodal points coincide at the center of curvature. The distance from principal points to nodal points is r.

Thick Lens. The term *thick lens* usually denotes a singlet whose vertex-to-vertex distant is not negligible, where negligibility depends on the application. For a singlet of index n in vacuum with curvatures c_1 and c_2 and thickness t, measured from vertex to vertex

$$\phi = \frac{1}{f'} = (n-1)\left[c_1 - c_2 - \frac{n-1}{n} t c_1 c_2\right] \tag{202}$$

A given power may be obtained with a variety of curvatures and indices. For a given power, higher refractive index gives lower curvatures. The principal planes are located relative to the vertices by

$$VP = \frac{n-1}{n}\frac{tc_2}{\phi} \qquad \text{and} \qquad V'P' = -\frac{n-1}{n}\frac{tc_1}{\phi} \tag{203}$$

These equations can be derived by treating the lens as the combination of two refracting surfaces. Two additional relationships are

$$PP' = VV' - \frac{n-1}{n}\frac{t(c_1+c_2)}{\phi} \qquad \text{and} \qquad \frac{V'P'}{VP} = \frac{r_2}{r_1} = \frac{c_1}{c_2} \tag{204}$$

Thin Lens. A *thin lens* is the limiting case of a refracting element whose thickness is negligible, so the principal planes coincide, and the ray bending occurs at a single surface, Fig. 17. In the limit as $t \to 0$, for a lens in vacuum the thick lens expressions give

$$\phi = \frac{1}{f'} = (n-1)(c_1 - c_2) \qquad VP = V'P' = 0 \qquad PP' = 0 \tag{205}$$

Single Reflecting Surface. A reflecting surface has power $\phi = 2n/r = 2nc$. The principal points are located at the vertex. The nodal points are at the center of curvature.

Mirror as a Thin Lens. In unfolding systems, a mirror can be thought of as a convex or

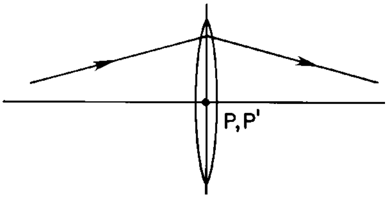

FIGURE 17 The thin lens approximation. The thickness of the lens is negligible, and the principal planes are coincident, so rays bend at the common plane.

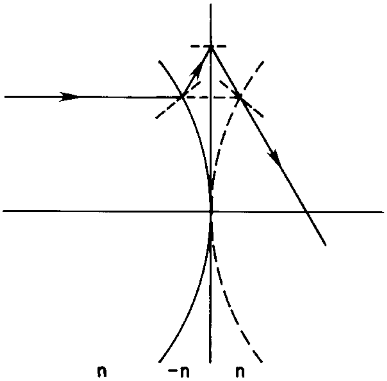

FIGURE 18 Reflecting surface represented unfolded. A convex mirror is represented as a convex-plano thin lens with index $n' = -n$, where n is the index of the medium. Snell's law gives $I' = -I$.

concave plano thin lens, with an index $-n$, where n is the index of the medium in which it works, Fig. 18. All the thin lens equations apply, as well as those for third-order aberration equations, which are not discussed here.

1.15 COLLINEATION

Introduction

Collineation is a mathematical transformation that approximates the imaging action of a lens with homogeneous refractive indices in both spaces. This transformation takes points to points, lines to lines, and planes to planes. With an actual lens, incoming rays become outgoing rays, so lines go exactly to lines. In general, however, rays that interest in object space do not intersect in image space, so points do not go to points, nor planes to planes. The collinear transformation is an approximate description of image geometry with the intervening optical system treated as a black box, not a theory that describes the process of image formation. Collineation is also referred to as *projective transformation.* The historical development of this approach, which was first applied to optics by Möbius (Möbius 1855[192]), is discussed by Southall (Southall, 1910[193]). Several authors give extensive discussions (Czapski 1893,[194] Drude 1901[195] Southall 1910,[193] Wandersleb 1920,[196] Chrétien 1980[197]). Projective transformation is used in computer graphics, and is discussed in this context in a number of recent books and papers.

The imaging described by collineation is, by definition, stigmatic everywhere, and planes are imaged without curvature. And for rotationally symmetric lenses, planes perpendicular to the axis are imaged without distortion. So the three conditions of maxwellian perfection are satisfied for all conjugates. Consequently, collineation is often taken as describing ideal imaging of the entire object space. However, it is physically impossible for a lens to image as described by collineation, except for the special case of an afocal lens with $m = m_L = n/n'$. The putative ray intersections of collineation violate the equality of optical path lengths for the rays involved in the imaging of each point. The intrinsic impossibility manifests itself in a variety of ways. As an example, for axial points in a plane with transverse magnification m and ray angles θ and θ' relative to the axis, collineation gives $m \propto \tan\theta/\tan\theta'$, but optical path length considerations require that $m \propto \sin\theta/\sin\theta'$. Another violation is that of the skew invariant $\mathcal{S} = n(\alpha y - \beta x)$. The ratio of this quantity before and after collineation is not unity, but $\mathcal{S}'/\mathcal{S} = \gamma'/\gamma$, where γ is the axial direction cosine in object space and γ' is that in image space.

The expressions for collineation do not contain refractive indices, another manifestation of their not accounting for optical path length. Rather than the refractive index ratio n'/n, which occurs in many imaging equations, the expressions of collineation involve ratios of focal lengths. For afocal lenses there are ratios of transverse and longitudinal magnifications or ratios of the focal lengths of the lenses making up the afocal system.

The expressions for actual ray behavior take the form of collineation in the paraxial, and, more generally, parabasal limits. So paraxial calculations provide the coefficients of the transformation for any particular system.

Collineation is most often treated by starting with the general form, and then reducing its complexity by applying the symmetries of a rotationally symmetric system, to give familiar simple equations such as Newton's (Born & Wolf 1980[198]). Alternatively, it is possible to begin with the simple forms and to derive the general ones therefrom with a succession of images, along with translations and rotations. However, the more important use of these properties is in treating lenses lacking rotational symmetry. This includes those comprised of elements that are arbitrarily oriented, that is, tilted or decentered—either intentionally or unintentionally. Other examples are nonplanar objects, tilted object planes, and arbitrary three-dimensional object surfaces.

Lenses, along with plane mirror systems, can form a succession of images and can produce translations and rotations. Correspondingly, a succession of collinear transformations is a collinear transformation, and these transformations form a group. It is associative, corresponding to the fact that a series of imaging operations can be associated pairwise in any way. There is a unit transformation, correspondingly physically to nothing or to a unit magnification afocal lens. There is an inverse, so an image distorted as a result of object or lens tilt can be rectified by an appropriately designed system—to the extent that collineation validly describes the effects.

General Equations

The general form of the collinear transformation is

$$x' = \frac{a_1 x + b_1 y + c_1 z + d_1}{ax + by + cz + d} \qquad y' = \frac{a_2 x + b_2 y + c_2 z + d_2}{ax + by + cz + d} \qquad z' = \frac{a_3 x + b_3 y + c_3 z + d_3}{ax + by + cz + d} \tag{206}$$

At least one of the denominator coefficients, a, b, c, d, is not zero. The equations can be inverted, so there is a one-to-one correspondence between a point (x, y, z) in object space and a point (x', y', z') in image space. The inverted equations are formally identical, and can be written by replacing unprimed quantities with primed ones and vice versa in the above equation. It is seen that a plane is transformed to a plane, since $a'x' + b'y' + c'z' + d' = 0$ has the same form as a function of (x, y, z). An intersection of two planes gives a line. It can also be shown that a line transforms to a line by writing the equation for a line in parametric form, with parameter σ, $x(\sigma) = x_0 + \alpha\sigma$, $y(\sigma) = y_0 + \beta\sigma$, $z(\sigma) = z_0 + \gamma\sigma$. Substituting in the transformation equations, it is found that $dx'/dy' = (dx'/d\sigma)/(dy'/d\sigma)$ is constant, as are other such ratios.

These equations contain 16 coefficients, but it is possible to divide all three equations through by one of the coefficients, so there are 15 independent coefficients in general. Since the location of an image point is described by three coordinates, five points that are not coplanar determine the transformation.

The ratios of the coefficient dimensions are determined by the fact that x, y, z and x', y', z' are lengths. A variety of schemes can be used and, in the expressions below, a given symbol may have different dimensions.

There are two major categories of the transformation, according to whether the denominator varies or is constant. That with a varying denominator corresponds to focal lenses. For afocal lenses, the demonimator is constant, and the general form of the transformation is

$$x' = a_1x + b_1y + c_1z + d_1 \qquad y' = a_2x + b_2y + c_2z + d_2 \qquad z' = a_3x + b_3y + c_3z + d_3 \tag{207}$$

Here coefficient d has been normalized to unity. Such a transformation is called *affine* or *telescopic.*

Coordinate Systems and Degrees of Freedom

The transformation involves two coordinate systems. The origin of each is located by three parameters, as is the orientation of each. This leaves three parameters that describe the other aspects of the transformation for the most general case of no symmetry. The number is reduced to two if there is rotational symmetry.

In addition to considering the transformation of the entire space, there are other cases, especially the imaging of planes. In each situation, there are specific coordinate systems in which the aspects of the relationship, other than position and orientation, are most simply expressed. Accordingly, different coordinate systems are used in the following sections. Thus, for example, the z axis in one expression may not be the same as that for another.

Simplest Form of the General Transformation

For focal lenses, the denominators are constant for a set of parallel planes

$$ax + by + cz + d = \text{constant} \tag{208}$$

Each such plane is conjugate to one of a set of parallel planes in the other space. Within each of these planes, the quantities $\partial x'/\partial x$, $\partial x'/\partial y$, $\partial x'/\partial z$ are constant, as are the other such derivatives. Therefore, magnifications do not vary with position over these planes, although they do vary with direction. There is one line that is perpendicular to these planes in one space whose conjugate is perpendicular to the conjugate planes in the other space. It can be taken to be the z axis in one space and the z' axis in the other. The aximuths of the x-y and x'-y' axes are found by imaging a circle in each space, which gives an ellipse in the other. The directions of the major and minor axes determine the orientations of these coordinate axes. The *principal focal planes,* are the members of this family of planes for which

$$0 = ax + by + cz + d \tag{209}$$

Lines that are parallel in one space have conjugates that intersect at the principal focal plane in the other. The *principal focal points* are the intersection of the axes with the focal planes.

Using these simplifying coordinate systems, the general transformation is

$$x' = \frac{a_1 x}{cz + d} \qquad y' = \frac{b_1 y}{cz + d} \qquad z' = \frac{c_3 z + d_3}{cz + d} \tag{210}$$

One of the six coefficients can be eliminated, and two of the others are determined by the choice of origins for the z axis and z' axis. If the origins are taken to be at the principal focal points, the transformation equations are

$$x' = \frac{e_x x}{z} \qquad y' = \frac{e_y y}{z} \qquad z' = \frac{e_z}{z} \tag{211}$$

where e_x, e_y, e_z are constants. Unless $e_x = e_y$, the images of shapes in constant z planes vary with their orientations. Squares in one orientation are imaged as rectangles, and in others as parallelograms. Squares in planes not perpendicular to the axes are imaged, in general, with four unequal sides.

For afocal lenses, the simplest form is

$$x' = m_x x \qquad y' = m_y y \qquad z' = m_z z \tag{212}$$

Spheres in one space are imaged as ellipsoids in the other. The principal axes of the ellipsoids give the directions of the axes for which the imaging equations are simplest.

Conjugate Planes

A pair of conjugate planes can be taken to have $x = 0$ and $x' = 0$, so the general transformation between such planes is

$$y' = \frac{b_2 y + c_2 z + d_2}{by + cz + d} \qquad z' = \frac{b_3 y + c_3 z + d_3}{by + cz + d} \tag{213}$$

There are eight independent coefficients, so four points that are not in a line define the transformation. In each space, two parameters specify the coordinate origins and one the orientation. Two parameters describe the other aspects of the transformation.

The simplest set of coordinates is found by a process like that described above. For focal lenses, constant denominators define a line set of parallel lines

$$by + cz + d = \text{constant} \tag{214}$$

with similar conjugate lines in the other space. There is a line that is perpendicular to this family in one space, whose conjugate is perpendicular in the other, which can be taken as the z axis on one side and the z' axis on the other. There is a *principal focal line* in the plane in each space, and a *principal focal point,* at its intersection with the axis. In this coordinate system the transformation is

$$y' = \frac{b_2 y}{cz + d} \qquad z' = \frac{c_3 z + d_3}{cz + d} \tag{215}$$

Of the five coefficients, four are independent and two are fixed by the choice of origins. If $z = 0$ and $z' = 0$ are at the principal focal points, then

$$y' = \frac{e_y y}{z} \qquad z' = \frac{e_z}{z} \tag{216}$$

where e_y and e_z are constants.

For afocal lenses, the general transformation between conjugate planes is

$$y' = b_2 y + c_2 z + d_2 \qquad z' = b_3 y + c_3 z + d_3 \tag{217}$$

The simplest form of the transformation is

$$y' = m_y y \qquad z' = m_z z \tag{218}$$

where m_y and m_z are constants.

Conjugate Lines

A line can be taken to have $x = 0$, $y = 0$, $x' = 0$, $y' = 0$, so its transformation is

$$z' = \frac{c_3 z + d_3}{cz + d} \tag{219}$$

There are three independent coefficients, so three points determine them. The origins in the two spaces account for two of the parameters, leaving one to describe the relative scaling. The simplest forms are

$$\text{Focal:} \quad z' = \frac{e_z}{z} \qquad \text{Afocal:} \quad z' = m_z z \tag{220}$$

There is a relationship between distances along a line (or ray) that is unchanged in collineation (Southall 1910,[193] Southall 1933[199]). If four points on a line A, B, C, D have images A', B', C', D', the *double ratio* or *cross ratio* is invariant under projective transformation, that is,

$$\frac{AC}{BC}\frac{BD}{AD} = \frac{A'C'}{B'C'}\frac{B'D}{A'D} \tag{221}$$

where AC is the distance from A to C, and likewise for other pairs.

Matrix Representation of the Transformation

The transformation can be expressed in linear form by using the variables (u_1, u_2, u_3, u_4) and (u_1', u_2', u_3', u_4'), where $x = u_1/u_4$, $y = u_2/u_4$, $z = u_3/u_4$ and $x' = u_1'/u_4'$, $y' = u_2'/u_4'$, $z' = u_3'/u_4'$. These are referred to as *homogeneous coordinates.* The transformation can be written

$$\begin{pmatrix} u_1' \\ u_2' \\ u_3' \\ u_4' \end{pmatrix} = \begin{pmatrix} a_1 & b_1 & c_1 & d_1 \\ a_2 & b_2 & c_2 & d_2 \\ a_3 & b_3 & c_3 & d_3 \\ a & b & c & d \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{pmatrix} \tag{222}$$

In terms of the cartesian coordinates and an additional pair of terms q and q', the transformation can be expressed as

$$\begin{pmatrix} q'x' \\ q'y' \\ q'z' \\ q' \end{pmatrix} = \begin{pmatrix} a_1 & b_1 & c_1 & d_1 \\ a_2 & b_2 & c_2 & d_2 \\ a_3 & b_3 & c_3 & d_3 \\ a & b & c & d \end{pmatrix} \begin{pmatrix} qx \\ qy \\ qz \\ q \end{pmatrix} \tag{223}$$

The dimensions of q and q' depend on the choice of coefficient dimensions. Here $q'/q = ax + by + cz + d$, the equation for the special set of planes.

Certain sections of the matrix are associated with various aspects the transformation (Penna & Patterson 1986[200]). The first three elements in the rightmost column have to do with translation. This is shown by setting $(x, y, z) = (0, 0, 0)$ to locate the conjugate in the other space. The first three elements in the bottom row are related to perspective transformation. The upper left-hand 3×3 array expresses rotation, skew, and local magnification variation.

For the simple form of the transformation expressed in Eq. (211), $a_1 = e_x$, $b_2 = e_y$, $d_3 = e_z$, $c = 1$, and the rest of the coefficients vanish. The general matrix representation for the afocal transformation is

$$\begin{pmatrix} x' \\ y' \\ z' \\ 1 \end{pmatrix} = \begin{pmatrix} a_1 & b_1 & c_1 & d_1 \\ a_2 & b_2 & c_2 & d_2 \\ a_3 & b_3 & c_3 & d_3 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} \tag{224}$$

The quantities q and q' can also be included, in which case $q' = q$. In the simplest afocal form, Eq. (212), the matrix is diagonal with $a_1 = m_x$, $b_2 = m_y$, $d_3 = m_z$, and the rest of the nondiagonal coefficients vanishing. A succession of collineations can be treated by multiplying the matrices that describe them (Chastang 1990[201]). To combine lenses with arbitrary orientations and to change coordinate systems, compatible rotation and translation matrices are required. The transformation for a pure rotation with direction cosines (L, M, N) is

$$\begin{pmatrix} x' \\ y' \\ z' \\ 1 \end{pmatrix} = \begin{pmatrix} 1 - 2L^2 & -2LM & -2LN & 0 \\ -2LM & 1 - 2M^2 & -2MN & 0 \\ -2LN & -2MN & 1 - 2N^2 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} \tag{225}$$

The transformation for translation by $(\Delta x, \Delta y, \Delta z)$ is

$$\begin{pmatrix} x' \\ y' \\ z' \\ 1 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 & \Delta x \\ 0 & 1 & 0 & \Delta y \\ 0 & 0 & 1 & \Delta z \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} \tag{226}$$

The quantities q and q' can be included if necessary. The transformations associated with conjugate planes can likewise be expressed with 3×3 matrices, and the transformations of lines with 2×2 matrices.

Rotationally Symmetric Lenses

For rotationally symmetric lenses, the simplest forms are obtained with the z and z' axes corresponding to the lens axis in the two spaces, and the x and x' meridians corresponding. There is one less degree of freedom than in the general case, and $a_1 = b_2$ in Eq. (210). The general transformation is thus

$$x' = \frac{a_1 x}{cz + d} \qquad y' = \frac{a_1 y}{cz + d} \qquad z' = \frac{c_3 z + d_3}{cz + d} \tag{227}$$

There are four degrees of freedom, two associated with the lens and two with the choice of coordinate origins. For focal lenses, the two axial length parameters are f and f'. If the coordinate origins are at the focal points,

$$x' = -\frac{fx}{z} \qquad y' = -\frac{fy}{z} \qquad z' = \frac{f'f}{z} \tag{228}$$

If the coordinate origins are conjugate and related by magnification m_0, then

$$x' = \frac{m_0 x}{1 + z/f} \qquad y' = \frac{m_0 y}{1 + z/f} \qquad z' = \frac{(f'/f)m_0^2 z}{1 + z/f} \tag{229}$$

The constant term in the numerator of the z' expression is the longitudinal magnification for $z = 0$, for which point $dz'/dz = (f'/f)m_0^2$. A special case of these equations is that for which the principal points are the origins, so $m_0 = 1$.

For rotationally symmetric afocal lenses, the two degrees of freedom are the transverse magnification $m_x = m_y = m$, and the longitudinal magnification $m_z = m_L$. The simplest set of transformation equations is

$$x' = mx \qquad y' = my \qquad z' = m_L z \tag{230}$$

where $z = 0$ and $z' = 0$ are conjugate. If $m = \pm 1$ and $m_L = \pm 1$ the image space replicates object space, except possibly for orientation. If $m_L = m$, the spaces are identical except for overall scaling and orientation. The m and m_L appear as functions of ratios of focal lengths of the lenses that make up the afocal system.

Rays for Rotationally Symmetric Lenses

A skew ray with direction cosines (α, β, γ) in object space is described in parametric form with parameter z as follows

$$x(z) = x_0 + \frac{\alpha}{\gamma} z \qquad y(z) = x_0 + \frac{\beta}{\gamma} z \tag{231}$$

For a focal lens, if $z = 0$ is taken to be the front focal plane, and $z' = 0$ is the rear focal plane, the parametric form of the ray in image space is

$$x'(z') = \left(-f\frac{\alpha}{\gamma}\right) + \left(-\frac{x_0}{f'}\right)z' \qquad y'(z') = \left(-f\frac{\beta}{\gamma}\right) + \left(-\frac{y_0}{f'}\right)z' \tag{232}$$

So $x_0' = -f\alpha/\gamma$, $y_0' = -f\beta/\gamma$, $\alpha'/\gamma' = -x_0/f'$, $\beta'/\gamma' = -y_0/f'$. For meridional rays with $x = 0$, if θ and θ' are the ray angles in the two spaces, then $\tan\theta = \beta/\gamma$, $\tan\theta' = -y_0/f'$, and

$$\frac{\tan\theta}{\tan\theta'} = \frac{f'}{f} m \tag{233}$$

where m is the transverse magnification in a plane where the meridional ray crosses the axis.

For afocal lenses, if $z = 0$ and $z' = 0$ are conjugate planes, the ray in image space is given by

$$x'(z') = mx_0 + \left(\frac{m}{m_L}\frac{\alpha}{\gamma}\right)z' \qquad y'(z') = my_0 + \left(\frac{m}{m_L}\frac{\beta}{\gamma}\right)z' \tag{234}$$

For meridianal rays with $x = 0$,

$$\frac{\tan\theta}{\tan\theta'} = \frac{m_L}{m} \tag{235}$$

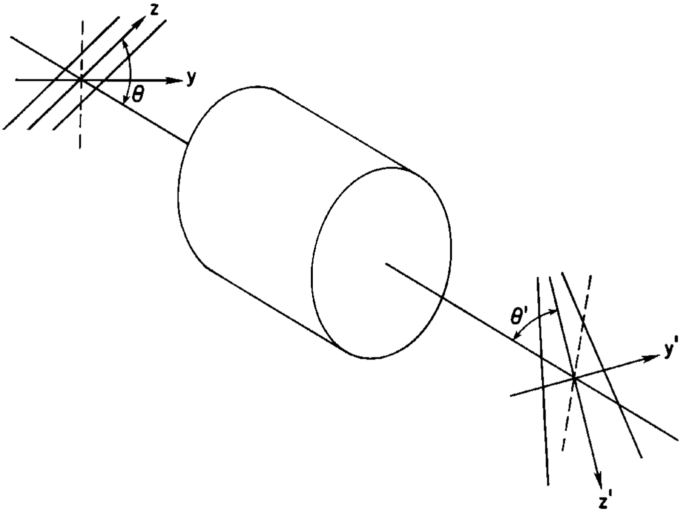

FIGURE 19 The image plane for a tilted object plane. The y-z plane is the object plane and the y'-z' plane is the image plane. The angles between the planes and the lens axis are θ and θ', which are related by Eq. (232). The conjugate points in these planes are related by Eq. (235).

Tilted Planes with Rotationally Symmetric Lenses

A plane making an angle θ with the lens axis in object space has an image plane that makes an angle θ', given by Eq. (233), the so-called *Scheimpflug condition* (Scheimpflug 1907,[202] Sasian 1992[203]). A tilted plane and its image are perpendicular to a meridian of the lens, Fig. 19. There is bilateral symmetry on these planes about the intersection line with the meridian, which is taken to be the z axis in object space and the z' axis in image space. The perpendicular, coordinates are y and y'. Letting m_0 be the transverse magnification for the axial point crossed by the planes, the transform equations are

$$y' = \frac{m_0 y}{1 + z/g} \qquad z' = \frac{(g'/g)m_0^2 z}{1 + z/g} \tag{236}$$

Here g and g' are the focal lengths in the tilted planes, the distances from the principal planes to the focal planes of the lens, measured along the symmetry line, so

$$g = \frac{f}{\cos\theta} \qquad g' = \frac{f'}{\cos\theta'} \qquad \text{and} \qquad \frac{g'}{g} = \sqrt{\left(\frac{f'}{f}\right)^2 \cos^2\theta + \frac{1}{m_0^2}\sin^2\theta} \tag{237}$$

As $\theta \rightarrow 90°$, g and g' become infinite, and $(g'/g)m_0 \rightarrow 1$, giving $y' \rightarrow m_0 y$ and $z' \rightarrow m_0 z$. (Forms like Newton's equations may be less convenient here, since the distances from the axes to the focal points may be large.)

For an afocal lens with transverse magnification m and longitudinal magnification m_L, the object and image plane angles are related by Eq. (235). The conjugate equations for points in the planes are

$$y' = my \qquad z' = (m_L^2 \cos^2\theta + m^2 \sin^2\theta)^{1/2} z \tag{238}$$

Here the origins may be the axial intersection point, or any other conjugate points.

Some General Properties

For all collinear transformations, points go to points, lines to lines, and planes to planes. In general, angles at intersections, areas, and volumes are changed. The degree of a curve is unchanged, so, for example, a conic is transformed into a conic. For focal systems, a "closed" conic, an ellipse or circle, may be imaged as either a closed or an "open" one, a parabola or hyperbola. For afocal systems, the closedness and openness are preserved. With focal systems, the imaging of a shape varies with its location, but for afocal systems it does not. For afocal systems parallelness of lines is maintained, but for focal systems the images of parallel lines intersect. For afocal systems, equal distances along lines are imaged as equal distances, but are different unless the magnification is unity.

1.16 SYSTEM COMBINATIONS—GAUSSIAN PROPERTIES

Introduction

This section deals with combinations of systems, each of which is of arbitrary complexity. From a gaussian description of each lens and the geometry of the combination, the gaussian description of the net system can be found. If two rotationally symmetric lenses are put in series with a common axis, the resultant system is also rotationally symmetric. Its gaussian description is found from that of the two constituent lenses and their separations. The net magnification is the product of the two contributions, i.e., $m = m_1 \times m_2$. Matrix methods are particularly convenient for handling such combinations, and the results below can be demonstrated easily thereby. If two rotationally symmetric lenses are combined so their axes do not coincide, the combination can be handled with appropriate coordinate translations and rotations in the intermediate space, or by means of collineation. In the most general case, where subsystems without rotational symmetry are combined, the general machinery of collineation can be applied. There are three classes of combinations: focal-focal, focal-afocal, and afocal-afocal.

Focal-Focal Combination—Coaxial

The first lens has power ϕ_1 and principal points at P_1 and P'_1, Fig. 20. The index preceding the lens is n and that following it is n_{12}. The second lens has power ϕ_2 and principal points at P_2 and P'_2, with preceding index n_{12} and following index n'. The directed distance from the rear principal point of the first lens to the first principal point of the second lens is

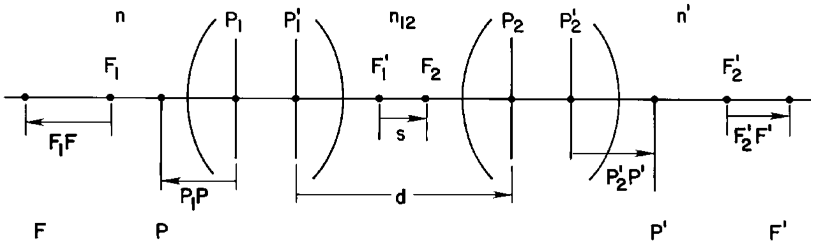

FIGURE 20 Coaxial combination of two focal lenses. The cardinal points of the two lenses are shown above the axis and those of the system below. The directions in this drawing are only one possible case.

$d = P_1'P_2'$, which may be positive or negative, since the lenses may have external principal planes. The power of the combination is

$$\phi = \phi_1 + \phi_2 - \frac{1}{n_{12}} d\phi_1\phi_2 \tag{239}$$

The two principal planes of the combination are located relative to those of the contributing lenses by directed distances

$$P_1P = +\frac{n}{n_{12}} d\frac{\phi_2}{\phi} \qquad P_2'P' = -\frac{n'}{n_{12}} d\frac{\phi_1}{\phi} \tag{240}$$

If $\phi = 0$, the combination is afocal and there are no principal planes. In applying these equations, the inner-space index n_{12} must be the same as that for which the two lenses are characterized. For example, if two thick lenses are characterized in air and combined with water between them, these equations cannot be used by simply changing n_{12}. It would be necessary to characterize the first lens with water following it and the second lens with water preceding it.

Another set of equations involves the directed distance from the rear focal point of the first lens to the front focal point of the second, $s = F_1'F_2$. The power and focal lengths of the combination are

$$\phi = -\frac{1}{n_{12}} s\phi_1\phi_2 \qquad f = +\frac{f_1f_2}{s} \qquad f' = -\frac{f_1'f_2'}{s} \tag{241}$$

The focal points are located with respect to those of the contributing lenses by

$$F_1F = +\frac{nn_{12}}{s\phi_1^2} = \frac{n_{12}f_1^2}{n\ \ s} \qquad F_2'F' = -\frac{n'n_{12}}{s\phi_2^2} = -\frac{n_{12}f_2'^2}{n'\ \ s} \tag{242}$$

Another relationship is $(F_1F)(F_2'F') = ff'$. The system is afocal if $s = 0$. There are many special cases of such combinations. Another case is that when the first principal point of the second lens is at the rear focal point of the first, in which case the system focal length is that of the first. These relationships are proven by Welford (Welford 1986, p. 35[204]).

Focal-Afocal—Coaxial

A focal lens combined with an afocal lens is focal, Fig. 21. Here we take the afocal lens to be to the left, with magnification m_1. The focal lens to the right has power ϕ_2 and rear

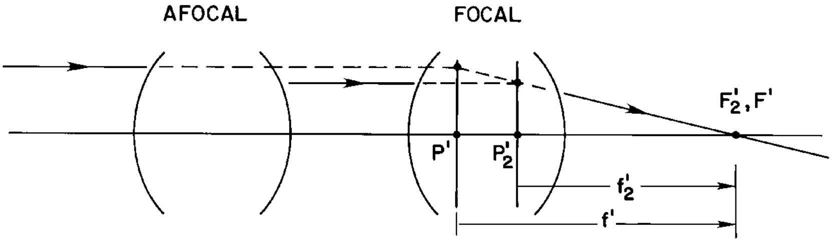

FIGURE 21 Coaxial combination of a focal lens and an afocal lens. In this drawing the afocal lens has a transverse magnification $0 < m_1 < 1$ and the focal lens has a positive power. The combination is a focal lens with focal length $f' = f_2'/m_1$. The focal point on the side of the focal lens is at the focal point of that lens alone.

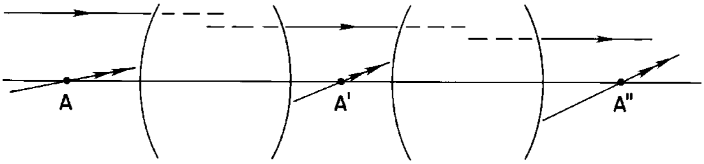

FIGURE 22 Coaxial combination of two afocal lenses. An internal point A' has an object space conjugate A and an image space conjugate A''. These two points can be used for position references in the overall object and image spaces.

focal length f_2'. The power of the combination is $\phi_2 m_1$, and the rear focal length of the combination is $f' = f_2'/m_1$. On the side of the focal lens, the location of the principal focal point is unchanged. On the side of the afocal lens, the system focal point is located at the image of the focal point of the focal lens in the space between the two. Changing the separation between the lenses does not change the power or the position of the principal focal point relative to that of the focal lens. The principal focal point on the afocal lens side does move.

Afocal-Afocal—Coaxial

The combination of two afocal lenses is itself afocal, Fig. 22. If the two lenses have transverse magnifications m_1 and m_2, the combination has $m = m_1 m_2$. A pair of conjugate reference positions is found from the conjugates in the outer regions to any axial point in the inner space. If the separation between the two lenses changes, the combination remains afocal and the magnification is fixed, but the conjugate positions change. This result extends to a combination of any number of afocal lenses.

Noncoaxial Combinations—General

The most general combinations can be handled by the machinery of collineation. The net collineation can be found by multiplying the matrices that describe the constituents, with additional rotation and translation matrices to account for their relative positions. After obtaining the overall matrix, object and image space coordinate systems can be found in which the transformation is simplest. This approach can also be used to demonstrate general properties of system combinations. For example, by multiplying matrices for afocal systems, it is seen that a succession of afocal lenses with any orientation is afocal.

1.17 PARAXIAL MATRIX METHODS

Introduction

Matrix methods provide a simple way of representing and calculating the paraxial properties of lenses and their actions on rays. These methods contain no physics beyond that contained in the paraxial power and transfer equations, Eq. (136) and Eq. (142), but they permit many useful results to be derived mechanically, and are especially useful for lens combinations. The matrix description of systems is also useful in elucidating fundamental paraxial properties. With the symbolic manipulation programs now available, matrix methods also provide a means of obtaining useful expressions.

The optical system is treated as a black box represented by a matrix. The axial positions of the input and output planes are arbitrary. The matrix describes the relationship between what enters and what leaves, but contains no information about the specifics of the system within, and there is an infinity of systems with the same matrix representation.

The origin of matrix methods in optics is not clear. Matrices were used by Samson (Samson 1897[205]) who referred to them as "schemes." Matrices appear without comment in a 1908 book (Leathem 1908[206]). Matrix methods are treated in papers (Halbach 1964,[207] Sinclair 1973[208]) and in many books (O'Neil 1963,[209] Brouwer 1964,[210] Blaker 1971,[211] Longhurst 1973,[212] Gerrard & Burch 1974,[213] Naussbaum & Phillips 1976,[214] Kogelnik 1979,[215] Klein & Furtak 1986,[216] Moller 1988,[217] Guenther 1990[218]). Notation is not standardized, and many treatments are complicated by notation that conceals the basic structures.

This section is limited to rotationally symmetric lenses with homogeneous media. References are provided for systems with cylindrical elements. This treatment is monochromatic, with the wavelength dependence of index not made explicit.

The matrices are simplified by using *reduced axial distances* $\tau = t/n$ and *reduced angles* $\omega = nu$. The paraxial angles u are equivalent to direction cosines, and the reduced angles are optical direction cosines in the paraxial limit. For brevity, ω and τ are usually referred to in this section simply as "angle" and "distance."

Basic Idea—Linearity

Paraxial optics is concerned with the paraxial heights and paraxial angles of rays. A meridional ray entering a system has a given height y and angle ω and leaves with another height y' and angle ω'. Paraxial optics is linear, as discussed above, in the sense that both the outgoing height and angle depend linearly on the incoming height and angle. Writing Eq. (148) in terms of ω's gives

$$y' = \left(\frac{\partial y'}{\partial y}\right) y + \left(\frac{\partial y'}{\partial \omega}\right)\omega \qquad \text{and} \qquad \omega' = \left(\frac{\partial \omega'}{\partial y}\right) y + \left(\frac{\partial \omega'}{\partial \omega}\right)\omega \tag{243}$$

The partial derivatives are constant for a given system. This linearity is the basis of the matrix treatment, since these equations can be written in matrix form:

$$\begin{pmatrix} y' \\ \\ \omega' \end{pmatrix} = \begin{pmatrix} \dfrac{\partial y'}{\partial y} & \dfrac{\partial y'}{\partial \omega} \\ \dfrac{\partial \omega'}{\partial y} & \dfrac{\partial \omega'}{\partial \omega} \end{pmatrix} \begin{pmatrix} y \\ \\ \omega \end{pmatrix} \tag{244}$$

Basic Operations

The basic operations in paraxial ray tracing are transfer, Eq. (136), between surfaces and refraction or reflection at surfaces, Eq. (142).

Transfer Matrix

Transfer changes the height of a ray, in general, leaving the angle unchanged. In terms of reduced quantities, the relationships are:

$$y' = y + tu = y + \frac{t}{n}un = y + \tau\omega \qquad \text{and} \qquad \omega' = \omega \tag{245}$$

The transfer matrix is:

$$\begin{pmatrix} 1 & \tau \\ 0 & 1 \end{pmatrix} \tag{246}$$

For left-to-right transfer, $\tau > 0$. This gives a difference in signs between some of the terms in expressions here and those in the gaussian section, where directed distances are measured from a reference point related to the lens to the object.

Power Matrix

Refraction or reflection changes the angle of a ray, but not its height. The equations for reduced quantities are

$$n'u' = nu - y\phi = \omega' = \omega - y\phi \qquad \text{and} \qquad y' = y \tag{247}$$

Here $\phi = c(n' - n)$ for refraction and $\phi = -2nc$ for reflection, where c is the surface curvature, Eq. (143). The power matrix is:

$$\begin{pmatrix} 1 & 0 \\ -\phi & 1 \end{pmatrix} \tag{248}$$

A planar reflecting or refracting surface has $\phi = 0$, so it is represented by the unit matrix.

Arbitrary System

A general system consists of a series of surfaces with powers $\phi_1, \phi_2, \ldots$ that are separated from one another by distances $\tau_1, \tau_2, \ldots$. Its matrix is the product

$$\begin{pmatrix} 1 & \tau_N \\ 0 & 1 \end{pmatrix} \cdots \begin{pmatrix} 1 & 0 \\ -\phi_2 & 1 \end{pmatrix} \begin{pmatrix} 1 & \tau_2 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -\phi_1 & 1 \end{pmatrix} \begin{pmatrix} 1 & \tau_1 \\ 0 & 1 \end{pmatrix} \tag{249}$$

By convention, the successive matrices are concatenated from right to left, whereas ray tracing is done left to right.

A special case is a succession of transfers, itself a transfer.

$$\text{Succession of transfers:} \quad \begin{pmatrix} 1 & \tau_1 + \tau_2 + \cdots \\ 0 & 1 \end{pmatrix} \tag{250}$$

Another is a series of refractions with no intervening transfer, itself a power operation.

$$\text{Succession of powers:} \quad \begin{pmatrix} 1 & 0 \\ -(\phi_1 + \phi_2 + \cdots) & 1 \end{pmatrix} \tag{251}$$

Matrix Elements

Each matrix element has a physical significance, and the terms can be given mnemonic symbols associated with the conditions under which they are zero. (This practice is not standard.) If the initial ray angle is zero, the outgoing angles depend on the incident ray heights and the power of the system, according to $\omega' = -\phi y$, so $\partial\omega'/\partial y = -\phi$. If the initial surface is at the front focal plane, the outgoing ray angles depend only on the incident height, so $\partial\omega'/\partial\omega = 0$. This term is denoted by F for "front." Similarly, if the final surface is at the real focal plane, the outgoing ray heights depend only on the incoming angles, so $\partial y'/\partial y = R$ for "rear." If the initial and final planes are conjugate, then all incoming rays at a given height y have the outgoing height $y' = my$, regardless of their angle, so $\partial y'/\partial\omega = 0$ for conjugate planes. Since this term is related to the condition of conjugacy, $\partial y'/\partial\omega = C$ for "conjugate." With this notation, the general matrix is

$$\begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} \tag{252}$$

Dimensions

The terms R and F are dimensionless. C has the dimensions of length, and those of ϕ are inverse length. Dimensional analysis, as well as the consideration of Eq. (248), shows that the F and R terms will always contain products of equal numbers of ϕ_l's and τ_k's, such as $\phi_k\tau_l$. The ϕ expression contains terms like ϕ_k and $\tau_k\phi_l\phi_m$, with one more power term than distance terms. Similarly, C has terms like τ_k and $\tau_k\tau_l\phi_m$.

Determinant

Both the transfer and power matrices have unit determinants. Therefore, any product of such matrices has a unit determinant, a fact that is related to the two-ray paraxial invariant.

$$\begin{vmatrix} R & C \\ -\phi & F \end{vmatrix} = FR + C\phi = 1 \tag{253}$$

This provides an algebraic check. For afocal lenses and conjugate arrangements, $FR = 1$.

Possible Zeros

The possible arrangements of zeros in a system matrix is limited by the unit determinant restriction. There can be a single zero anywhere. In this case, either $C = 1/\phi$ or $F = 1/R$, and the remaining nonzero term can have any value. There can be two zeros on either diagonal. No row or column can contain two zeros, since a system represented by such a matrix would violate conservation of brightness. A matrix with double zeros in the bottom row would collimate all rays, regardless of their incoming position and direction. A matrix with all zeros in the top row represents a system that would bring all incoming light to a single point. A system whose matrix has double zeros in the first column would bring all incoming light to a focus on the axis. For double zeros in the second row, the system would concentrate all light diverging from an input point in a single output point with a single direction.

Operation on Two Rays

Instead of considering a single input and output ray, the matrix formalism can be used to treat a pair of rays, represented by a 2 × 2 matrix. In this case

$$\begin{pmatrix} y_1' & y_2' \\ \omega_1' & \omega_2' \end{pmatrix} = \begin{pmatrix} R & C \\ -\phi & F \end{pmatrix}\begin{pmatrix} y_1 & y_2 \\ \omega_1 & \omega_2 \end{pmatrix} \tag{254}$$

Since the system matrix has a unit determinant, the determinants of the incoming and outgoing ray matrices are identical:

$$L_{12} = y_1' \omega_2' - y_2' \omega_1' = y_1 \omega_2 - y_2 \omega_1 \tag{255}$$

This is the paraxial invariant, Eq. (149). It is possible to operate on more than two rays, but never necessary, since any third ray is a linear combination of two, Eq. (154). Operations on two rays can also be handled with a complex notation in which two ray heights and two angles are each represented by a complex number (Marechal 1956,[219] Marechal 1961[220]).

Conjugate Matrix

For conjugate planes, $y' = my$, so $C = 0$, $R = m$, and $F = 1/m$, giving

$$\begin{pmatrix} m & 0 \\ -\phi & 1/m \end{pmatrix} \tag{256}$$

The $1/m$ term gives the angular magnification, $u'/u = n/n'm$, Eq. (196). This matrix also holds for afocal lenses, in which case $\phi = 0$.

Translated Input and Output Planes

For a given system, the locations of the input and output planes are arbitrary. If the input plane is translated by τ and the output plane by τ', the resultant matrix is

$$\begin{pmatrix} R - \tau'\phi & C + \tau R + \tau' F - \tau\tau'\phi \\ -\phi & F - \tau\phi \end{pmatrix} \tag{257}$$

Note that the object-space translation term τ is grouped with F and the image-space term τ' with R. The equation $C = 0 = \tau R - \tau' F - \tau\tau'\phi$ gives all pairs of τ and τ' for which the input and output surfaces are conjugate.

Principal Plane-to-Principal Plane

If the input and output planes are the principal planes, then the matrix is a conjugate one, for which $m = +1$.

$$\begin{pmatrix} 1 & 0 \\ -\phi & 1 \end{pmatrix} \tag{258}$$

This is also the matrix representing a thin lens.

Nodal Plane-to-Nodal Plane

The nodal points are conjugate, with unit angular magnification, so $u' = u$ and $\omega' = n'\omega/n$. Thus

$$\begin{pmatrix} n/n' & 0 \\ -\phi & n'/n \end{pmatrix} \tag{259}$$

The transverse magnification $m_N = n/n'$ equals unity when $n = n'$. This matrix has no meaning for afocal lenses.

Focal Plane-to-Focal Plane

If the initial surface is at the front principal focal plane and the final surface is at the rear focal plane, the matrix is

$$\begin{pmatrix} 0 & 1/\phi \\ -\phi & 0 \end{pmatrix} \tag{260}$$

This is the "Fourier transform" arrangement, in which incident heights are mapped as angles and vice versa.

Translation from Conjugate Positions

If the input plane is translated τ from a plane associated with magnification m and the output plane is translated a distance τ' from the conjugate plane, the matrix is

$$\begin{pmatrix} m - \tau'\phi & m\tau + \tau'/m - \tau\tau'\phi \\ -\phi & 1/m - \tau\phi \end{pmatrix} \tag{261}$$

Setting $C = 0$ gives an equation that locates all other pairs of conjugate planes relative to the first one, Eq. (172).

Translation from Principal Planes

If the initial conjugate planes are the principal planes, then

$$\begin{pmatrix} 1 - \tau'\phi & \tau + \tau' - \tau\tau'\phi \\ -\phi & 1 - \tau\phi \end{pmatrix} \tag{262}$$

The equation for other conjugates is $C = 0 = \tau + \tau' - \tau\tau'\phi$, corresponding to Eq. (170). It follows that the distance from the input surface to the first principal plane is $\tau = (1 - F)/\phi$ and the distance from the output surface to the second principal plane is $\tau' = (1 - R)/\phi$.

Translation from Focal Planes

If the input plane is a distance τ from the front focal plane and the output plane a distance τ' from the rear focal plane, the matrix is

$$\begin{pmatrix} -\phi\tau' & \dfrac{1}{\phi}(1 - \phi^2\tau\tau') \\ -\phi & -\phi\tau \end{pmatrix} \tag{263}$$

Thus F and R are proportional to the distances of the input and output surfaces from the object space and image space focal planes. Using Newton's formulas, this can also be written

$$\begin{pmatrix} m' & \dfrac{1}{\phi}\left(1-\dfrac{m'}{m}\right) \\ -\phi & \dfrac{1}{m} \end{pmatrix} \tag{264}$$

Here m' is the magnification that would obtain if the image point were as located by R, and m is that if the object point were located by F. The conjugate term vanishes when $m = m'$.

Conjugate Relative to Principal Focal Planes

If Eq. (263) is a conjugate matrix, it becomes

$$\begin{pmatrix} -\phi\tau' & 0 \\ -\phi & -\phi\tau \end{pmatrix} \tag{265}$$

The vanishing C term gives $0 = 1/\phi - \phi\tau\tau'$, which is the Newton equation usually written as $zz' = ff'$. The magnification terms are the other Newton's equations, $m = -\phi\tau'$ and $1/m = -\phi\tau$, which are usually written as $m = -z'/f' = -f/z$.

Afocal Lens

For afocal lenses $\phi = 0$. Since the determinant is unity, $F = 1/R$. And since the transverse magnification is constant, $R = m$, giving

$$\begin{pmatrix} m & C \\ 0 & 1/m \end{pmatrix} \tag{266}$$

A ray with $\omega = 0$ has $y' = my$, and $\omega' = \omega/m$ for all y. At conjugate positions, an afocal lens has the matrix

$$\begin{pmatrix} m & 0 \\ 0 & 1/m \end{pmatrix} \tag{267}$$

Performing a translation in both object and images spaces from the conjugate position gives

$$\begin{pmatrix} m & m\tau + \dfrac{\tau'}{m} \\ 0 & 1/m \end{pmatrix} \tag{268}$$

Setting $C = 0$ gives $\tau' = -m^2\tau$, which relates the location of a single conjugate pair to all others, Eq. (200).

Symmetrical Lenses

For lenses with symmetry about a central plane and symmetrically located input and output surfaces, $F = R$, so the matrix has the form

$$\begin{pmatrix} B & C \\ -\phi & B \end{pmatrix} \tag{269}$$

where $B^2 = 1 - \phi C$. The conjugate matrix has $m = \pm 1$.

Reversing Lenses

When a lens is flipped left to right, the matrix of the reversed system is obtained from that of the original one by switching the F and R terms.

$$\begin{pmatrix} F & C \\ -\phi & R \end{pmatrix} \tag{270}$$

This reversal maintains the exterior references planes, that is, the input surface for the initial system becomes the output surface for the flipped one and vice versa.

Inverse Systems

By the "inverse" of a lens is meant a second system that undoes the effect of a given one. That is, the rays at the output surface of the second system have the same height and angle as those at the input of the first system. The combination of a system and its inverse is afocal with unit magnification. The matrix representing the inverse system is the inverse of that representing the system.

$$\begin{pmatrix} F & -C \\ \phi & R \end{pmatrix} \tag{271}$$

The matrix provides no instruction as to how such a lens is made up. Alternatively, the inverse matrix can be interpreted as that whose input is y' and ω', with outputs y and ω.

Series of Arbitrary Lenses

The matrix for two successive lenses is

$$\begin{pmatrix} R_1R_2 - C_2\phi_1 & C_1R_2 + C_2F_1 \\ -\phi_1F_2 - \phi_2R_1 & F_1F_2 - C_1\phi_2 \end{pmatrix} = \begin{pmatrix} R_2 & C_2 \\ -\phi_2 & F_2 \end{pmatrix} \begin{pmatrix} R_1 & C_1 \\ -\phi_1 & F_1 \end{pmatrix} \tag{272}$$

For example, two given lenses separated by some distance have the matrix

$$\begin{pmatrix} R_2 & C_2 \\ -\phi_2 & F_2 \end{pmatrix} \begin{pmatrix} 1 & \tau \\ 0 & 1 \end{pmatrix} \begin{pmatrix} R_1 & C_1 \\ -\phi_1 & F_1 \end{pmatrix} \tag{273}$$

Multiplying from right to left gives a running product or "cumulative matrix," that shows the effect of the system up to a given plane.

Decomposition

Matrix multiplication is associative, so the system representation can be broken up in a number of ways. For example, the portion of a lens before and after the aperture stop can be used to find the pupil locations and magnifications. An arbitrary lens matrix can be written as a product of three matrices (Macukow & Arsenault 1983[221]):

$$\begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ -\phi/R & 1 \end{pmatrix} \begin{pmatrix} R & 0 \\ 0 & 1/R \end{pmatrix} \begin{pmatrix} 1 & C/R \\ 0 & 1 \end{pmatrix} \tag{274}$$

or

$$\begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} = \begin{pmatrix} 1 & C/F \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1/F & 0 \\ 0 & F \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -\phi/F & 1 \end{pmatrix} \tag{275}$$

Thus a general lens is equivalent to a succession of three systems. One has power and works at unit magnification. The second is a conjugate afocal matrix. The third is a translation. Each of these systems is defined by one of the three terms, either *R*, ϕ/R, C/R or *F*, ϕ/F, C/F. This is another manifestation of the three degrees of freedom of paraxial systems.

Matrix Determination by Two-Ray Specification

If a two-ray input matrix is given along with the desired output, or the two input and output rays are measured to determine the matrix of an unknown lens, Eq. (254) gives

$$\begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} = \begin{pmatrix} y_1' & y_2' \\ \omega_1' & \omega_2' \end{pmatrix} \begin{pmatrix} y_1 & y_2 \\ \omega_1 & \omega_2 \end{pmatrix}^{-1} \tag{276}$$

so

$$\begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} = \frac{1}{y_1\omega_2 - y_2\omega_1} \begin{pmatrix} y_1'\omega_2 - y_2'\omega_1 & y_2'y_1 - y_1'y_2 \\ \omega_1'\omega_2 - \omega_2'\omega_1 & \omega_2'y_1 - y_2\omega_1' \end{pmatrix} \tag{277}$$

The denominator of the multiplicative factor is the paraxial invariant associated with the two rays, Eq. (149). As a special case, the two rays could be the marginal and chief rays. The input and output pairs must have the same invariant, or the matrix thus found will not have a unit determinant.

Experimental Determination of Matrix Elements

The matrix elements for an unknown lens can, in principle, be determined experimentally. One method, as mentioned in the preceding section, is to measure the heights and angles of an arbitrary pair of rays. Another method is as follows. The power term is found in the usual way by sending a ray into the lens parallel to the axis and measuring its outgoing angle. To find $C = \partial y'/\partial\omega$, the input ray angle is varied, while its height is unchanged. If the output height is graphed, its slope is *C*. Likewise, the other partial derivatives in Eq. (243) can be found by changing one of the input parameters while the other is fixed. The four measurements are redundant, the unit determinant providing a check of consistency.

Angle Instead of Reduced Angle

The matrices above can be modified to use the angles u and u', instead of the reduced angles. In terms of matrix theory, this amounts to a change in basis vectors, which is accomplished by multiplying by diagonal vectors with elements 1 and n or 1 and n'. The result is

$$\begin{pmatrix} y \\ u' \end{pmatrix} = \begin{pmatrix} R & nC \\ -\dfrac{1}{n'}\phi & \dfrac{n}{n'}F \end{pmatrix} \begin{pmatrix} y \\ u \end{pmatrix} \tag{278}$$

This matrix has a constant determinant n/n'. The form Eq. (252) is simpler.

Other Input-Output Combinations

Referring to Eq. (244), any pair of the four quantities y, ω, y', and ω' can be taken as inputs, with the other two as outputs, and the relationships can be expressed in matrix form. The four matrices in this section cannot be multiplied to account for the concatenation of lenses. If the angles are given, the heights are

$$\begin{pmatrix} y \\ y' \end{pmatrix} = \frac{1}{\phi} \begin{pmatrix} F & -1 \\ 1 & -R \end{pmatrix} \begin{pmatrix} \omega \\ \omega' \end{pmatrix} \tag{279}$$

The matrix is undefined for afocal lenses, for which the relationship of ω and ω' is independent of heights. Similarly, the angles can be expressed as functions of the heights by

$$\begin{pmatrix} \omega \\ \omega' \end{pmatrix} = \frac{1}{C} \begin{pmatrix} -R & 1 \\ -1 & F \end{pmatrix} \begin{pmatrix} y \\ y' \end{pmatrix} \tag{280}$$

For conjugates the expression breaks down, since there is no fixed relationship between heights and angles. If the input is a height on one side and an angle on the other, then

$$\begin{pmatrix} y' \\ \omega \end{pmatrix} = \frac{1}{F} \begin{pmatrix} 1 & C \\ \phi & 1 \end{pmatrix} \begin{pmatrix} y \\ \omega' \end{pmatrix} \tag{281}$$

For the inverse situation,

$$\begin{pmatrix} y \\ \omega' \end{pmatrix} = \frac{1}{R} \begin{pmatrix} 1 & -C \\ -\phi & 1 \end{pmatrix} \begin{pmatrix} y' \\ \omega \end{pmatrix} \tag{282}$$

The determinants of these matrices are, respectively, C, ϕ, R, and F.

Derivative Matrices

If the axial position of the input surface changes, the rate of change of the output quantities is

$$\begin{pmatrix} dy'/dz \\ d\omega'/dz \end{pmatrix} = \begin{pmatrix} 0 & R \\ 0 & -\phi \end{pmatrix} \begin{pmatrix} y \\ \omega \end{pmatrix} \tag{283}$$

If the axial position of the output surface can change, the rate of change of output quantities is

$$\begin{pmatrix} dy'/dz' \\ d\omega'/dz' \end{pmatrix} = \begin{pmatrix} -\phi & F \\ 0 & 0 \end{pmatrix} \begin{pmatrix} y \\ \omega \end{pmatrix} \tag{284}$$

Higher derivatives vanish.

Skew rays

The matrix formalism can be used to treat a paraxial skew ray, represented by a 2×2 matrix of x and y positions and directions α and β. In this case

$$\begin{pmatrix} x' & y' \\ n'\alpha' & n'\beta' \end{pmatrix} = \begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} \begin{pmatrix} x & y \\ n\alpha & n\beta \end{pmatrix} \tag{285}$$

Since the lens matrix has a unit determinant, the determinants of the incoming and outgoing ray matrices are identical:

$$n'(y'\alpha' - x'\beta') = n(y\alpha - x\beta) \tag{286}$$

From Eq. (73), this is the skew invariant.

Relationship to Characteristic Functions

A lens matrix can be related to any one of the four paraxial characteristic functions, Eqs. (34) through (37), each of which has three first coefficients, associated with the three degrees of freedom of the matrix. Brouwer and Walther (Brouwer & Walther 1967[222]) derive the paraxial matrices from more general matrices based on the point angle characteristic function.

Nonrotationally Symmetric Systems

Systems comprised of cylindrical lenses can also be treated paraxially by matrices (Arsenault 1979,[223] Arsenault 1980,[224] Arsenault 1980,[225] Keating 1981,[226] Arsenault & Macukow 1983,[227] Macukow & Arsenault 1983,[221] Attard 1984[228]). The more general case of a treatment around an arbitrary ray is also represented by a 4×4 matrix (Stone & Forbes 1992[229]). This is treated by several of the references to the section ‘‘Images About Known Rays.’’

1.18 APERTURES, PUPILS, STOPS, FIELDS, AND RELATED MATTERS

Introduction

This section is concerned with the finite sizes of lens and their fields, as expressed in various limitations of linear dimensions and angles, and with some of the consequences of these limits. (Other consequences, for example, resolution limitations, are in the domain of wave optics.) Terminology in this area is not well defined, and the terms typically used are insufficient for all the aspects of the subject, so this section deals considerably with definitions.

Field Size and Field Stop

The *field* or *field of view* of a lens is the region of object space from which light is captured or the region of image space that is used. The field size may be described in angular, linear, or area units, depending on the circumstances. (It can be described in still other ways, e.g., the number of pixels.) In and of itself, a lens does not have a definite field size, but

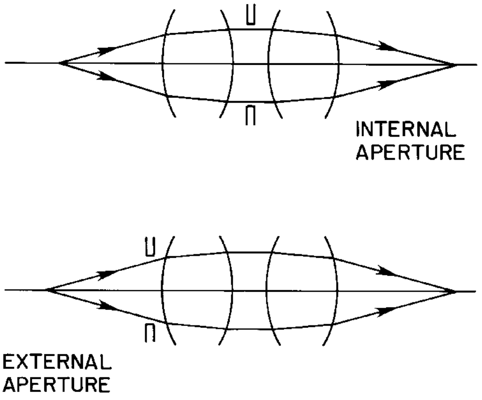

FIGURE 23 Axial ray cone and aperture stop. The upper lens has an internal aperture, and the lower one has an external aperture on the object side.

beyond a certain size, image quality diminishes, both with respect to aberration correction and to light collection. A *field stop* is a physical delimiter of the field, which may be in either object or image space. A detector may be the delimiter.

Aperture Stop

Each object point can be thought of as emitting rays in all directions. Since lenses are finite in size, only some of the rays pass through them. The rays that do pass are referred to as *image-forming rays,* the ensemble of which is the *image-forming bundle,* also called the *image-forming cone,* although the bundle may not be conical. The bundle associated with each object point is delimited by one or more physical structures of the lens. For axial object points, the delimiting structure is called the *aperture,* the *stop,* or the *aperture stop.* The aperture may be either within the lens or outside of it on either side, Fig. 23. The aperture may be a structure whose sole purpose is delimiting the bundle, or it may be the edge of an optical element or a lens mount. The aperture stop may be fixed or adjustable, for instance an iris. Which structure acts as the aperture can change with object position, Fig. 24. The size and position of the aperture do not effect the gaussian properties of the lens, i.e., the cardinal points and the conjugate locations and magnifications. They do

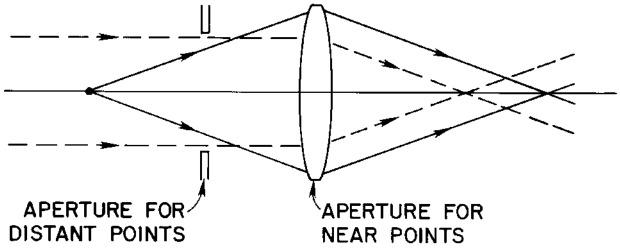

FIGURE 24 An example of change of aperture with axial object position. For distant points the aperture is the nominal stop. For near points the aperture is the rim of the lens.

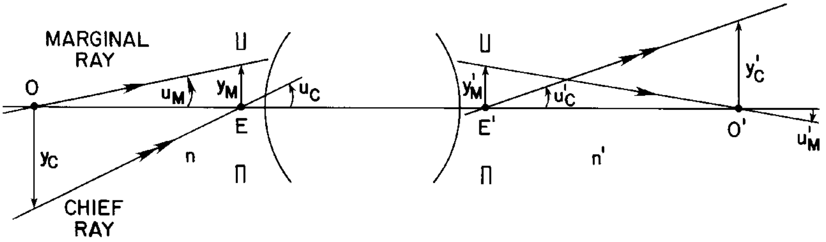

FIGURE 25 Schematic diagram of a lens with object and image planes, entrance and exit pupils, and marginal and chief rays. The entrance pupil is located at E and the exit pupil at E'. The chief ray passes through the edges of the fields and the centers of the pupils. The marginal ray passes through the axial object and image points and the edges of the pupils.

affect the image irradiance, the aberrations, and the effects of defocus. The aperture is most commonly centered on axis, but this is not always so. With visual instruments, the aperture stop for the entire system may be either an aperture in the optics or the iris of the observer's eye.

Marginal Rays and Chief Rays

Ray bundles are described to a considerable extent by specifying their central and extreme rays. For object planes perpendicular to the lens axis, there are two meridional rays of particular importance, defining the extremities of field and aperture, Fig. 25. These rays are reciprocal in that one is to the pupil what the other is to the field.

The *marginal ray* originates at the axial object point, intersects the conjugate image point, and passes through the edge of the aperture. This term is also used for rays from other field points that pass through the extremes of the aperture. The *paraxial marginal ray* is the marginal ray in the paraxial limit.

The *chief ray* or *principal ray* originates at the edge of the object field, intersects the edge of the image field, and passes approximately through the center of the aperture, and hence approximately through the center of the pupils. (Here we use "chief ray," since the prefix "principal" is so commonly used for other entities.) The term is also used for the central ray of other bundles. The *paraxial chief ray* passes exactly through the centers of the aperture and both paraxial pupils.

Field Angle

The *field angle* is that subtended by the field of view at the lens. This term is ambiguous, since several angles can be used, as well as angles in both object and image space. A nodal ray angle is the same in both spaces. If the nodal points are not at the pupils, the chief ray angle differs on the two sides. The ratio of paraxial chief ray angles is proportional to the paraxial pupil magnification, as discussed later, Eq. (289). If the lens is telecentric, the chief ray angle is zero. An afocal lens has no nodal points, and the paraxial ratio of output angles to input angles is constant. The concept of field angle is most useful with objects and/or images at large distances, in which case on the long conjugate side the various ray angles are nearly identical. On the short conjugate side, ambiguity is removed by giving the focal length, the linear size of the detector, and the principal plane and exit pupil positions. For finite conjugates, such information should be provided for both spaces.

Pupils

The term *pupil* is used in several ways, and care should be taken to distinguish between them. There are paraxial pupils, ''real'' pupils, pupils defined as ranges of angles, and pupil reference spheres used for aberration definition and diffraction calculations. The *entrance pupil* is the aperture as seen from object space—more precisely, as seen from a particular point in object space. If the aperture is physically located in object space, the entrance pupil is identical to the aperture. Otherwise, the entrance pupil is the image of the aperture in object space formed by the portion of the lens on the object side of the aperture. If the aperture is in image space, the entrance pupil is its image formed by the entire lens. Similarly, the *exit pupil* is the aperture as seen from image space. A *real pupil* is a physically accessible image of the aperture or the aperture itself, and a *virtual pupil* is an inaccessible image. Visual instruments often have external pupils, where the user's eye is located. The axial entrance pupil point is denoted here by E and the exit pupil by E'.

The pupils can be located anywhere on axis, except that they cannot coincide with the object or image. It is common to draw pupils as shown in Fig. 25, but they can also be on the side of the object or image away from the lens. The pupils are usually centered on axis, but not necessarily. Aberrations may shift pupils from nominal axial centration.

Both pupils are conjugate to the aperture, so they are conjugate to each other. The term *pupil imaging* refers to the relationship of the pupils with respect to each other and to the aperture. In pupil imaging, the chief ray of the lens is the marginal ray and vice versa. The *pupil magnification* m_P denotes the ratio of exit pupil size to entrance pupil size. The size may be specificed as linear or an angular extent, and the pupil magnification may be a transverse magnification, finite or paraxial, or a ratio of angular subtenses. In general, there is *pupil aberration,* so the image of the aperture in each space is aberrated, as is that of the imaging of one pupil to the other. Pupil imaging is subject to chromatic aberration, so positions, sizes, and shapes of pupils may vary with wavelength.

There is ambiguity about pupil centers and chief rays for several reasons. The center can be taken with respect to linear, angular, or direction cosine dimensions. Because of spherical pupil aberration, a ray through the center of the pupil may not also pass through the center of the aperture, and vice versa. The angular dimensions of pupils may change with field position. Pupil aberrations cause the actual pupil shape to be different from that of the paraxial pupil.

Pupils that are not apertures can have any linear size, since the aperture can be imaged at any magnification. If the aperture is within the lens, there is no particular relationship between the positions and linear sizes of the entrance and exit pupils, since the portions of the lens that precede and follow the aperture have no specific relationship. There is a relationship between the angular subtense of the pupils, as discussed below.

The angular size and shape of the pupils can vary with field position, and the pupils can change position if the aperture changes with object position. If the lens changes internally, as with a zoom, the sizes and positions of the pupils change.

Paraxial Description

The *paraxial pupils* are the paraxial images of the aperture. They are usually planar and perpendicular to the axis and are implicitly free from aberration. The paraxial chief ray passes through the center of both pupils and the aperture, and the paraxial marginal ray through the edges. The object and pupil magnifications and the distances from object to entrance pupil and from exit pupil to image are related by Eq. (194). If the object at O

is imaged at O' with magnification m, and the pupil magnification from entrance pupil at E to exit pupil at E' is m_E, then from Eq. (194)

$$O'E' = \frac{n'}{n} m m_E OE \tag{287}$$

Paraxial Invariant for Full Field and Full Aperture

Let the height of the paraxial marginal ray be y_M at the entrance pupil and y'_M at the exit pupil, and that of the paraxial chief ray by y_C, at the object plane and y'_C at the image plane, Fig. 25. Let the angles of these rays be u_M, u_C, u'_M, u'_C. The two-ray paraxial invariant, Eq. (149), is

$$L = n y_C u_M = n y_M u_C = n' y'_M u'_C = n' y'_C u'_M \tag{288}$$

This relationship was rediscovered several times, so the conserved quantity is referred to by a variety of names, including the *Lagrange invariant,* the *Helmholtz invariant,* the *Smith invariant,* and with various hyphenated combinations of the proper names (Rayleigh 1886,[230] Southall 1910[231]). Further discussions are found in the sections on paraxial optics and on the étendue. The paraxial transverse magnification and paraxial pupil magnifications are related to the paraxial marginal and chief ray angles by

$$m = \frac{y'_C}{y_C} = \frac{n u_M}{n' u'_M} \qquad \text{and} \qquad m_P = \frac{y'_M}{y_M} = \frac{n u_C}{n' u'_C} \tag{289}$$

Pupil Directions

For some purposes, pupils are best described as ranges of directions, specified in direction cosines, rather than by linear extents of aperture images. Here the term *pupil directions* (NS) is used. This is particularly the case when dealing with a given region of the object. The construction for this description is shown in Fig. 26. The x and y axes of the

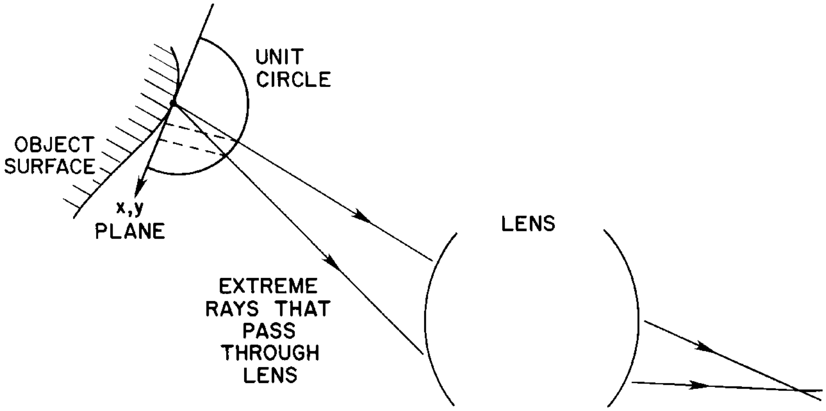

FIGURE 26 Construction for the description of the pupils with direction cosines. An x-y plane is tangent to the object surface at the object point, and a unit sphere is centered on the point. The intersections with the unit sphere of the rays are projected to the tangent plane to give the pupil direction cosines.

object-space coordinate system lie in the object surface, and the x' and y' axes. From a point on the object plane, the extreme set of rays that passes through the lens is found. Its intersection with a unit sphere about the object point is found, and perpendiculars are dropped to the unit circle on (or tangent to) the object plane, giving the extent in direction cosines.

The entrance pupil is delimited by a closed curve described by a relationship $0 = P(\alpha, \beta; x, y)$, and the exit pupil is likewise defined by $0 = P'(\alpha', \beta'; x', y')$. The spatial argument is included to indicate that the shape varies, in general, with the field position. There may be multiple regions, as in the case of central obstructions. It is usually preferable to define the pupils relative to *principal directions* (NS) (α_0, β_0) in object space and (α'_0, β'_0) in image space, where the two directions are those of the same ray in the two spaces, usually a meridional ray. The principal directions are analogous to the chief rays. The entrance pupil is then given by $0 = Q(\alpha - \alpha_0,\ \beta - \beta_0;\ x, y)$ and the exit pupil by $0 = Q'(\alpha' - \alpha'_0,\ \beta' - \beta'_0;\ x', y')$. For example, for a field point on the $x = 0$ meridian, the expression for the pupil might be well approximated by an ellipse, $0 = a\alpha^2 + b(\beta - \beta_0)^2$, where $(0, \beta_0)$ is the chief ray direction. If the imaging is stigmatic, the relationship between entrance and exit pupil angular shapes is provided by the cosine condition, Eq. (104).

$$Q'(\alpha', \beta'; x', y') = Q(m_P\alpha' - \alpha'_0, m_P\beta' - \beta'_0; x, y) \tag{290}$$

The entrance and exit pupils have the same shapes when described in direction cosine space. They are scaled according to the *pupil angular magnification* (NS) $m_P = n/n'm$. The orientations may be the same or rotated 180°. There is no particular relationship between (α_0, β_0) and (α'_0, β'_0), which can, for example, be changed by field lenses. The principal directions are, however, usually in the same meridian as the object and image points, in which case $\alpha_0/\beta_0 = \alpha'_0/\beta'_0$. If the field point is in the x meridian, and the central ray is in this meridian, then $\alpha_0 = 0$ and $\alpha'_0 = 0$. Even with aberrations, Eq. (290) usually holds to a good approximation. The aberration *pupil distortion* refers to a deviation from this shape constancy.

Pupil Directional Extent: Numerical Aperture and Its Generalizations

The angular extent of a pupil extent is limited by some extreme directions. In the example above of the elliptical shape, for instance, there are two half widths

$$\tfrac{1}{2}(\alpha_{\max} - \alpha_{\min}) \qquad \text{and} \qquad \tfrac{1}{2}(\beta_{\max} - \beta_{\min}) \tag{291}$$

For a rotationally symmetric lens with a circular aperture, the light from an axial object point in a medium of index n is accepted over a cone whose vertex angle is $\theta_{\max}$. The *object space numerical aperture* is defined as

$$NA = n \sin\theta_{\max} = n\sqrt{(\alpha^2 + \beta^2)_{\max}} = n\alpha_{\max} = n\beta_{\max} \tag{292}$$

Likewise, on the image side, where the index is n' and the maximum angle is $\theta'_{\max}$, the *image space numerical aperture* is

$$NA' = n' \sin\theta'_{\max} = n'\sqrt{(\alpha'^2 + \beta'^2)_{\max}} = n'\alpha'_{\max} = n'\beta'_{\max} \tag{293}$$

If the lens is free of coma, the sine condition, Eq. (106), gives for finite conjugates

$$m = \frac{n \sin \theta_{\max}}{n' \sin \theta'_{\max}} = \frac{NA}{NA'} \tag{294}$$

For infinite conjugates

$$\sin \theta'_{\max} = -\frac{y_{\max}}{f'} \qquad \text{or} \qquad n' \sin \theta'_{\max} = NA' = n\beta_{\max} = -y_{\max}\phi \tag{295}$$

If there is coma, these relationships are still good approximations. For a given lens and a given aperture size, the numerical aperture varies with the axial object position.

F-Number and Its Problems

The *F-number* is written in a variety of ways, including F/no. and F/#. It is denoted here by *FN*. The F-number is not a natural physical quantity, is not defined and used consistently in the literature, and is often used in ways that are both wrong and confusing (Hatch 1980,[232] Goodman 1993[233]). Moreover, there is no need to use the F-number, since everything that it purports to describe or approximately describes is treated properly with direction cosines. The most common definition for F-number, applied to the case of an object at infinity, is

$$FN = \frac{\text{focal length}}{\text{entrance pupil diameter}} = \frac{1}{2 \tan \theta'} \tag{296}$$

where θ' is the outgoing angle of the axial imaging done. In general, the F-number is associated with the tangents of collinear transformations, rather than the sines (or direction cosines) that are physically appropriate. It presumes that a nonparaxial ray entering parallel to the axis at height y leaves the rear principal plane at the same height and intersects the rear focal point, so that $\tan \theta' = y/f'$. However, this particular presumption contradicts Eq. (294), and in general, collineation does not accurately describe lens behavior, as discussed above.

Other problems with F-number, as it is used in the literature, include the following: (1) It is not defined consistently. For example, the literature also contains the definition F-number = (focal length)/(exit pupil diameter). (2) For lenses used at finite conjugates, the F-number is often stated for an object at infinity. In fact, given only the numerical aperture for an object at infinity, that for other conjugates cannot be determined. (3) There are confusing descriptions of variation of F-number with conjugates, for example, the equation $FN_m = (1 + m)FN_\infty$, where FN_m is the F-number for magnification m and FN_∞ is that for an object at infinity. In fact, numerical apertures for various magnification are not so related. (4) The object and image space numerical apertures are related by Eq. (293), but there is no such relationship for tangents of angles, except that predicted by collineation, Eq. (232), which is approximate. (5) With off-axis field points and noncircular pupils, the interpretation of F-number is more ambiguous. (6) Afocal systems have finite numerical apertures when used at finite conjugates, but they have no analogue to Eq. (295). (7) Object and image space refractive indices are not accounted for by the F-number, whereas they are by the numerical aperture. (8) The F-number is often used as a descriptor of radiometric throughput, rather than of ray angles per se.

A related quantity is the *T-number* (W. J. Smith 1992[234]), which accounts for both the convergence angle of the imaging cone and the fraction of power transmitted by the lens.

This is useful as a single-number descriptor, but it is subject to all the confusion associated with the F-number.

Image Irradiance for Lambertian Objects

If the light from a region of an object is lambertian with a power/area M, then the emitted power per angle with angle according to $(M/\pi)\cos\theta\, d\omega = (M/\pi)\, d\alpha\, d\beta$. The power captured by the entrance pupil from a small object area dA is

$$dP = \frac{1}{\pi} M\, dA \int_{\text{entrance pupil}} d\alpha\, d\beta \tag{297}$$

(For a full hemisphere $\int d\alpha\, d\beta = \pi$, giving $dP = M\, dA$.) If there are no losses within the lens, the power reaching the conjugate image region dA' is the same. Using the conservation of étendue equation, Eq. (72), the image irradiance is

$$E = \frac{dP}{dA'} = \frac{1}{\pi} M \frac{n'^2}{n^2} \int_{\text{exit pupil}} d\alpha'\, d\beta' \tag{298}$$

The image irradiance does not depend explicitly on the magnification, but magnification is included implicitly, since, for a given lens, the subtense of the exit pupil varies with conjugates.

This equation obtains everywhere in the field, and it applies to arbitrary object surface positions and orientations, so long as the direction cosines are defined with respect to the local object and image surface normals. These equations apply regardless of the chief ray angles, so they are applicable, for example, with telecentricity. In general, the pupil shape and principal direction vary with field position, so there is a gradation of irradiance in the image of a uniform lambertian object.

These equations do not account for all that influences image irradiance, for example lens absorption and reflection. These effects can be included in the above expressions by adding an appropriate weighting function of angle and field in the above integrals, giving

$$E(x', y') = \frac{dP}{dA'} = \frac{1}{\pi} M(x, y) \frac{n'^2}{n^2} \int \tau(\alpha', \beta'; x', y')\, d\alpha'\, d\beta' \tag{299}$$

where $\tau(\alpha', \beta'; x', y')$ is the lens transmittance as a function of the direction cosines for the image point (x', y'). With externally illuminated objects that are not lambertian scatterers, these relationships do not hold. For example, in optical projectors the illumination is matched to the object and imaging lens to give nominally uniform image irradiance.

Axial Image Irradiance for Lambertian Objects

In the special case of circular pupils and axial object surfaces perpendicular to the axis, the collected power and image irradiance given above are

$$dP = M\, dA \sin^2\theta \qquad \text{and} \qquad E = M \frac{n'^2}{n^2} \sin^2\theta' \tag{300}$$

Power/Pixel

From wave optics, a lens working at the "resolution limit" has an image pixel size $q\lambda/n' \sin\theta'$, where λ is the vacuum wavelength and q is a dimensionless factor, typically of the order of unity. Applying Eq. (300), this gives

$$\text{Power/pixel} = q^2 M \left(\frac{\lambda}{n}\right)^2 \tag{301}$$

$M(\lambda/n)^2$ is the energy emitted per square wavelength of object area. This is a fundamental radiometric quantity. Increasing q gives a greater numerical aperture than is nominally required for resolution, but in practice the aberration correction may be such that the actual resolution is not greater.

Cosine-to-the-Fourth Approximation

For distant, planar, uniform lambertian objects perpendicular to the lens axis, if the entrance pupil is well approximated by a circle, then the image irradiance varies approximately with the object space field angle ψ according to the *cosine-to-the-fourth* relationship

$$E(\psi) = E_0 \cos^4 \psi \tag{302}$$

where E_0 is the axial irradiance. There are three contributions to this dependence. (1) The angular distribution of a lambertian emitter varies as $\cos\psi$. (2) The distance from the field point to the entrance pupil varies as $1/d^2 \propto \cos^2\psi$. (3) Insofar as the pupil behaves as a rigid circle, its projected solid angle varies approximately as $\cos\psi$. The cosine-to-the-fourth relationship should be used only as a guideline, since ray tracing permits more accurate calculations, and because of the ambiguities in the meaning of the field angle, as discussed above, and elsewhere (Kingslake 1945,[235] Reiss 1945,[236] Gardner 1947,[237] Reiss 1948,[238] Kingslake 1965[239]). For example, field angle is meaningless with telecentricity. Some lenses, especially wide-angle ones, are specifically designed so the pupil subtense increases with the field angle in order to compensate for effects (1) and (2) above, to produce a sufficiently uniform image (Slyusarev 1941[240]).

Total Lens Étendue

The total amount of power from a lambertian object that can be transferred through a lens is

$$\frac{1}{\pi} M \int_{\text{field}} dx\, dy \int_{\text{pupil}} d\alpha\, d\beta \tag{303}$$

The pupil integral may vary over the field. If the pupil is round and constant over the field, the étendue is proportional to $A(\text{NA})^2$, where A is the area of the field. This quantity is also related to the total number of pixels in the field, and the ability of the lens to transfer information (Gabor 1961[241]). The term "area-solid angle product" is sometimes used, but this is an approximation. The total etendue is proportional paraxially to $\sim L^2$, where L is given by Eq. (288).

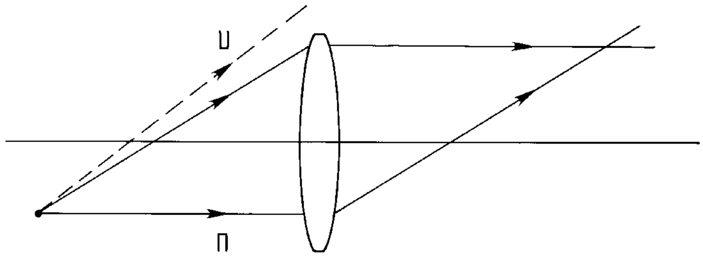

FIGURE 27 Example of vignetting. The dashed ray passes through the aperture, but misses the lens.

Vignetting

Vignetting occurs when an image-forming bundle is truncated by two or more physical structures in different planes, Fig. 27. Typically, one is the nominal aperture and another is the edge of a lens. Another case is that of central obstructions away from the aperture. When vignetting occurs, the image irradiance is changed, and its diminution with field height is faster than it otherwise would be. Aberration properties are also changed, so vignetting is sometimes used to eliminate light that would unacceptably blur the image.

Lens Combinations and Field Lenses

When lenses are used to relay images, the light is transferred without loss only if the exit pupil of one corresponds with the entrance pupil of the next. An example of the failure to meet this requirement is shown in Fig. 28. The axial point is reimaged satisfactorily, but off-axis bundles are vignetted. To transfer the light properly, a *field lens* in the vicinity

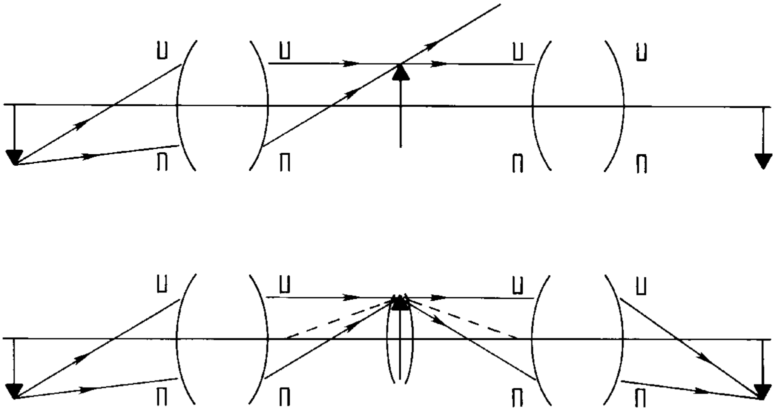

FIGURE 28 A pair of lenses relaying an image with and without a field lens. In the top figure, there is no field lens, and some of the light forming the intermediate image does not pass through the second lens. The amount lost depends on the two numerical apertures and increases with distance from the axis. In the lower figure, a field lens at the intermediate image forms an image of the exit pupil of the first lens into the entrance pupil of the next. No light is lost unless the numerical aperture of the second lens is less than that of the first.

of the intermediate image is used to image the exit pupil of the preceding lens into the entrance pupil of the next one. If the field lens is a thin lens in the image plane, then its magnification with respect to the image is unity. In practice, the field lens is usually shifted axially, so scratches or dust on its surface are out of focus. Its magnification then differs from unity. The focal length of a thin field lens in air is given by $1/f' = 1/a + 1/b$, where a is the distance from exit pupil of first lens to the field lens, and b is that from field lens to the entrance pupil of the second lens. The exit pupil is reimaged with a magnification b/a. If the sizes of the various pupils and their images are not matched, then the aperture of the combination is determined by the smallest. Field lenses affect aberrations.

Defocus

When the object and image-receiving surface are not conjugate there is *defocus*. If either the object or the receiving surface is considered to be correctly positioned, the defocus is associated with the other. Another situation is that in which the object and receiving surfaces are conjugate, but both are wrongly located, so that the image is sharp but the magnification is not what is desired, a condition that might be called *misfocus* (NS).

Defocus has two basic geometric effects, if there are no aberrations, Fig. 29. One is blurring, since the rays from an object point do not converge to a single point on the receiving surface. The blur size varies linearly with the axial defocus in image space and with the cone angle of the image-forming bundle. The shape of the blur is that of the exit pupil, projected on the receiving surface. The other effect of defocus is a lateral shift in position of the blur's centroid relative to that of the correctly focused point. The shift depends on the chief ray angle on the side of the lens where the defocus occurs. In the simplest case, the shift is approximately linear with field height, so acts as a change of magnification. If the object is tilted or is not flat, the effects of defocus vary across the field in a more complicated way. Aberrations affect the nature of the blur. With some aberrations, the blur is different on the two sides of focus. With spherical aberration, the blur changes in quality, and with astigmatism the orientation of the blur changes.

In considering the geometrical imaging of a small region of a lambertian object, there is an implict assumption that the pupil is filled uniformly with light. In imaging an extended object that is externally illuminated, the light from a given region may not fill the pupil uniformly, so the character of the blurring is affected by the angular properties of the illumination and scattering properties of the object.

The amount of defocus can be described in either object or image space, and it can be measured in a variety of ways, for example, axial displacement, displacement along a chief ray, geometrical blur size, and wavefront aberration. The axial displacements in object

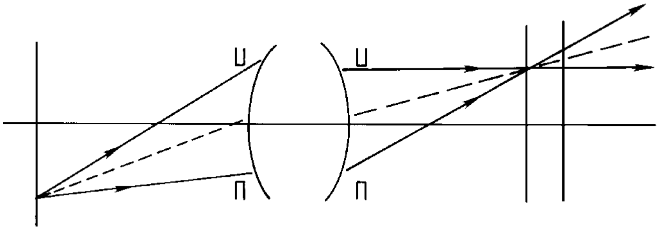

FIGURE 29 Defocus of the receiving surface. A receiving surface is shown in focus and shifted axially. The image of a point on the shifted surface is blurred, and its centroid is translated radially.

and image space differ, in general, and are related by the longitudinal magnification. As expressed in wavefront aberration, i.e., optical path length, defocus is the same in both spaces. There are also various functional measurements of defocus, for example, the sizes of recorded images through focus.

Telecentricity

A lens is *telecentric* if the chief rays are parallel to one another. Most commonly, they are also parallel to the lens axis and perpendicular to the object and/or image planes that are perpendicular to the axis, Fig. 30. Telecentricity is often described by speaking of pupils at infinity, but the consideration of ray angles is more concrete and more directly relevant. A lens is *telecentric in object space* if the chief rays in object space are parallel to the axis, $\alpha_0 = 0$ and $\beta_0 = 0$. In this case the image of the aperture formed by the portion of the lens preceding it is at infinity and the aperture is at the rear focal plane of the portion preceding it. Similarly, a lens is *telecentric in image space* if the aperture is at the front focal point of the subsequent optics, so $\alpha_0' = 0$ and $\beta_0' = 0$. More generally, but less commonly, the chief rays can be parallel to each other, but not necessarily to the axis, and not necessarily perpendicular to a (possibly tilted) object or image plane.

With tilted object and image surfaces and nonaxial pupils, the chief rays are not perpendicular to the object and/or image surfaces, but their angles are everywhere the same, so defocus can result in a rigid shift of the entire image.

A focal lens can be nontelecentric or telecentric on either side, but it cannot be doubly telecentric. An afocal lens can be nontelecentric, or doubly telecentric, but it cannot be telecentric on one side. A doubly telecentric lens must be afocal, and a singly telecentric lens cannot be afocal.

For a lens that is telecentric in image space, if the receiving surface is defocused, the image of a point is blurred, but its centroid is fixed. However, if it is not telecentric in object space, then the scale changes if the object is defocused. The converse holds for object-space telecentricity without image-space telecentricity. For a doubly telecentric lens, an axial shift of either the object or the receiving plane produces blurring without a centroid shift. Although the magnification of an afocal lens does not change with conjugates, there can be an effective change with defocus if it is not telecentric. If the pupil is not on the axis or if the object and image planes are tilted, there can be telecentricity without the chief rays being perpendicular to the object and/or image planes. In these cases, defocus results in a rigid shift of the entire image.

Nominal telecentricity can be negated in several ways. Pupil aberrations may change the chief ray angles across the field. For an extended object that is externally illuminated the pupil may not be filled uniformly by light from a given region, so defocus can product a lateral image shift.

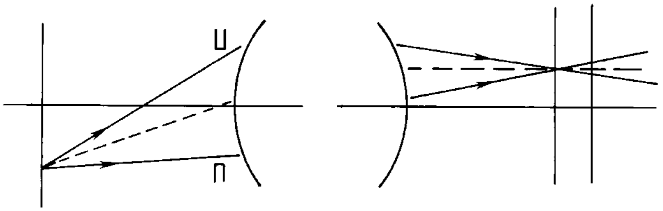

FIGURE 30 Example of telecentricity. The lens shown is telecentric in image space, in which ray bundles are parallel to the axis. An axial shift in the receiving surface results in blurring, but does not translate the centroid, so there is no change in image scale.

Depth of Focus and Depth of Field

The *depth of focus* and *depth of field* are the amounts of defocus that the receiving surface or object may undergo before the recorded image becomes unacceptable. The criterion depends on the application—the nature of the object, the method of image detection, and so on, and there are both ray and wave optics criteria for goodness of focus. For example, a field of separated point objects differs from that of extended objects. Depth of focus is usually discussed in terms of blurring, but there are cases where lateral shifts become unacceptable before blurring. For example, in nature photography blurring is more critical than geometrical deformation, while the opposite may be true in metrology.

Range of Focus and Hyperfocal Distance

In some cases, a geometrical description of defocus is applicable, and the allowable blur is specified as an angle (Ray 1988,[242] Kingslake 1992,[243] W. Smith 1992[234]). The *hyperfocal distance* is

$$\text{Hyperfocal distance} = \frac{\text{diameter of the entrance pupil}}{\text{maximum acceptable angular blur}} = d_H \tag{304}$$

Let the object distance at which the lens is focused be d, the nearest distance at which the image is acceptable be d_N, and the furthest distance be d_F. All of these quantities are positive definite. The following relations obtain:

$$d_F = \frac{d_H d}{d_H - d} \qquad \text{and} \qquad d_N = \frac{d_H d}{d_H + d} \tag{305}$$

The distances to either side of best focus are

$$d_F - d = \frac{d^2}{d_H - d} \qquad \text{and} \qquad d - d_N = \frac{d^2}{d_H + d} \tag{306}$$

The total range of focus is

$$d_F - d_N = \frac{2d^2 d_H}{d_H^2 - d^2} = \frac{2d}{(d_H/d)^2 - 1} \tag{307}$$

For $d > d_H$ the above quantities involving d_F are infinite (not negative). If the lens is focused at the hyperfocal distance or beyond, then everything more distant is adequately focused. If the lens is focused at the hyperfocal distance, i.e., $d = d_H$, the focus is adequate everywhere beyond half this distance, and this setting gives the greatest total range. If the lens is focused at infinity, then objects beyond hyperfocal distance are adequately focused. The hyperfocal distance decreases as the lens is stopped down.

1.19 GEOMETRIC ABERRATIONS OF POINT IMAGES—DESCRIPTION

Introduction

In instrumental optics, the term *aberration* refers to a departure from what is desired, whether or not it is physically possible. Terms such as "perfect system" and "ideal system" indicate what the actual is compared to, and these terms themselves are not absolute, but depend on what is wished for. The ideal may be intrinsically impossible, in which case a deviation therefrom is not a defect. A further distinction is between aberrations inherent in a design and those that result from shortcomings in fabrication.

This section considers only the description of aberrations of point images, with the lens treated as a black box, whose action with respect to aberrations is accounted for by what leaves the exit pupil. A full consideration of aberrations involves, among other things, their causes, their correction, their various manifestations, and their evaluation. Aberrated images of extended objects are formed by overlapping blurs from the individual points. The analysis of such images is object- and application-dependent, and is beyond the scope of this section. Aberrations do vary with wavelength, but most of this discussion involves monochromatic aberrations, those at a single wavelength. In addition, aberrations vary with magnification. Aberrations are discussed to some extent in many books that treat geometric optics (Conrady 1929,[244] H. Hopkins 1950,[245] Buchdahl 1954,[246] Herzberger 1958,[247] Kingslake 1978,[248] Born & Wolf 1980,[249] Slyusarev 1984,[250] Welford 1986,[251] Welford 1986,[252] W. Smith 1992[253]).

Descriptions

Aberration has many manifestations, and can be described in a variety of ways. For example, geometric wavefronts, path lengths, ray angles, and ray intersection points can all differ from the nominal (and in wave optics there are additional manifestations). Terms such as ‘‘wavefront aberration’’ and ‘‘ray aberration’’ do not refer to fundamentally different things, but to different aspects of the same thing. Often, a single manifestation of the aberration is considered, according to what is measurable, what best describes the degradation in a particular application, or what a lens designer prefers to use for optimization during the design process.

Classification

Aberrations are classified and categorized in a variety of ways. These include pupil dependence, field dependence, order, evenness and oddness, pupil and field symmetry, and the nature of change through focus—symmetrical and unsymmetrical. In addition, there are natural groupings, e.g., astigmatism and field curvature. The classification systems overlap, and the decompositions are not unique. The complete aberration is often described as a series of terms, several schemes being used, as discussed below. The names of aberrations, such as ‘‘spherical,’’ ‘‘coma,’’ and ‘‘astigmatism,’’ are not standardized, and a given name may have different meanings with respect to different expansions. Furthermore, the effects of aberrations are not simply separated. For example, ‘‘pure coma’’ can have effects usually associated with distortion. Defocus is sometimes taken to be a type of aberration, and it is useful to think of it in this way, since it is represented by a term in the same expansion and since the effects of aberrations vary with focus. The number of terms in an expansion is infinite, and familiar names are sometimes associated with unfamiliar terms. To improve clarity, it is recommended that all the terms in an expansion be made explicit up to agreed-upon values too small to matter, and that, in addition, the net effect be shown graphically. Further, it is often helpful to show more than one of an aberration’s manifestations.

Pupil and Field Coordinates

In this section, all the quantities in the equation are in image space, so primes are omitted. Field coordinates are x and y, with $h^2 = x^2 + y^2$, and (x, y) is the nominal image point in a plane $z = 0$. Direction cosines equally spaced on the exit pupil should be used for pupil coordinates but, in practice, different types of coordinates are used, including linear positions, spatial frequencies, and direction cosines. Here the pupil coordinates are ξ and

η, which are dimensionless, with $\rho^2 = \xi^2 + \eta^2$. The overall direction of the pupil may vary with field. Here the $(\xi, \eta) = (0, 0)$ is always taken at the pupil center, the meaning of which may not be simple, as discussed in the section on pupils above. The angle of a meridian in the pupil is ψ. Entrance and exit pupil coordinates must be distinguished. For diffraction calculations, the exit pupil should be sampled at equal intervals in direction cosines, but a set of rays from an object point that is equally spaced in direction cosines may leave with uneven spacing, as a result of aberrations.

Wavefront Aberration

If an object point is imaged stigmatically, then the optical path lengths of all rays from the object point to its image are identical, and the geometric wavefronts leaving the exit pupil are spherical. In the presence of aberrations, the wavefront is no longer spherical. Rather than describing the wavefront shape, it is usually preferable to consider the difference between the actual wavefront, and a nominal wavefront, often called the *reference sphere,* centered at a *reference point* that is usually the nominal image point. This reference sphere is usually taken to intersect the center of the pupil, since this gives the most accurate diffraction calculations. The *wavefront aberration* W is the optical path length from reference sphere to wavefront, or vice versa, according to the convention used, Fig. 31. Two sign conventions are in use; a positive wavefront aberration may correspond either to a wavefront which lags or leads the reference sphere. For each nominal image point (x, y, z), the wavefront aberration is a function of the pupil coordinates (ξ, η), so the functional form is $W(\xi, \eta; x, y, z)$, with the z usually suppressed, since the image plane is usually taken to be fixed. For a given lens prescription, W is found by tracing a set of rays from each object point to the reference sphere and calculating their path lengths. If the absolute path length is unimportant, the choice of the reference sphere's radius is not critical. Considered from the point of view of wave optics, the image of a point is degraded by phase differences across the reference sphere, so absolute phase is of no consequence, and the zero of the wavefront aberration can be chosen arbitrarily. By convention and convenience, the zero is usually taken at the center of the pupil, so $W(0, 0, x, y) = 0$.

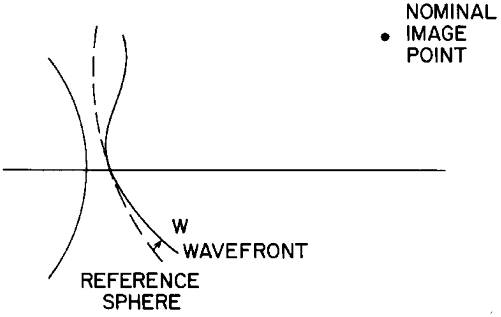

FIGURE 31 Wavefront aberration. The reference sphere is concentric with the nominal image point. The wavefront is taken that is tangent to the reference sphere in the center of the pupil. The wavefront aberration function is the distance from the reference sphere to the wavefront as a function of pupil coordiantes.

Absolute optical path lengths are significant for imaging systems with paths that separate between object and image in cases where there is coherence between the various image contributions. An error in absolute optical path length is called *piston error.* This results in no ray aberrations, so it is omitted from some discussions.

Ray Aberrations

In the presence of aberrations, the rays intersect any surface at different points than they would otherwise. The intersection of the rays with the receiving surface, usually a plane perpendicular to the axis, is most often of interest. The *transverse ray aberration* is the vectorial displacement $(\varepsilon_x, \varepsilon_y)$ between a nominal intersection point and the actual one. The displacement is a function of the position of the nominal image point (x, y) and the position in the pupil through which the ray passes (ξ, η). A complete description of transverse ray aberrations is given by

$$\varepsilon_x(\xi, \eta; x, y) \qquad \text{and} \qquad \varepsilon_y(\xi, \eta; x, y) \tag{308}$$

The *longitudinal aberration* is the axial displacement from nominal of an axial intersection point. This description is useful for points on the axis of rotationally symmetrical systems, in which case all rays intersect the axis. Such aberrations have both transverse and longitudinal aspects. The intersection with a meridian can also be used. The *diapoint* is the point where a ray intersects the same meridian as that containing the object point (Herzberger 1958[247]). For an image nominally located at infinity, aberrations can be described by the slope of the wavefront relative to that of the nominal, that is, by ray angles rather than intersection points. A hypothetical ideal focusing lens can also be imagined to convert to transverse aberrations.

A *ray intercept diagram* shows the intersection points of a group of rays with the receiving surface (O'Shea 1994[254]). The rays are usually taken to arise from a single object point and to uniformly sample the pupil, with square or hexagonal arrays commonly used. The ray intercept diagrams can suffer from artifacts of the sampling array, which can be checked for by using more than one type of array. Other pupil loci, for instance, principal meridians and annuli, can be employed to show particular aspects of the aberration. Intercept diagrams can also be produced for a series of surfaces through focus. Image quality may be better than ray diagrams suggest, since destructive interference can reduce the irradiance in a region relative to that predicted by the ray density.

Relationship of Wavefront and Ray Aberrations

Since rays are normal to geometric wavefronts, Fig. 32, transverse ray aberrations are proportional to the slope of the wavefront aberration function. For systems of rotation

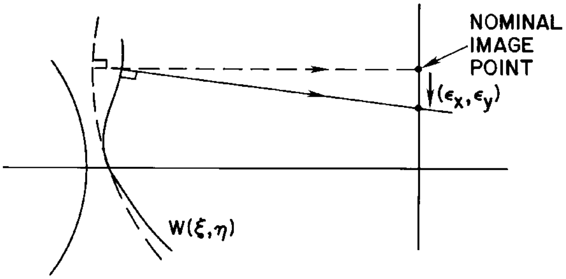

FIGURE 32 Ray aberration. Rays intersect the receiving plane at positions shifted from the nominal.

with image space index n and marginal ray angle θ, the transverse aberrations are to a good approximation (Welford 1986[251])

$$\varepsilon_x = \frac{1}{n \sin \theta} \frac{\partial W}{\partial \xi} \qquad \varepsilon_y = \frac{1}{n \sin \theta} \frac{\partial W}{\partial \eta} \tag{309}$$

The refractive index appears since W is an optical path length. If the rays are nominally parallel, then the partial derivatives give the angular ray errors

$$\Delta\alpha = \frac{1}{np} \frac{\partial W}{\partial \xi} \qquad \Delta\beta = \frac{1}{np} \frac{\partial W}{\partial \eta} \tag{310}$$

where p is the linear radius of the exit pupil, which cannot be infinite if the image is at infinity. These expressions may also have a multiplicative factor of -1, depending on the sign conventions. A sum of wavefront aberrations gives a transverse aberration that is the sum of the contributing ones.

Ray Densities

The density of rays near the nominal image point is (Welford 1986[251])

$$\frac{1}{\text{Density}} \propto \left(\frac{\partial^2 W}{\partial \xi^2}\right)\left(\frac{\partial^2 W}{\partial \eta^2}\right) - 2\left(\frac{\partial^2 W}{\partial \xi\, \partial \eta}\right)^2 \tag{311}$$

Caustics are the surfaces where ray densities are infinite. Here, geometric optics predicts infinite power/area, so the ray model is quantitatively inaccurate in this case.

Change of Reference Points

The center of the reference sphere may be displaced from the nominal image point. If the reference point is changed by linear displacement $(\delta x, \delta y, \delta z)$, then the wavefront aberration function changes from W to W' according to

$$W'(\xi, \eta; x, y; \delta x, \delta y, \delta z) = W(\xi, \eta; x, y) + W_x \xi + W_y \eta + W_z(\xi^2 + \eta^2) \tag{312}$$

where $W_x = n \sin \theta\, \delta x,$

$$\begin{aligned} W_y &= n \sin \theta\, \delta y \\ W_z &= \tfrac{1}{2} n \sin^2 \theta\, \delta z \end{aligned} \tag{313}$$

The transverse ray aberration ε_x' and ε_y' with respect to the new reference points are

$$\varepsilon_x' = \varepsilon_x + \delta x + \sin \theta\, \delta z \qquad \varepsilon_y' = \varepsilon_y + \delta y + \sin \theta\, \delta z \tag{314}$$

The change through focus is accounted for by varying δz. Setting $\varepsilon_x' = \varepsilon_y' = 0$ gives the parametric equations $x(\delta z)$ and $y(\delta z)$ for a ray with pupil coordinates (ξ, η), relative to the nominal ray near the nominal image point.

Aberration Symmetries for Systems with Rotational Symmetry

If the lens, including the aperture, is a figure of rotation, only certain aberration forms are possible. For object points on axis, the wavefront aberration and the image blur are figures of revolution. For off-axis points, both wavefront aberration and blur are bilaterally symmetrical about the meridional plane containing the object point. For object points on a circle centered on the axis, the wavefront and ray aberrations are independent of azimuth, relative to the local meridian. In practice, there is always some imperfection, so the symmetries are imperfect and additional aberration forms arise.

Wavefront Aberration Forms for Systems with Rotational Symmetry

Here the pupil is taken to be circular, with the coordinate zero taken at the center. The field coordinates are normalized so $x^2 + y^2 = h^2 = 1$ at the edge of the field. The pupil coordinates are normalized, so that $\xi^2 + \eta^2 = \rho^2 = 1$ on the rim of the pupil. The algebra is simplified by using dimensionless coordinates. To add dimensions and actual sizes, replace the ξ by ξ/ξ_{max}, and likewise for other variables. The simplest combinations of pupil and field coordinates with rotational symmetry are

$$x^2 + y^2 = h^2 \qquad \xi^2 + \eta^2 = \rho^2 \qquad \xi x + \eta y \tag{315}$$

The general wavefront aberration function can be expressed as a series of such terms raised to integral powers,

$$W(x, y; \xi, \eta) = \sum_{L,M,N=0} W_{LMN}(x^2 + y^2)^L(\xi^2 + \eta^2)^M(x\xi + y\eta)^N \tag{316}$$

where L, M, N are positive integers. The terms can be grouped in *orders* according to the sum $L + M + N$, where, by convention, the order equals $2(L + M + N) - 1$. The order number refers more directly to ray aberration forms than to wavefront forms, and it is always odd. The first-order terms are those for which $L + M + N = 1$, for the third-order terms the sum is two, and so on. The number of terms in the Qth order is $1 + (Q + 1)(Q + 7)/8$. For orders 1, 3, 5, 7, 9 the number of terms is 3, 6, 10, 15, 21. For each order, one contribution is a piston error, which is sometimes excluded from the count.

The expression of Eq. (316) is related to the characteristic function for a rotationally symmetrical system, Eq. (32). If the spatial coordinates are taken to be those of the object point, this is the point-angle characteristic function. In the hamiltonian optics viewpoint, the characteristic function is a sum of two parts. The first-order terms specify the nominal properties, and those of higher orders the deviation therefrom. This is discussed in the references given in that section. The term for which $L = M = N = 0$ has to do with absolute optical path length.

Since there is bilateral symmetry about all meridians, the expansion can be simplified by considering object points in a single meridian, customarily taken to be that for which $x = 0$. Doing so and letting the fractional field height be $y = h$ gives the wavefront aberration function

$$W(h; \rho, \eta) = \sum_{L,M,N=0} W_{LMN}h^{2L+N}\rho^{2M}\eta^N = \sum_{A,B,C} W'_{ABC}h^A\rho^B\eta^C \tag{317}$$

where $A = 2L + N$, $B = 2M$, $C = N$, and the order equals $(A + B + C) - 1$. Another form is obtained with the fractional pupil radius ρ and the pupil azimuth ψ, the angle from the $x = 0$ meridian, so $\eta = \rho \cos \psi$. With these pupil variables the wavefront aberration function is

$$W(h; \rho, \psi) = \sum_{L,M,N=0} W_{LMN} h^{2L+N} \rho^{2M+N} \cos^N \psi = \sum_{A,B,C} W''_{ABC} h^A \rho^B \cos^C \psi \tag{318}$$

where $A = 2L + N$, $B = 2M + N$, $C = N$, and the order is $A + B - 1$. For orders above the first, the W_{LMN}, W'_{ABC}, and W''_{ABC} are the *wavefront aberration coefficients.*

For a given field position, the wavefront aberration function for circular pupils can also be decomposed into the *Zernike polynomials,* also called *circle polynomials,* a set of functions complete and orthonormal on a circle (Zernike 1934,[255] Kim & Shannon 1987,[256] Malacara 1978,[257] Born & Wolf 1980[249]).

Third-Order Aberrations and Their Near Relatives

There are six third-order terms. The *Seidel aberrations* are spherical, coma, astigmatism, field curvature, distortion, and there is also a piston-error term. Expressions for these aberrations are given below, along with some higher-order ones that fall in the same classification. The terminology of higher-order aberrations is not standardized, and there are forms that do not have third-order analogues. This section uses the notation of the second expression of Eq. (318), without the primes on the coefficients.

It is useful to include *defocus* as a term in aberration expansions. Its wavefront aberration and transverse ray aberrations are

$$W = W_{020} \rho^2 \qquad \varepsilon_x \propto 2W_{020} \xi \qquad \varepsilon_y \propto 2W_{020} \eta \tag{319}$$

Coefficient W_{020} is identical to W_z, Eq. (313).

In *spherical aberration* the wavefront error is a figure of revolution in the pupil. The individual terms of the expansion have the form ρ^{2N}. The form that appears on axis, and which is independent of field position is

$$W = W_{020} \rho^2 + W_{040} \rho^4 + W_{060} \rho^6 + \cdots \tag{320}$$

where defocus has been included. The W_{040} term is the third-order term, the W_{060} is the fifth-order term, etc. The ray aberrations are

$$\begin{aligned} \varepsilon_x &\propto 2W_{020} \xi + 4W_{040} \rho^2 \xi + 6W_{060} \rho^4 \xi + \cdots \\ \varepsilon_y &\propto 2W_{020} \eta + 4W_{040} \rho^2 \eta + 6W_{060} \rho^4 \eta + \cdots \end{aligned} \tag{321}$$

There are also higher-order off-axis terms, called *oblique spherical aberration,* with forms $h^{2L} \rho^{2M}$. Spherical is an even aberration.

In *coma,* the wavefront aberration varies linearly with field height, so the general form is $h\rho^{2M} \eta = h\rho^{2M+1} \cos \psi$. Coma is an odd aberration. The wavefront expansion is

$$W = (W_{131} \rho^2 + W_{151} \rho^4 + \cdots) \eta h = (W_{131} \rho^3 + W_{151} \rho^5 + \cdots) \cos \psi h \tag{322}$$

The ray aberrations are

$$\begin{aligned} \varepsilon_x &\propto [W_{131}(2\xi\eta) + 4W_{151}(\xi^2 + \eta^2)\xi\eta + \cdots] h \\ \varepsilon_y &\propto [W_{131}(\xi^2 + 3\eta^2) + W_{151}(\xi^4 + 5\xi^2\eta^2 + 6\eta^4) + \cdots] h \end{aligned} \tag{323}$$

In *astigmatism* the wavefront aberration is cylindrical. The third-order term is

$$W = W_{222} h^2 \eta^2 = W_{222} h^2 \rho^2 \cos^2 \psi \tag{324}$$

with ray aberration

$$\varepsilon_x = 0 \qquad \varepsilon_y \propto 2W_{222}h^2\eta \tag{325}$$

Field curvature, also known as *Petzval curvature,* is a variation of focal position in the axial direction with field height. In its presence, the best image of a planar object lies on a nonplanar surface. Its absence is called *field flatness.* The wavefront aberration form is

$$W = (W_{220}h^2 + W_{420}h^4 + W_{620}h^6 + \cdots)\rho^2 \tag{326}$$

with symmetrical blurs given by

$$\begin{aligned} \varepsilon_x &\propto (W_{220}h^2 + W_{420}h^4 + W_{620}h^6 + \cdots)\xi \\ \varepsilon_y &\propto (W_{220}h^2 + W_{420}h^4 + W_{620}h^6 + \cdots)\eta \end{aligned} \tag{327}$$

The curvature of the best focus surface may have the same sign across the field, or there may be curvatures of both signs.

Astigmatism and field curvature are often grouped together. Combining defocus, third-order astigmatism, and third-order field curvature, the wavefront aberration can be written

$$W = W_{020}(\xi^2 + \eta^2) + [W_{220}\xi^2 + (W_{220} + W_{222})\eta^2]h^2 \tag{328}$$

The resultant ray aberration is

$$\varepsilon_x \propto [W_{020} + W_{220}h^2]\xi \qquad \varepsilon_y \propto [W_{020} + (W_{222} + W_{220})h^2]\eta \tag{329}$$

A tangential fan of rays, one that lies in the $x = 0$ meridian, has $\xi = 0$, so $\varepsilon_x = 0$. The *tangential focus* occurs where $\varepsilon_y = 0$, which occurs for a defocus of $W_{020} = -(W_{220} + W_{222})h^2$. Combining this result with Eq. (314) gives $\delta z \propto h^2$, the equation for the tangential focal surface. A sagittal fan of rays crosses the pupil in the $\eta = 0$ meridian, so $\varepsilon_y = 0$. The *sagittal focus* occurs where $\varepsilon_x = 0$, i.e., on the surface given by $W_{020} = -W_{220}h^2$.

In general, *distortion* is a deviation from geometric similarity between object and image. For rotationally symmetrical lenses and object and image planes perpendicular to the axis, the error is purely radial, and can be thought of as a variation of magnification with field height. The aberration forms are

$$W = (W_{111}h + W_{311}h^3 + W_{511}h^5 + \cdots)\eta \tag{330}$$

with

$$\varepsilon_x = 0 \qquad \varepsilon_y \propto W_{111}h + W_{311}h^3 + W_{511}h^5 + \cdots \tag{331}$$

In *pincushion* distortion the magnitude of magnification increases monotonically with field height, so the image is stretched radially. In *barrel distortion* the magnitude decreases, so the image is squeezed. In general, the aberration coefficients can be both positive and negative, so the direction of distortion can change as a function of field height and the distortion may vanish for one or more field heights.

For *piston error* the wavefront differs uniformly across the pupil from its nominal in a way that varies with field height.

$$W = W_{000} + W_{200}h^2 + W_{400}h^4 + W_{600}h^6 + \cdots \qquad \varepsilon_x = \varepsilon_y = 0 \tag{332}$$

There are no transverse ray aberrations.

Chromatic Aberrations

In general, the properties of optical systems vary with wavelength. The term *chromatic aberration* often refers to the variation in paraxial properties as a function of wavelength. Thus, *axial color* is related to differences of focal length and principal plane location with wavelength, and *lateral color* is related to variations of magnification with wavelength. Also, the monochromatic aberrations vary in magnitude with wavelength. Reflective systems have identical ray properties at all wavelengths, but their wave properties vary with color, since a given variation in path length has an effect on phase that varies with wavelength.

Stop Size and Aberration Variation

For a given system, if the size of the aperture is changed, the marginal ray is changed, but not the chief ray. If the aperture is reduced, depth of focus and depth of field increase and image irradiance decreases. The rays from axial object points are more nearly paraxial, so the imaging tends to be better corrected. For off-axis points, some aberrations are changed and others are not. Distortion, as defined with respect to the chief ray, is not changed. Field curvature per se does not change, since the aperture size does not change the location of the best image surface (if there are no other aberrations), but the depth of focus does change, so a flat detector can cover a larger field.

Stop Position and Aberration Variation

For a given system, if the aperture is moved axially, the image-forming bundle passes through different portions of the lens elements. Accordingly, some aberrations vary with the position of the stop. Lens design involves an operation called the *stop shift,* in which the aperture is moved axially while its size is adjusted to keep the numerical apertures constant. In this operation, the marginal ray is fixed, while the chief ray is changed. This does not change the aberrations on axis. Most of those for off-axis points are changed, but third-order field curvature is unchanged.

GEOMETRIC OPTICS

CHAPTER 1

GENERAL PRINCIPLES OF GEOMETRIC OPTICS

Douglas S. Goodman
Polaroid
Cambridge, Massachusetts

1.1 GLOSSARY

(NS)	indicates nonstandard terminology
italics	definition or first usage
∇	gradient $(\partial/\partial x, \partial/\partial y, \partial/\partial z)$
prime, unprime	before and after, object and image space (not derivatives)
A	auxiliary function for ray tracing
A, A'	area, total field areas, object and image points
AB	directed distance from A to B
$\mathbf{a}$	unit axis vector, vectors
a_O, a_B, a_I	coefficients in characteristic function expansion
B	matrix element for symmetrical systems
B	auxiliary function for ray tracing
B, B'	arbitrary object and image points
$\mathbf{b}$	binormal unit vector of a ray path
$\mathcal{B}$	interspace (between) term in expansion
C	matrix element for conjugacy
$C(\mathcal{O}, \mathcal{B}, \mathcal{I})$	characteristic function
c	speed of light in vacuum
c	surface vertex curvature, spherical surface curvature
c_s	sagittal curvature
c_t	tangential curvature
D	auxiliary distance function for ray tracing
d	distance from origin to mirror
d	nominal focal distance
d, d'	arbitrary point to conjugate object, image points $d = AO$, $d' = A'O'$
d, d'	axial distances, distances along rays
d_H	hyperfocal distance

d_N	near focal distance
d_F	far focal distance
dA	differential area
ds	differential geometric path length
E	image irradiance
E_0	axial image irradiance
E, E'	entrance and exit pupil locations
e	eccentricity
e_x, e_y, e_z	coefficients for collineation
F	matrix element for front side
F, F'	front and rear focal points
FN	F-number
FN_m	F-number for magnification m
$F(\ )$	general function
$F(x, y, z)$	general surface function
f, f'	front and rear focal lengths $f = PF$, $f' = P'F'$
G	diffraction order
g, g'	focal lengths in tilted planes
h, h'	ray heights at objects and images, field heights, $\sqrt{x^2 + y^2}$
$\mathscr{H}$	hamiltonian
I, I'	incidence angles
$\mathbf{I}$	unit matrix
i, i'	paraxial incidence angles
$\mathscr{I}$	image space term in characteristic function expansion
L	surface x-direction cosine
L	paraxial invariant
l, l'	principal points to object and image axial points $l = PO$, $l' = P'O'$ axial distances from vertices of refracting surface $l = VO$, $l' = V'O'$
$\mathscr{L}$	lagrangian for heterogeneous media
M	lambertian emittance
M	surface z-direction cosine
m	transverse magnification
m_L	longitudinal magnification
m_α	angular magnification
m_E	paraxial pupil magnification
m_N	nodal point magnification $= n/n'$
m_P	pupil magnification in direction cosines
m_O	magnification at axial point
m_x, m_y, m_z	magnifications in the x, y, and z directions
N	surface z-direction cosine
N, N'	nodal points
NA, NA'	numerical aperture
n	refractive index

$\mathbf{n}$	normal unit vector of a ray path
O, O'	axial object and image points
$\mathcal{O}$	object space term in expansion
P	power (radiometric)
P, P'	principal points
$P(\alpha, \beta; x, y)$	pupil shape functions
$P'(\alpha', \beta'; x', y')$	
p	period of grating
$\mathbf{p}$	ray vector, optical direction cosine $\mathbf{p} = n\ \mathbf{r} = (p_x, p_y, p_z)$
p	pupil radius
p_x, p_y, p_z	optical direction cosines
$Q(\alpha, \beta; x, y)$	pupil shape functions relative to principal direction cosines
$Q'(\alpha', \beta'; x', y')$	
q	resolution parameter
q_i	coordinate for Lagrange equations
$\dot{q}_i$	derivative with respect to parameter
q, q'	auxiliary functions for collineation
$\mathbf{q}$	unit vector along grating lines
R	matrix element for rear side
r	radius of curvature, vertex radius of curvature
$\mathbf{r}$	ray unit direction vector $\mathbf{r} = (\alpha, \beta, \gamma)$
$\mathbf{S}$	surface normal $\mathbf{S} = (L, M, N)$
$S(x, y, x', y')$	point eikonal $V(x, y, z_0; x', y', z_{0'})$
s	geometric length
s	axial length
s, s'	distances associated with sagittal foci
$\mathcal{S}$	skew invariant
$T(\alpha, \beta; \alpha', \beta')$	angle characteristic function
t	thickness, vertex-to-vertex distance
t, t'	distances associated with tangential foci
t	time
$\mathbf{t}$	tangent unit vector of a ray path
U, U'	meridional ray angles relative to axis
u, u'	paraxial ray angles relative to axis
u_M	paraxial marginal ray angle
u_C	paraxial chief ray angle
u_1, u_2, u_3, u_4	homogeneous coordinates for collineation
V	optical path length
$V(\mathbf{x}; \mathbf{x}')$	point characteristic function
V, V'	vertex points

v	speed of light in medium
W_{LMN}	wavefront aberration term
W_x, W_y, W_z	wavefront aberration terms for reference shift
$W(\xi, \eta; x, y, z)$	wavefront aberration function
$W'(\alpha, \beta; x', y')$	angle-point characteristic function
$W(x, y; \alpha', \beta')$	point-angle characteristic function
$\mathbf{x} = (x, y, z)$	position vector
$\mathbf{x}(\sigma)$	parametric description of ray path
$\dot{\mathbf{x}}(\sigma)$	derivative with respect to parameter
$\ddot{\mathbf{x}}(\sigma)$	second derivative with respect to parameter
y	meridional ray height, paraxial ray height
y_M	paraxial marginal ray height
y_C	paraxial chief ray height
y_P, y'_P	paraxial ray height at the principal planes
z	axis of revolution
$z(\rho)$	surface sag
z_{sphere}	sag of a sphere
z_{conic}	sag of a conic
z, z'	focal point to object and image distances $z = FO$, $z' = F'O'$
α, β, γ	ray direction cosines
α, β, γ	entrance pupil directions
α', β', γ'	exit pupil direction cosines
α_0, β_0	principal direction of entrance pupil
α'_0, β'_0	principal direction of exit pupil
$\alpha_{\max}, \alpha_{\min}$	extreme pupil directions
$\beta_{\max}, \beta_{\min}$	extreme pupil directions
Γ	$n' \cos I' - n \cos I$
$\delta x, \delta y, \delta z$	reference point shifts
$\Delta\alpha, \Delta\beta$	angular aberrations
$\Delta x, \Delta y, \Delta z$	shifts
ε	surface shape parameter
$\varepsilon_x, \varepsilon_y$	transverse ray aberrations
ξ, η	pupil coordinates—not specific
θ	ray angle to surface normal marginal ray angle plane tilt angle

κ	conic parameter
κ	curvature of a ray path
λ	wavelength
ψ	aximuth angle field angle
ϕ	power, surface power azimuth
ρ	radius of curvature of a ray path distance from axis radial pupil coordinate
σ	ray path parameter general parameter for a curve
τ	reduced axial distances torsion of a ray path
$\tau(\alpha', \beta'; x', y')$	pupil transmittance function
ω, ω'	reduced angle $\omega = nu,\ \omega' = n'u'$
$d\omega$	differential solid angle

1.2 INTRODUCTION

The Subject

Geometrical optics is both the object of abstract study and a body of knowledge necessary for design and engineering. The subject of geometric optics is small, since so much can be derived from a single principle, that of Fermat, and large since the consequences are infinite and far from obvious. Geometric optics is deceptive in that much that seems simple is loaded with content and implications, as might be suggested by the fact that some of the most basic results required the likes of Newton and Gauss to discover them. Most of what appears complicated seems so because of obscuration with mathematical terminology and excessive abstraction. Since it is so old, geometric optics tends to be taken for granted and treated too casually by those who consider it to be ''understood.'' One consequence is that what has been long known can be lost if it is not recirculated by successive generations of textbook authors, who are pressed to fit newer material in a fairly constant number of pages.

The Contents

The material in this chapter is intended to be that which is most fundamental, most general, and most useful to the greatest number of people. Some of this material is often thought to be more esoteric than practical, but this opinion is less related to its essence than to its typical presentation. There are no applications per se here, but everything is applicable, at least to understanding. An effort has been made to compensate here for what is lacking elsewhere and to correct some common errors. Many basic ideas and useful results have not found their way into textbooks, so are little known. Moreover, some basic principles are rarely stated explicitly. The contents are weighted toward the most common type of optical system, that with rotational symmetry consisting of mirrors and/or lens elements of homogeneous materials. There is a section on heterogeneous media, an application of which is gradient index optics discussed in another chapter. The treatment here is mostly monochromatic. The topics of caustics and anisotropic media are omitted, and there is little specifically about systems that are not figures of revolution. The section on aberrations is short and mostly descriptive, with no discussion of lens design, a vast field concerned with the practice of aberration control. Because of space limitations, there are too few diagrams.

Terminology

Because of the complicated history of geometric optics, its terminology is far from standardized. Geometric optics developed over centuries in many countries, and much of it has been rediscovered and renamed. Moreover, concepts have come into use without being named, and important terms are often used without formal definitions. This lack of standardization complicates communication between workers at different organizations, each of which tends to develop its own optical dialect. Accordingly, an attempt has been made here to provide precise definitions. Terms are italicized where defined or first used. Some needed nonstandard terms have been introduced, and these are likewise italicized, as well as indicated by ''NS'' for ''nonstandard.''

Notation

As with terminology, there is little standardization. And, as usual, the alphabet has too few letters to represent all the needed quantities. The choice here has been to use some of the same symbols more than once, rather than to encumber them with superscripts and subscripts. No symbol is used in a given section with more than one meaning. As a general practice nonprimed and primed quantities are used to indicate before and after, input and output, and object and image space.

References

No effort has been made to provide complete references, either technical or historical. (Such a list would fill the entire section.) The references were not chosen for priority, but for elucidation or interest, or because of their own references. Newer papers can be found by computer searches, so the older ones have been emphasized, especially since older work is receding from view beneath the current flood of papers. In geometric optics, nothing goes out of date, and much of what is included here has been known for a century or so—even if it has been subsequently forgotten.

Communication

Because of the confusion in terminology and notation, it is recommended that communication involving geometric optics be augmented with diagrams, graphs, equations, and numeric results, as appropriate. It also helps to provide diagrams showing both first order properties of systems, with object and image positions, pupil positions, and principal planes, as well as direction cosine space diagrams, as required, to show angular subtenses of pupils.

1.3 FUNDAMENTALS

What Is a Ray?

Geometric optics, which might better be called *ray optics,* is concerned with the light ray, an entity that does not exist. It is customary, therefore, to begin discussions of geometric optics with a theoretical justification for the use of the ray. The real justification is that, like other successful models in physics, rays are indispensable to our thinking, notwithstanding their shortcomings. The ray is a model that works well in some cases and not at all in others, and light is necessarily thought about in terms of rays, scalar waves, electromagnetic waves, and with quantum physics—depending on the class of phenomena under consideration.

Rays have been defined with both corpuscular and wave theory. In corpuscular theory, some definitions are (1) the path of a corpuscle and (2) the path of a photon. A difficulty here is that energy densities can become infinite. Other efforts have been made to define rays as quantities related to the wave theory, both scalar and electromagnetic. Some are (1) wavefront normals, (2) the Poynting vector, (3) a discontinuity in the electromagnetic field (Luneburg 1964,[1] Kline & Kay 1965[2]), (4) a descriptor of wave behavior in short wavelength or high frequency limit, (Born & Wolf 1980[3]) (5) quantum mechanically (Marcuse 1989[4]). One problem with these definitions is that there are many ordinary and simple cases where wavefronts and Poynting vectors become complicated and/or meaningless. For example, in the simple case of two coherent plane waves interfering, there is no well-defined wavefront in the overlap region. In addition, rays defined in what seems to be a reasonble way can have undesirable properties. For example, if rays are defined as normals to wavefronts, then, in the case of gaussian beams, rays bend in a vacuum.

An approach that avoids the difficulties of a physical definition is that of treating rays as mathematical entities. From definitions and postulates, a variety of results is found, which may be more or less useful and valid for light. Even with this approach, it is virtually impossible to think "purely geometrically"—unless rays are treated as objects of geometry, rather than optics. In fact, we often switch between ray thinking and wave thinking without noticing it, for instance in considering the dependence of refractive index on wavelength. Moreover, geometric optics makes use of quantities that must be calculated from other models, for example, the index of refraction. As usual, Rayleigh (Rayleigh 1884[5]) has put it well: "We shall, however, find it advisable not to exclude altogether the conceptions of the wave theory, for on certain most important and practical questions no conclusion can be drawn without the use of facts which are scarcely otherwise interpretable. Indeed it is not to be denied that the too rigid separation of optics into geometrical and physical has done a good deal of harm, much that is essential to a proper comprehension of the subject having fallen between the two stools."

The ray is inherently ill-defined, and attempts to refine a definition always break down. A definition that seems better in some ways is worse in others. Each definition provides some insight into the behavior of light, but does not give the full picture. There seems to be a problem associated with the uncertainty principle involved with attempts at definition, since what is really wanted from a ray is a specification of both position and direction, which is impossible by virtue of both classical wave properties and quantum behavior. So the approach taken here is to treat rays without precisely defining them, and there are few reminders hereafter that the predictions of ray optics are imperfect.

Refractive Index

For the purposes of this chapter, the optical characteristics of matter are completely specified by its refractive index. The *index of refraction* of a medium is defined in geometrical optics as

$$n = \frac{\text{speed of light in vacuum}}{\text{speed of light in medium}} = \frac{\mathrm{c}}{\mathrm{v}} \tag{1}$$

A *homogeneous medium* is one in which n is everywhere the same. In an *inhomogeneous* or *heterogeneous medium* the index varies with position. In an *isotropic medium n* is the same at each point for light traveling in all directions and with all polarizations, so the index is described by a scalar function of position. Anisotropic media are not treated here.

Care must be taken with equations using the symbol n, since it sometimes denotes the ratio of indices, sometimes with the implication that one of the two is unity. In many cases, the difference from unity of the index of air ($\simeq$1.0003) is important. Index varies with wavelength, but this dependence is not made explicit in this section, most of which is implicitly limited to monochromatic light. The output of a system in polychromatic light is the sum of outputs at the constituent wavelengths.

Systems Considered

The optical systems considered here are those in which spatial variations of surface features or refractive indices are large compared to the wavelength. In such systems ray identity is preserved; there is no "splitting" of one ray into many as occurs at a grating or scattering surface.

The term *lens* is used here to include a variety of systems. *Dioptric* or *refractive* systems employ only refraction. *Catoptric* or *reflective* systems employ only reflection. *Catadioptric* systems employ both refraction and reflection. No distinction is made here insofar as refraction and reflection can be treated in a common way. And the term lens may refer here to anything from a single surface to a system of arbitrary complexity.

Summary of the Behavior and Attributes of Rays

Rays propagate in straight lines in homogeneous media and have curved paths in heterogeneous media. Rays have positions, directions, and speeds. Between any pair of points on a given ray there is a geometrical path length and an optical path length. At smooth interfaces between media with different indices rays refract and reflect. Ray paths are reversible. Rays carry energy, and power per area is approximated by ray density.

Reversibility

Rays are reversible; a path can be taken in either direction, and reflection and refraction angles are the same in either direction. However, it is usually easier to think of light as traveling along rays in a particular direction, and, of course, in cases of real instruments there usually is such a direction. The solutions to some equations may have directional ambiguity.

Groups of Rays

Certain types of groups of rays are of particular importance. Rays that originate at a single point are called a *normal congruence* or *orthotomic system,* since as they propagate in isotropic media they are associated with perpendicular wavefronts. Such groups are also of interest in image formation, where their reconvergence to a point is important, as is the path length of the rays to a reference surface used for diffraction calculations. Important in radiometric considerations are groups of rays emanating from regions of a source over a range of angles. The changes of such groups as they propagate are constrained by conservation of brightness. Another group is that of two meridional paraxial rays, related by the two-ray invariant.

Invariance Properties

Individual rays and groups of rays may have *invariance properties*—relationships between the positions, directions, and path lengths—that remain constant as a ray or group of rays passes through an optical system (Welford 1986, chap. 6[6]). Some of these properties are completely general, e.g., the conservation of etendue and the perpendicularity of rays to wavefronts in isotropic media. Others arise from symmetries of the system, e.g., the skew invariant for rotationally symmetric systems. Other invariances hold in the paraxial limit. There are also differential invariance properties (Herzberger 1935,[7] Stavroudis 1972, chap. 13[8]). Some ray properties not ordinarily thought of in this way can be thought of as invariances. For example, Snell's law can be thought of as a refraction invariant $n \sin I$.

Description of Ray Paths

A *ray path* can be described parametrically as a locus of points $\mathbf{x}(\sigma)$, where σ is any monotonic parameter that labels points along the ray. The description of curved rays is elaborated in the section on heterogeneous media.

Real Rays and Virtual Rays

Since rays in homogeneous media are straight, they can be extrapolated infinitely from a given region. The term *real* refers to the portion of the ray that "really" exists, or the accessible part, and the term *virtual* refers to the extrapolated, or inaccessible, part.

Direction

At each position where the refractive index is continuous a ray has a unique direction. The direction is given by that of its unit *direction vector* **r**, whose cartesian components are direction cosines (α, β, γ), i.e.,

$$\mathbf{r} = (\alpha, \beta, \gamma)$$

where $|\mathbf{r}|^2 = \alpha^2 + \beta^2 + \gamma^2 = 1.$ (2)

The three direction cosines are not independent, and one is often taken to depend implicitly on the other two. In this chapter it is usually γ, which is

$$\gamma(\alpha, \beta) = \sqrt{1 - \alpha^2 - \beta^2} \tag{3}$$

Another vector with the same direction as **r** is

$$\mathbf{p} = n\mathbf{r} = (n\alpha, n\beta, n\gamma) = (p_x, p_y, p_z)$$

where $|\mathbf{p}|^2 = n^2$. (4)

Several names are used for this vector, including the *optical direction cosine* and the *ray vector.*

Geometric Path Length

Geometric path length is geometric distance measured along a ray between any two points. The differential unit of length is

$$ds = \sqrt{dx^2 + dy^2 + dz^2} \tag{5}$$

The path length between points $\mathbf{x}_1$ and $\mathbf{x}_2$ on a ray described parametrically by $\mathbf{x}(\sigma)$, with derivative $\dot{\mathbf{x}}(\sigma) = d\mathbf{x}(\sigma)/d\sigma$ is

$$s(\mathbf{x}_1; \mathbf{x}_2) = \int_{\mathbf{x}_1}^{\mathbf{x}_2} ds = \int_{\mathbf{x}_1}^{\mathbf{x}_2} \frac{ds}{d\sigma} d\sigma = \int_{\mathbf{x}_1}^{\mathbf{x}_2} \sqrt{|\dot{\mathbf{x}}(\sigma)|^2}\, d\sigma \tag{6}$$

Optical Path Length

The *optical path length* between two points $\mathbf{x}_1$ and $\mathbf{x}_2$ through which a ray passes is

$$\text{Optical path length} = V(\mathbf{x}_1; \mathbf{x}_2) = \int_{\mathbf{x}_1}^{\mathbf{x}_2} n(\mathbf{x})\, ds = \mathrm{c} \int \frac{ds}{\mathrm{v}} = \mathrm{c} \int d\mathrm{t} \tag{7}$$

The integral is taken along the ray path, which may traverse homogeneous and inhomogeneous media, and include any number of reflections and refractions. Path length can be defined for virtual rays. In some cases, path length should be considered positive definite, but in others it can be either positive or negative, depending on direction (Forbes & Stone 1993[9]). If $\mathbf{x}_0$, $\mathbf{x}_1$, and $\mathbf{x}_2$ are three points on the same ray, then

$$V(\mathbf{x}_0; \mathbf{x}_2) = V(\mathbf{x}_0; \mathbf{x}_1) + V(\mathbf{x}_1; \mathbf{x}_2) \tag{8}$$

Equivalently, the time required for light to travel between the two points is

$$\text{Time} = \frac{\text{optical path length}}{\mathrm{c}} = \frac{V}{\mathrm{c}} = \frac{1}{\mathrm{c}} \int_{\mathbf{x}_1}^{\mathbf{x}_2} n(\mathbf{x})\, ds = \int_{\mathbf{x}_1}^{\mathbf{x}_2} \frac{ds}{\mathrm{v}} \tag{9}$$

In homogeneous media, rays are straight lines, and the optical path length is $V = n \int ds =$ (index) × (distance between the points).

The optical path length integral has several interpretations, and much of geometrical optics involves the examination of its meanings. (1) With both points fixed, it is simply a scalar, the optical path length from one point to another. (2) With one point fixed, say $\mathbf{x}_0$, then treated as a function of $\mathbf{x}$, the surfaces $V(\mathbf{x}_0; \mathbf{x}) = \text{constant}$ are geometric wavefronts for light originating at $\mathbf{x}_0$. (3) Most generally, as a function of both arguments $V(\mathbf{x}_1; \mathbf{x}_2)$ is the *point characteristic function,* which contains all the information about the rays between the region containing $\mathbf{x}_1$ and that containing $\mathbf{x}_2$. There may not be a ray between all pairs of points.

Fermat's Principle

According to Fermat's principle (Magie 1963,[10] Fermat 1891,[11,12] Feynman 1963,[13] Rossi 1956,[14] Hecht 1987[15]) the optical path between two points through which a ray passes is an extremum. Light passing through these points along any other nearby path would take either more or less time. The principle applies to different *neighboring* paths. The optical path length of a ray may not be a global extremum. For example, the path lengths of rays through different facets of a Fresnel lens have no particular relationship. Fermat's principle applies to entire systems, as well as to any portion of a system, for example to any section of a ray. In a homogeneous medium, the extremum is a straight line or, if there are reflections, a series of straight line segments.

The extremum principle can be described mathematically as follows (Klein 1986[16]). With the end points fixed, if a nonphysical path differs from a physical one by an amount proportional to δ, the nonphysical optical path length differs from the actual one by a quantity proportional to δ^2 or to a higher order. If the order is three or higher, the first point is imaged at the second-to-first order. Roughly speaking, the higher the order, the better the image. A point is imaged stigmatically when a continuum of neighboring paths have the same length, so the equality holds to all orders. If they are sufficiently close, but vary slightly, the deviation from equality is a measure of the aberration of the imaging. An extension of Fermat's principle is given by Hopkins (H. Hopkins 1970[17]).

Ray and wave optics are related by the importance of path length in both (Walther 1967,[18] Walther 1969[19]). In wave optics, optical path length is proportional to phase change, and the extremum principle is associated with constructive interference. The more alike the path lengths are from an object point to its image, the less the differences in phase of the wave contributions, and the greater the magnitude of the net field. In imaging this connection is manifested in the relationship of the wavefront aberration and the eikonal.

Fermat's principle is a unifying principle of geometric optics that can be used to derive laws of reflection and refraction, and to find the equations that describe ray paths and geometric wavefronts in heterogeneous and homogeneous media. Fermat's is one of a number of variational principles based historically on the idea that nature is economical, a unifying principle of physics. The idea that the path length is an extremum could be used mathematically without interpreting the refractive index in terms of the speed of light.

Geometric Wavefronts

For rays originating at a single point, a *geometric wavefront* is a surface that is a locus of constant optical path length from the source. If the source point is located at $\mathbf{x}_0$ and light leaves at time t_0, then the wavefront at time t is given by

$$V(\mathbf{x}_0; \mathbf{x}) = \mathrm{c}(\mathrm{t} - \mathrm{t}_0) \tag{10}$$

The function $V(\mathbf{x}; \mathbf{x}_0)$, as a function of $\mathbf{x}$, satisfies the *eikonal equation*

$$\begin{aligned} n(\mathbf{x})^2 &= \left(\frac{\partial V}{\partial x}\right)^2 + \left(\frac{\partial V}{\partial y}\right)^2 + \left(\frac{\partial V}{\partial z}\right)^2 \\ &= |\nabla V(\mathbf{x}; \mathbf{x}_0)|^2 \end{aligned} \tag{11}$$

This equation can also be written in relativistic form, with a four-dimensional gradient as $0 = \sum (\partial V/\partial x_i)^2$ (Landau & Lifshitz 1951, sec. 7.1[20]).

For constant refractive index, the eikonal equation has some simple solutions, one of which is $V = n[\alpha(x - x_0) + \beta(y - y_0) + \gamma(z - z_0)]$, corresponding to a parallel bundle of rays with directions (α, β, γ). Another is $V = n[(x - x_0)^2 + (y - y_0)^2 + (z - z_0)^2]^{1/2}$, describing rays traveling radially from a point (x_0, y_0, z_0).

In isotropic media, rays and wavefronts are everywhere perpendicular, a condition referred to as *orthotomic.* According to the *Malus-Dupin principle*, if a group of rays emanating fron a single point is reflected and/or refracted any number of times, the perpendicularity of rays to wavefronts is maintained. The direction of a ray from $\mathbf{x}_0$ at $\mathbf{x}$ is that of the gradient of $V(\mathbf{x}_0; \mathbf{x})$

$$\mathbf{p} = n\mathbf{r} = \nabla V$$

or

$$n\alpha = \frac{\partial V}{\partial x} \qquad n\beta = \frac{\partial V}{\partial y} \qquad n\gamma = \frac{\partial V}{\partial z} \tag{12}$$

In a homogeneous medium, all wavefronts can be found from any one wavefront by a construction. Wavefront normals, i.e., rays, are projected from the known wavefront, and loci of points equidistant therefrom are other wavefronts. This gives wavefronts in both directions, that is, both subsequent and previous wavefronts. (A single wavefront contains no directional information.) The construction also gives virtual wavefronts, those which would occur or would have occurred if the medium extended infinitely. This construction is related to that of Huygens for wave optics. At each point on a wavefront there are two principal curvatures, so there are two foci along each ray and two caustic surfaces (Stavroudis 1972,[8] Kneisly 1964[21]).

The geometric wavefront is analogous to the surface of constant phase in wave optics, and the eikonal equation can be obtained from the wave equation in the limit of small wavelength (Born & Wolf 1980,[3] Marcuse 1989[4]). A way in which wave optics differs from ray optics is that the phase fronts can be modified by phase changes that occur on reflection, transmission, or in passing through foci.

Fields of Rays

In many cases the optical direction cosine vectors $\mathbf{p}$ form a field, where the optical path length is the potential, and the geometric wavefronts are equipotential surfaces. The potential changes with position according to

$$dV = n\alpha\, dx + n\beta\, dy + n\gamma\, dz = n\mathbf{r} \cdot d\mathbf{x} = \mathbf{p} \cdot d\mathbf{x} \tag{13}$$

If $d\mathbf{x}$ is in the direction of a ray, then $dV/dx = n$, the maximum rate of change. If $d\mathbf{x}$ is perpendicular to a ray, then $dV/dx = 0$. The potential difference between any two wavefronts is

$$V_2 - V_1 = \int_{\mathbf{x}_1}^{\mathbf{x}_2} dV \tag{14}$$

where $\mathbf{x}_1$ and $\mathbf{x}_2$ are any two points on the respective wavefronts, and the integrand is independent of the path. Other relationships for rays originating at a single point are

$$0 = \nabla \times \mathbf{p} = \nabla \times (n\mathbf{r}) \qquad \text{and} \qquad 0 = \oint \mathbf{p} \cdot d\mathbf{x} \tag{15}$$

where the integral is about a closed path (Born & Wolf 1980[3]). These follow since $\mathbf{p}$ is a gradient, Eq. (13). In regions where rays are folded onto themselves by refraction or reflections, **p** and V are not single-valued, so there is not a field.

1.4 CHARACTERISTIC FUNCTIONS

Introduction

Characteristic functions contain all the information about the path lengths between pairs of points, which may either be in a contiguous region or physically separated, e.g., on the two sides of a lens. These functions were first considered by Hamilton (Hamilton 1931[22]), so their study is referred to as *hamiltonian optics.* They were rediscovered in somewhat different form by Bruns (Bruns 1895,[23] Schwarzschild 1905[24]) and referred to as eikonals, leading to a confusing set of names for the various functions. The subject is discussed in a number of books (Czapski-Eppenstein 1924,[25] Steward 1928,[26] Herzberger 1931,[27] Synge 1937,[28] Caratheodory 1937,[29] Rayleigh 1908,[30] Pegis 1961,[31] Luneburg 1964,[32] Brouwer and Walther 1967,[33] Buchdahl 1970,[34] Born & Wolf 1980,[35] Herzberger 1958[36]).

Four parameters are required to specify a ray. For example, an input ray is defined in the $z = 0$ plane by coordinates (x, y) and direction (α, β). So four functions of four variables specify how an incident ray emerges from a system. In an output plane $z' = 0$, the ray has coordinates $x' = x'(x, y, \alpha, \beta)$, $y' = y'(x, y, \alpha, \beta)$, and directions $\alpha' = \alpha'(x, y, \alpha, \beta)$, $\beta' = \beta'(x, y, \alpha, \beta)$. Because of Fermat's principle, these four functions are not independent, and the geometrical optics properties of a system can be fully characterized by a single function (Luneburg 1964, sec. 19[32]).

For any given system, there is a variety of characteristic functions related by Legendre transformations, with different combinations of spatial and angular variables (Buchdahl 1970[34]). The different functions are suited for different types of analysis. *Mixed* characteristic functions have both spatial and angular arguments. Those functions that are of most general use are discussed below. The others may be useful in special circumstances. If the regions have constant refractive indices, the volumes over which the characteristic functions are defined can be extended virtually from physically accessible to inaccessible regions.

From any of its characteristic functions, all the properties of a system involving ray paths can be found, for example, ray positions, directions, and geometric wavefronts. An important use of characteristic functions is demonstrating general principles and fundamental limitations. Much of this can be done by using the general properties, e.g., symmetry under rotation. (Unfortunately, it is not always known how closely the impossible can be approached.)

Point Characteristic Function

The *point characteristic function* is the optical path integral $V(\mathbf{x}; \mathbf{x}') = V(x, y, z; x', y', z')$ taken as a function of both points **x** and **x**$'$. At point **x** where the index is n,

$$-n\alpha = \frac{\partial V}{\partial x} \qquad -n\beta = \frac{\partial V}{\partial y} \qquad -n\gamma = \frac{\partial V}{\partial z} \qquad \text{or} \qquad -\mathbf{p} = \nabla V \tag{16}$$

Similarly, at $\mathbf{x}'$, where the index is n',

$$n'\alpha' = \frac{\partial V}{\partial x'} \qquad n'\beta' = \frac{\partial V}{\partial y'} \qquad n'\gamma' = \frac{\partial V}{\partial z'} \qquad \text{or} \qquad \mathbf{p}' = \nabla' V \tag{17}$$

It follows from the above equations and Eq. (4) that the point characteristic satisfies two conditions:

$$n^2 = |\nabla V|^2 \qquad \text{and} \qquad n'^2 = |\nabla' V|^2 \tag{18}$$

Therefore, the point characteristic is not an arbitrary function of six variables. The total differential of V is

$$dV(\mathbf{x}; \mathbf{x}') = \mathbf{p}' \cdot \mathrm{d}\mathbf{x}' - \mathbf{p} \cdot d\mathbf{x} \tag{19}$$

"This expression can be said to contain all the basic laws of optics" (Herzberger 1958[36]).

Point Eikonal

If reference planes in object and image space are fixed, for which we use z_0 and z_0', then the *point eikonal* is $S(x, y; x', y') = V(x, y, z_0; x', y', z_0')$. This is the optical path length between pairs of points on the two planes. The function is not useful if the planes are conjugate, since more than one ray through a pair of points can have the same path length. The function is arbitrary, except for the requirement (Herzberger 1936[38]) that

$$\frac{\partial^2 S}{\partial x\, \partial x'} \frac{\partial^2 S}{\partial y\, \partial y'} - \frac{\partial^2 S}{\partial x\, \partial y'} \frac{\partial^2 S}{\partial x'\, \partial y} \neq 0 \tag{20}$$

The partial derivatives of the point eikonal are

$$-n\alpha = \frac{\partial S}{\partial x} \qquad -n\beta = \frac{\partial S}{\partial y} \qquad \text{and} \qquad n'\alpha' = \frac{\partial S}{\partial x'} \qquad n'\beta' = \frac{\partial S}{\partial y'} \tag{21}$$

The relative merits of the point characteristic function and point eikonal have been debated. (Herzberger 1936,[38] Herzberger 1937,[39] Synge 1937[40]).

Angle Characteristic

The *angle characteristic function* $T(\alpha, \beta; \alpha', \beta')$, also called the *eikonal*, is related to the point characteristic by

$$\begin{aligned} T(\alpha, \beta; \alpha', \beta') = V(x, y, z; x', y', z') + n(\alpha x + \beta y + \gamma z) \\ - n'(\alpha' x' + \beta' y' + \gamma' z') \end{aligned} \tag{22}$$

Here the input plane z and output plane z' are fixed and are implicit parameters of T.

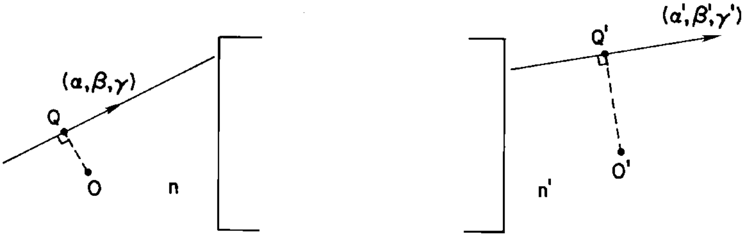

FIGURE 1 Geometrical interpretation of the angle characteristic function for constant object and image space indices. There is, in general, a single ray with directions (α, β, γ) in object space and $(\alpha', \beta', \gamma')$ in image space. Point O is the coordinate origin in object space, and O' is that in image space. From the origins, perpendiculars to the ray are constructed, which intersect the ray at Q and Q'. The angle characteristic function $T(\alpha, \beta; \alpha', \beta')$ is the path length from Q to Q'.

This equation is really shorthand for a Legendre transformation to coordinates $p_x = \partial V / \partial x$, etc. In principle, the expressions of Eq. (16) are used to solve for x and y in terms of α and β, and likewise Eq. (17) gives x' and y' in terms of α' and β', so

$$\begin{aligned} T(\alpha, \beta; \alpha', \beta') = {} & V(x(\alpha, \beta), y(\alpha, \beta), z; x'(\alpha', \beta'), y'(\alpha', \beta'), z') \\ & + n[\alpha x(\alpha, \beta) + \beta y(\alpha, \beta) + \sqrt{1 - \alpha^2 - \beta^2}\, z] \\ & - n'[\alpha' x'(\alpha', \beta') + \beta' y'(\alpha', \beta') + \sqrt{1 - \alpha'^2 - \beta'^2}\, z'] \end{aligned} \tag{23}$$

The angle characteristic is an arbitrary function of four variables that completely specify the directions of rays in two regions. This function is not useful if parallel incoming rays give rise to parallel outgoing rays, as is the case with afocal systems, since the relationship between incoming and outgoing directions is not unique. The partial derivatives of the angular characteristic function are

$$\frac{\partial T}{\partial \alpha} = n\left(x - \frac{\alpha}{\gamma} z\right) \qquad \frac{\partial T}{\partial \beta} = n\left(y - \frac{\beta}{\gamma} z\right) \tag{24}$$

$$\frac{\partial T}{\partial \alpha'} = -n'\left(x' - \frac{\alpha'}{\gamma'} z'\right) \qquad \frac{\partial T}{\partial \beta'} = -n'\left(y' - \frac{\beta'}{\gamma'} z'\right) \tag{25}$$

These expressions are simplified if the reference planes are taken to be $z = 0$ and $z' = 0$. The geometrical interpretation of T is that it is the path length between the intersection point of rays with perpendicular planes through the coordinate origins in the two spaces, as shown in Fig. 1 for the case of constant n and n'. If the indices are heterogeneous, the construction applies to the tangents to the rays. Of all the characteristic functions, T is most easily found for single surfaces and most easily concatenated for series of surfaces.

Point-Angle Characteristic

The *point-angle characteristic function* is a mixed function defined by

$$\begin{aligned} W(x, y, z; \alpha', \beta') &= V(x, y, z; x', y', z') - n'(\alpha' x' + \beta' y' + \gamma' z') \\ &= T(\alpha, \beta; \alpha', \beta') - n(\alpha x + \beta y + \gamma z) \end{aligned} \tag{26}$$

As with Eq. (22), this equation is to be understood as shorthand for a Legendre transformation. The partial derivatives with respect to the spatial variables are related by equations like those of Eq. (16), so $n^2 = |\nabla W|^2$, and the derivatives with respect to the angular variables are like those of Eq. (25). This function is useful for examining transverse ray aberrations for a given object point, since $\partial W/\partial\alpha'$, $\partial W/\partial\beta'$ give the intersection points (x', y') in plane z for rays originating at (x, y) in plane z.

Angle-Point Characteristic

The *angle-point characteristic function* is

$$\begin{aligned} W'(\alpha, \beta; x', y', z') &= V(x, y, z; x', y', z') + n(\alpha x + \beta y + \gamma z) \\ &= T(\alpha, \beta; \alpha', \beta') - n'(\alpha' x' + \beta' y' + \gamma' z) \end{aligned} \tag{27}$$

Again, this is shorthand for the Legendre transformation. This function satisfies relationships like those of Eq. (17) and satisfies $n'^2 = |\nabla' W'|^2$. Derivatives with respect to spatial variables are like those of Eq. (21). It is useful when input angles are given, and output angles are to be found.

Expansions About an Arbitrary Ray

If two points on a ray that are not conjugate are taken as coordinate origins, and the z axes of the coordinate systems are taken to lie along the rays, then the expansion to second order of the point eikonal about these points is

$$\begin{aligned} S(x_1, y_1; x_2, y_2) &= v + a_1 x_1^2 + b_1 x_1 y_1 + c_1 y_1^2 + a_2 x_2^2 + b_2 x_2 y_2 + c_2 y_2^2 \\ &\quad + d x_1 x_2 + e y_1 y_2 + f x_1 x_2 + g y_1 x_2 \end{aligned} \tag{28}$$

The other characteristic functions have similar expansions. These expansions have three types of terms, those associated with the input space, the output space, and "interspace" terms. From the coefficients, information about imaging along a known ray is obtained. This subject is treated in the references for the section "Images About Known Rays."

Expansions About the Axis

For rotationally symmetric systems, the building blocks for an expansion about the axis are

$$\text{Object space term:}\quad \mathscr{O} = x^2 + y^2 \qquad \text{or} \qquad \alpha^2 + \beta^2 \tag{29}$$

$$\text{Image space term:}\quad \mathscr{I} = x'^2 + y'^2 \qquad \text{or} \qquad \alpha'^2 + \beta'^2 \tag{30}$$

$$\begin{aligned} \text{Interspace term:}\quad \mathscr{B} = xx' + yy' \qquad \text{or} \qquad \alpha\alpha' + \beta\beta' \qquad \text{or} \qquad x\alpha' + y\beta' \\ \text{or} \qquad \alpha x' + \beta y' \end{aligned} \tag{31}$$

(Here $\mathscr{B}$ = "between.") The interspace term combines the variables included in $\mathscr{O}$ and $\mathscr{I}$. The general form can be written as a series

$$C(\mathscr{O}, \mathscr{B}, \mathscr{I}) = \sum_{L,M,N} a_{LMN} \mathscr{O}^L \mathscr{B}^M \mathscr{I}^N \tag{32}$$

To second order, the expansion is

$$\begin{aligned} C(\mathscr{O}, \mathscr{B}, \mathscr{I}) &= a_0 + a_{100}\mathscr{O} + a_{010}\mathscr{B} + a_{001}\mathscr{I} + a_{200}\mathscr{O}^2 + a_{020}\mathscr{B}^2 + a_{002}\mathscr{I}^2 \\ &\quad + a_{110}\mathscr{O}\mathscr{B} + a_{101}\mathscr{O}\mathscr{I} + a_{011}\mathscr{B}\mathscr{I} + \cdots \end{aligned} \tag{33}$$

The constant term is the optical path length between coordinate origins in the two spaces. It is often unimportant, but it does matter if two systems are used in parallel, as in an interferometer. The three first-order terms give the paraxial approximation. For imaging systems, the second-order terms are associated with third-order ray aberrations, and so on (Rayleigh 1908[30]). It is also possible to expand the characteristic functions in terms of three linear combinations of $\mathscr{O}$, $\mathscr{B}$, and $\mathscr{I}$. These combinations can be chosen so that the characteristic function of an aberration-free system depends on only one of the three terms, and the other two describe the aberrations (Steward 1928,[26] Smith 1945,[37] Pegis 1961[31]).

Paraxial Forms for Rotationally Symmetric Systems

These functions contain one each of the object space, image space, and interspace terms, with coefficients a_O, a_I, and a_B. The coefficients of the object and image space terms depend on the input and output plane locations. That of the interspace term depends on the system power. Point eikonal:

$$S(x', y'; x, y) = a + a_O(x^2 + y^2) + a_B(xx' + yy') + a_I(x'^2 + y'^2) \tag{34}$$

Angle characteristic:

$$T(\alpha', \beta'; \alpha, \beta) = a + a_O(\alpha^2 + \beta^2) + a_B(\alpha\alpha' + \beta\beta') + a_I(\alpha'^2 + \beta'^2) \tag{35}$$

Point-angle characteristic:

$$W(x, y; \alpha', \beta') = a + a_O(x^2 + y^2) + a_B(x\alpha' + y\beta') + a_I(\alpha'^2 + \beta'^2) \tag{36}$$

Angle-point characteristic:

$$W'(\alpha, \beta, x', y') = a + a_O(\alpha^2 + \beta^2) + a_B(\alpha x' + \beta y') + a_I(x'^2 + y'^2) \tag{37}$$

The coefficients in these expressions are different. The familiar properties of paraxial and gaussian optics can be found from these functions by taking the appropriate partial derivatives.

Some Ideal Characteristic Functions

For a system that satisfies certain conditions, the form of a characteristic function can sometimes be found. Thereafter, some of its properties can be determined. Some examples of characteristic functions follow, in each of which expression the function F is arbitrary.

For maxwellian perfect imaging (defined below) by a rotationally symmetric system between planes at $z = 0$ and $z' = 0$ related by transverse magnification m, the point characteristic function, defined for $z' \neq 0$, is

$$V(x', y', z'; x, y) = F(x^2 + y^2) + [(x' - mx)^2 + (y' - my)^2 + z'^2]^{1/2} \tag{38}$$

Expanding the expression above for small x, x', y, y' give the paraxial form, Eq. (34). The form of the point-angle characteristic is

$$W(x, y; \alpha', \beta') = F(x^2 + y^2) - m(n'\alpha' x + n'\beta' y) \tag{39}$$

The form of the angle-point characteristic is

$$W'(\alpha, \beta; x', y') = F(x'^2 + y'^2) + \frac{1}{m}(n\alpha x' + n\beta y') \tag{40}$$

The functions F are determined if the imaging is also stigmatic at one additional point, for example, at the center of the pupil (Steward 1928,[26] T. Smith 1945,[37] Buchdahl 1970,[34] Velzel 1991[41]). The angular characteristic function has the form

$$T(\alpha, \beta; \alpha', \beta') = F((n\alpha - mn'\alpha')^2 + (n\beta - mn'\beta')^2) \tag{41}$$

where F is any function.

For a lens of power ϕ that stigmatically images objects at infinity in a plane, and does so in either direction,

$$S(x, y; x', y') = -\phi(xx' + yy') \qquad \text{and} \qquad T(\alpha, \beta; \alpha', \beta') = \frac{nn'}{\phi}(\alpha\alpha' + \beta\beta') \tag{42}$$

Partially differentiating with respect to the appropriate variables shows that for such a system, the heights of point images in the rear focal plane are proportional to the sines of the incident angles, rather than the tangents.

1.5 RAYS IN HETEROGENEOUS MEDIA

Introduction

This section provides equations for describing and determining the curved ray paths in a heterogeneous or inhomogeneous medium, one whose refractive index varies with position. It is assumed here that $n(\mathbf{x})$ and the other relevant functions are continuous and have continuous derivatives to whatever order is needed. Various aspects of this subject are discussed in a number of books and papers (Heath 1895,[42] Herman 1900,[43] Synge 1937,[44] Luneburg 1964,[45] Stavroudis 1972,[46] Ghatak 1978,[47] Born & Wolf 1980,[48] Marcuse 1989[49]). This material is often discussed in the literature on gradient index lenses (Marchand 1973,[50] Marchand 1978,[51] Sharma, Kumar, & Ghatak 1982,[52] Moore 1992,[53] Moore 1994[54]) and in discussions of microwave lenses (Brown 1953,[55] Cornbleet 1976,[56] Cornbleet 1983,[57] Cornbleet 1984[58]).

Differential Geometry of Space Curves

A curved ray path is a space curve, which can be described by a standard parametric description, $\mathbf{x}(\sigma) = (x(\sigma), y(\sigma), z(\sigma))$, where σ is an arbitrary parameter (Blaschke 1945,[59] Kreyszig 1991,[60] Stoker 1969,[61] Struik 1990,[62] Stavroudis 1972[46]).

Different parameters may be used according to the situation. The path length s along the ray is sometimes used, as is the axial position z. Some equations change form according to the parameter, and those involving derivatives are simplest when the parameter is s. Derivatives with respect to the parameter are denoted by dots, so $\dot{\mathbf{x}}(\sigma) = d\mathbf{x}(\sigma)/d\sigma = (\dot{x}(\sigma), \dot{y}(\sigma), \dot{z}(\sigma))$. A parameter other than s is a function of s, so $d\mathbf{x}(\sigma)/ds = (d\mathbf{x}/d\sigma)(d\sigma/ds)$.

Associated with space curves are three mutually perpendicular unit vectors, the tangent vector **t**, the principal normal **n**, and the binormal **b**, as well as two scalars, the curvature and the torsion. The direction of a ray is that of its unit *tangent vector*

$$\mathbf{t} = \frac{\dot{\mathbf{x}}(\sigma)}{|\dot{\mathbf{x}}(\sigma)|} = \dot{\mathbf{x}}(s) = (\alpha, \beta, \gamma) \tag{43}$$

The tangent vector **t** is the same as the direction vector **r** used elsewhere in this chapter. The rate of change of the tangent vector with respect to path length is

$$\kappa\mathbf{n} = \dot{\mathbf{t}}(s) = \ddot{\mathbf{x}}(s) = \left(\frac{d\alpha}{dx}, \frac{d\beta}{ds}, \frac{d\gamma}{ds}\right) \tag{44}$$

The *normal vector* is the unit vector in this direction

$$\mathbf{n} = \frac{\ddot{\mathbf{x}}(s)}{|\ddot{\mathbf{x}}(s)|} \tag{45}$$

The vectors **t** and **n** define the *osculating plane.* The *curvature* $\kappa = |\ddot{\mathbf{x}}(s)|$ is the rate of change of direction of **t** in the osculating plane.

$$\kappa^2 = \frac{|\dot{\mathbf{x}}(\sigma) \times \ddot{\mathbf{x}}(\sigma)|^2}{|\dot{\mathbf{x}}(\sigma)|^6} = |\ddot{\mathbf{x}}(s)|^2 = \left(\frac{d\alpha}{ds}\right)^2 + \left(\frac{d\beta}{ds}\right)^2 + \left(\frac{d\gamma}{ds}\right)^2 \tag{46}$$

The radius of curvature is $\rho = 1/\kappa$. Perpendicular to the osculating plane is the unit *binormal vector*

$$\mathbf{b} = \mathbf{t} \times \mathbf{n} = \frac{\dot{\mathbf{x}}(s) \times \ddot{\mathbf{x}}(s)}{|\ddot{\mathbf{x}}(s)|} \tag{47}$$

The *torsion* is the rate of change of the normal to the osculating plane

$$\tau = \mathbf{b}(s) \cdot \frac{d\mathbf{n}(s)}{ds} = \frac{(\dot{\mathbf{x}}(\sigma) \times \ddot{\mathbf{x}}(\sigma)) \cdot \dddot{\mathbf{x}}(\sigma)}{|\dot{\mathbf{x}}(\sigma) \times \ddot{\mathbf{x}}(\sigma)|^2} = \frac{(\dot{\mathbf{x}}(s) \times \ddot{\mathbf{x}}(s)) \cdot \dddot{\mathbf{x}}(s)}{|\ddot{\mathbf{x}}(s)|^2} \tag{48}$$

The quantity $1/\tau$ is the *radius of torsion.* For a plane curve, $\tau = 0$ and **b** is constant. The rates of change of **t**, **n**, and **b** are given by the Frenet equations:

$$\dot{\mathbf{t}}(s) = \kappa\mathbf{n} \qquad \dot{\mathbf{n}}(s) = -\kappa\mathbf{t} + \tau\mathbf{b} \qquad \dot{\mathbf{b}}(s) = -\tau\mathbf{n} \tag{49}$$

In some books, $1/\kappa$ and $1/\tau$ are used for what are denoted here by κ and τ.

Differential Geometry Equations Specific to Rays

From the general space curve equations above and the differential equations below specific to rays, the following equations for rays are obtained. Note that n here is the refractive index, unrelated to **n**. The tangent and normal vectors are related by Eq. (59), which can be written

$$\nabla \log n = \kappa\mathbf{n} + (\nabla \log n \cdot \mathbf{t})\mathbf{t} \tag{50}$$

The osculating plane always contains the vector ∇n. Taking the dot product with **n** in the above equation gives

$$\kappa = \frac{\partial \log n}{\partial N} = \mathbf{n} \cdot \nabla \log n = \mathbf{b} \cdot (\dot{\mathbf{x}} \times \nabla \log n) \tag{51}$$

The partial derivative $\partial/\partial N$ is in the direction of the principal normal, so rays bend toward regions of higher refractive index. Other relations (Stavroudis 1972[46]) are

$$\mathbf{n} = \rho \dot{\mathbf{x}}(s) \times (\nabla \log n \times \dot{\mathbf{x}}(s)) \tag{52}$$

$$\mathbf{b} = \rho \dot{\mathbf{x}}(s) \times \nabla \log n \qquad \text{and} \qquad 0 = \mathbf{b} \cdot \nabla n \tag{53}$$

$$\tau = \frac{(\dot{\mathbf{x}}(s) \times \nabla n) \cdot \nabla \dot{n}}{|\nabla n \times \dot{\mathbf{x}}(s)|^2} \tag{54}$$

Variational Integral

Written in terms of parameter σ, the optical path length integral, Eq. (7) is

$$V = \int n\, ds = \int \left(n \frac{ds}{d\sigma} \right) d\sigma = \int \mathscr{L}\, d\sigma \tag{55}$$

The solution for ray paths involves the calculus of variations in a way analogous to that used in classical mechanics, where the time integral of the lagrangian $\mathscr{L}$ is an extremum (Goldstein 1980[63]). If $\mathscr{L}$ has no explicit dependence on σ, the mechanical analogue to the optics case is that of no explicit time dependence.

Differential Equations for Rays

General Differential Equations. Because the optical path length integral is an extremum, the integrand $\mathscr{L}$ satisfies the Euler equations (Stavroudis 1972[46]). For an arbitrary coordinate system, with coordinates q_1, q_2, q_3 and the derivatives with respect to the parameter $\dot{q}_i = dq_i/d\sigma$, the differential equations for the path are

$$0 = \frac{d}{d\sigma} \frac{\partial \mathscr{L}}{\partial \dot{q}_i} - \frac{\partial \mathscr{L}}{\partial q_i} = \frac{d}{d\sigma} \left(n \frac{\partial}{\partial \dot{q}_i} \frac{ds}{d\sigma} \right) - \frac{\partial}{\partial q_i} \left(n \frac{ds}{d\sigma} \right) \qquad i = 1, 2, 3 \tag{56}$$

Cartesian Coordinates with Unspecified Parameter. In cartesian coordinates $ds/d\sigma = (\dot{x}^2 + \dot{y}^2 + \dot{z}^2)^{1/2}$, so the x equation is

$$0 = \frac{d}{d\sigma} \left(n \frac{\partial}{\partial \dot{x}} \frac{ds}{d\sigma} \right) - \frac{ds}{d\sigma} \frac{\partial n}{\partial x} = \frac{d}{d\sigma} \left[\frac{n \dot{x}}{(\dot{x}^2 + \dot{y}^2 + \dot{z}^2)^{1/2}} \right] - (\dot{x}^2 + \dot{y}^2 + \dot{z}^2)^{1/2} \frac{\partial n}{\partial x} \tag{57}$$

Similar equations hold for y and z.

Cartesian Coordinates with Parameter $\sigma = s$. With $\sigma = s$, so $ds/d\sigma = 1$, an expression, sometimes called the *ray equation,* is obtained (Synge 1937[28]).

$$\nabla n = \frac{d}{ds} \left(n \frac{d\mathbf{x}(s)}{ds} \right) = n \frac{d^2 \mathbf{x}(s)}{ds^2} + \frac{dn(\mathbf{x}(s))}{ds} \frac{d\mathbf{x}(s)}{ds} \tag{58}$$

Using $dn/ds = \nabla n \cdot \dot{\mathbf{x}}$, the ray equation can also be written

$$\nabla n = n \ddot{\mathbf{x}} + (\nabla n \cdot \dot{\mathbf{x}}) \dot{\mathbf{x}} \qquad \text{or} \qquad \nabla \log n = \ddot{\mathbf{x}} + (\nabla \log n \cdot \dot{\mathbf{x}}) \dot{\mathbf{x}} \tag{59}$$

Only two of the component equations are independent, since $|\dot{\mathbf{x}}| = 1$.

Cartesian Coordinates with Parameter $\sigma = \int ds/n$. The parameter $\sigma = \int ds/n$, for which $ds/d\sigma = n$ and $n^2 = \dot{x}^2 + \dot{y}^2 + \dot{z}^2$, gives (Synge 1937[44])

$$\frac{d^2\mathbf{x}}{d\sigma^2} = \nabla(\tfrac{1}{2}n^2) \tag{60}$$

This equation is analogous to Newton's law of motion for a particle, $\mathbf{F} = m\, d^2\mathbf{x}/dt^2$, so the ray paths are like the paths of particles in a field with a potential proportional to $n^2(\mathbf{x})$. This analogy describes paths, but not speeds, since light travels slower where n is greater, whereas the particles would have greater speeds (Arnaud 1979,[64] Evans & Rosenquist 1986[65]).

Euler Equations for Parameter $\sigma = z$. If $\sigma = z$, then $ds/d\sigma = (\dot{x}^2 + \dot{y}^2 + 1)^{1/2}$ and $\mathscr{L} = \mathscr{L}(x, y; \dot{x}, \dot{y}; z)$. This gives (Luneburg 1964,[45] Marcuse 1989[49])

$$0 = \frac{d}{dz}\left(n \frac{\partial}{\partial \dot{x}} \frac{ds}{dz}\right) - \frac{ds}{dz}\frac{\partial n}{\partial x} = \frac{d}{dz}\left[\frac{n\dot{x}}{(1 + \dot{x}^2 + \dot{y}^2)^{1/2}}\right] - (1 + \dot{x}^2 + \dot{y}^2)^{1/2}\frac{\partial n}{\partial x} \tag{61}$$

with a similar equation for y. The equations can also be written (Moore 1975,[66] Marchand 1978, app. A[51]) as

$$n\ddot{x} = (1 + \dot{x}^2 + \dot{y}^2)\left(\frac{\partial n}{\partial x} - \frac{\partial n}{\partial z}\dot{x}\right) \qquad n\ddot{y} = (1 + \dot{x}^2 + \dot{y}^2)\left(\frac{\partial n}{\partial y} - \frac{\partial n}{\partial z}\dot{y}\right) \tag{62}$$

This parameter is particularly useful when n is rotationally symmetric about the z axis.

Hamilton's Equations with Cartesian Coordinates for Parameter $\sigma = z$. A set of Hamilton's equations can also be written in cartesian coordinates using z as the parameter. (Luneburg 1964,[45] Marcuse 1989[49]) The canonical momenta in cartesian coordinates are the optical direction cosines

$$p_x = \frac{\partial \mathscr{L}}{\partial \dot{x}} = n\alpha \qquad p_y = \frac{\partial \mathscr{L}}{\partial \dot{y}} = n\beta \tag{63}$$

The hamiltonian is

$$\mathscr{H}(x, y, ; p_x, p_y; z) = \dot{x}p_x + \dot{y}p_y - \mathscr{L} = -\sqrt{n^2(x, y, z) - (p_x^2 + p_y^2)} \tag{64}$$

Hamilton's equations are

$$\frac{dx}{dz} = \frac{\partial \mathscr{H}}{\partial p_x} \qquad \frac{dy}{dz} = \frac{\partial \mathscr{H}}{\partial p_y} \qquad \frac{dp_x}{dz} = -\frac{\partial \mathscr{H}}{\partial x} \qquad \frac{dp_y}{dz} = -\frac{\partial \mathscr{H}}{\partial y} \tag{65}$$

It is not possible to write a set of Hamilton's equations using an arbitrary parameter and three canonical momenta, since they are not independent (Forbes 1991[67]). Another equation is

$$\frac{\partial \mathscr{H}}{\partial z} = \frac{d\mathscr{H}}{dz} = \frac{1}{\gamma}\frac{\partial n}{\partial z} \tag{66}$$

Paraxial Form of Hamilton's Equations for $\sigma = z$. In the paraxial limit, if n_0 is the average index, the above set of equations gives (Marcuse 1989[49])

$$\frac{d^2x(z)}{dz^2} = \frac{1}{n_0}\frac{\partial n}{\partial x} \qquad \frac{d^2y(z)}{dz^2} = \frac{1}{n_0}\frac{\partial n}{\partial y} \tag{67}$$

Other Forms. A variety of additional differential equations can be obtained with various parameters (Forbes 1991[67]). Time cannot be used as a parameter (Landau & Lifshitz 1951[68]). The equations can also be expressed in a variety of coordinate systems (Buchdahl 1973,[69] Cornbleet 1976,[56] Cornbleet 1978,[70] Cornbleet 1979,[71] Cornbleet 1984[58]).

Refractive Index Symmetries

When the refractive index has symmetry or does not vary with one or more of the spatial variables, the above equations may simplify and take special forms. If, in some coordinate system, n does not vary with a coordinate q_i, so $\partial n / \partial q_i = 0$, and if, in addition, $\partial / \partial q_i (ds / d\sigma) = 0$, then

$$\frac{\partial \mathscr{L}}{\partial q_i} = 0 \qquad \text{and} \qquad \frac{\partial \mathscr{L}}{\partial \dot{q}} = n \frac{\partial}{\partial \dot{q}} \left(\frac{ds}{d\sigma} \right) = \text{constant} \tag{68}$$

There is an associated invariance of the ray path (Synge 1937,[44] Cornbleet 1976,[56] 1984,[58] Marcuse 1989[49]). (This is analogous to the case in mechanics where a potential does not vary with some coordinate.) A more esoteric approach to symmetries involves Noether's theorem (Blaker 1974,[72] Joyce 1975[73]). There are a number of special cases.

If the index is rotationally symmetric about the z axis, $n = n(x^2 + y^2, z)$, then $\partial \mathscr{L} / \partial \phi = 0$, where ϕ is the azimuth angle, and the constant of motion is analogous to that of the z component of angular momentum in mechanics for a potential with rotational symmetry. The constant quantity is the *skew invariant*, discussed elsewhere.

If the refractive index is a function of radius, $n = n(r)$, there are two constants of motion. The ray paths lie in planes through the center ($r = 0$) and have constant angular motion about an axis through the center that is perpendicular to this plane, so $\mathbf{x} \times \mathbf{p}$ is constant. If the plane is in the x-y plane, then $n(\alpha y - \beta x)$ is constant. This is analogous to motion of a particle in a central force field. Two of the best-known examples are the Maxwell fisheye (Maxwell 1854,[74] Born & Wolf 1980[48]) for which $n(r) \propto (1 + r^2)^{-1}$, and the Luneburg lens (Luneburg 1964,[45] Morgan 1958[75]), for which $n(r) = \sqrt{2 - r^2}$ for $r \leq 1$ and $n = 1$ for $r > 1$.

If n does not vary with z, then $\mathscr{H} = n\gamma$ is constant for a ray as a function of z, according to Eq. (66).

If the medium is layered, so the index varies in only the z direction, then $n\alpha$ and $n\beta$ are constant. If θ is the angle relative to the z axis, then $n(z) \sin \theta(z)$ is constant, giving Snell's law as a special case.

The homogeneous medium, where $\partial n / \partial x = \partial n / \partial y = \partial n / \partial z = 0$, is a special case in which there are three constants of motion, $n\alpha$, $n\beta$, and $n\gamma$, so rays travel in straight lines.

1.6 CONSERVATION OF ÉTENDUE

If a bundle of rays intersects a constant z plane in a small region of size $dx\, dy$ and has a small range of angles $d\alpha\, d\beta$, then as the light propagates through a lossless system, the following quantity remains constant:

$$n^2\, dx\, dy\, d\alpha\, d\beta = n^2\, dA\, d\alpha\, d\beta = n^2\, dA \cos\theta\, d\omega = dx\, dy\, dp_x\, dp_y \tag{69}$$

Here $dA = dx\,dy$ is the differential area, $d\omega$ is the solid angle, and θ is measured relative to the normal to the plane. The integral of this quantity

$$\int n^2\,dx\,dy\,d\alpha\,d\beta = \int n^2\,dA\,d\alpha\,d\beta = \int n^2\,dA\cos\theta\,d\omega = \int dx\,dy\,dp_x\,dp_y \tag{70}$$

is the *étendue,* and is also conserved. For lambertian radiation of radiance L_e, the total power transferred is $P = \int L_e n^2\,d\alpha\,d\beta\,dx\,dy$. The étendue and related quantities are known by a variety of names (Steel 1974[76]), including *generalized Lagrange invariant, luminosity, light-gathering power, light grasp, throughput, acceptance, optical extent,* and *area-solid-angle-product.* The angle term is not actually a solid angle, but is weighted. It does approach a solid angle in the limit of small extent. In addition, the integrations can be over area, giving $n^2\,d\alpha\,d\beta \int dA$, or over angle, giving $n^2\,dA \int d\alpha\,d\beta$. A related quantity is the geometrical vector flux (Winston 1979[77]), with components $(\int dp_y\,dp_z, \int dp_x\,dp_z, \int dp_x\,dp_y)$. In some cases these quantities include a brightness factor, and in others they are purely geometrical. The étendue is related to the information capacity of a system (Gabor 1961[78]).

As special case, if the initial and final planes are conjugate with transverse magnification $m = dx'/dx = dy'/dy$, then

$$n^2\,d\alpha\,d\beta = n'^2 m^2\,d\alpha'\,d\beta' \tag{71}$$

Consequently, the angular extents of the entrance and exit pupil in direction cosine coordinates are related by

$$n^2 \int_{\text{entrance pupil}} d\alpha\,d\beta = n'^2 m^2 \int_{\text{exit pupil}} d\alpha'\,d\beta' \tag{72}$$

See also the discussion of image irradiance in the section on apertures and pupils.

This conservation law is general; it does not depend on index homogeneity or on axial symmetry. It can be proven in a variety of ways, one of which is with characteristic functions (Welford & Winston 1978,[79] Welford 1986,[80] Welford & Winston 1989[81]). Phase space arguments involving Liouville's theorem can also be applied (di Francia 1950,[82] Winston 1970,[83] Jannson & Winston 1986,[84] Marcuse 1989[85]). Another type of proof involves thermodynamics, using conservation of radiance (or brightness) or the principal of detailed balance (Clausius 1864,[86] Clausius 1879,[87] Helmholtz 1874,[88] Liebes 1969[89]). Conversely, the thermodynamic principle can be proven from the geometric optics one (Nicodemus 1963,[90] Boyd 1983,[91] Klein 1986[92]). In the paraxial limit for systems of revolution the conservation of etendue between object and image planes is related to the two-ray paraxial invariant, Eq. (152). Some historical aspects are discussed by Rayleigh (Rayleigh 1886[93]) and Southall (Southall 1910[94]).

1.7 SKEW INVARIANT

In a rotationally symmetric system, whose indices may be constant or varying, a *skew ray* is one that does not lie in a plane containing the axis. The *skewness* of such a ray is

$$\mathcal{S} = n(\alpha y - \beta x) = n\alpha y - n\beta x = p_x y - p_y x \tag{73}$$

As a skew ray propagates through the system, this quantity, known as the *skew invariant,* does not change (T. Smith 1921,[95] H. Hopkins 1947,[96] Marshall 1952,[97] Buchdahl 1954, sec. 4,[98] M. Herzberger 1958,[99] Welford 1968,[100] Stavroudis 1972, p. 208,[101] Welford 1974, sec. 5.4,[102] Welford 1986, sec. 6.4[103] Welford & Winston 1989, p. 228[104]). For a meridional ray, one lying in a plane containing the axis, $\mathscr{S} = 0$. The skewness can be written in vector form as

$$\mathscr{S} = \mathbf{a} \cdot (\mathbf{x} \times \mathbf{p}) \tag{74}$$

where $\mathbf{a}$ is a unit vector along the axis, $\mathbf{x}$ is the position on a ray, and $\mathbf{p}$ is the optical cosine and vector at that position.

This invariance is analogous to the conservation of the axial component of angular momentum in a cylindrical force field, and it can be proven in several ways. One is by performing the rotation operations on α, β, x, and y (as discussed in the section on heterogeneous media). Another is by means of characteristic functions. It can also be demonstrated that $\mathscr{S}$ is not changed by refraction or reflection by surfaces with radial gradients. The invariance holds also for diffractive optics that are figures of rotation.

A special case of the invariant relates the intersection points of a skew ray with a given meridian. If a ray with directions (α, β) in a space of index n intersects the $x = 0$ meridian with height y, then at another intersection with this meridian in a space with index n', its height y' and direction cosine α' are related by

$$n\alpha y = n'\alpha' y' \tag{75}$$

The points where rays intersect the same meridian are known as *diapoints* and the ratio y'/y as the *diamagnification* (Herzberger 1958[99]).

1.8 REFRACTION AND REFLECTION AT INTERFACES BETWEEN HOMOGENEOUS MEDIA

Introduction

The initial ray direction is specified by the unit vector $\mathbf{r} = (\alpha, \beta, \gamma)$. After refraction or reflection the direction is $\mathbf{r}' = (\alpha', \beta', \gamma')$. At the point where the ray intersects the surface, its normal has direction $\mathbf{S} = (L, M, N)$.

The *angle of incidence* I is the angle between a ray and the surface normal at the intersection point. This angle and the corresponding outgoing angle I' are given by

$$\begin{aligned} |\cos I| &= |\mathbf{r} \cdot \mathbf{S}| = |\alpha L + \beta M + \gamma N| \\ |\cos I'| &= |\mathbf{r}' \cdot \mathbf{S}| = |\alpha' L + \beta' M + \gamma' N| \end{aligned} \tag{76}$$

In addition

$$|\sin I| = |\mathbf{r} \times \mathbf{S}| \qquad |\sin I'| = |\mathbf{r}' \times \mathbf{S}| \tag{77}$$

The signs of these expressions depend on which way the surface normal vector is directed. The surface normal and the ray direction define the *plane of incidence*, which is perpendicular to the vector cross product $\mathbf{S} \times \mathbf{r} = (M\gamma - N\beta, N\alpha - L\gamma, L\beta - M\alpha)$. After refraction or reflection, the outgoing ray is in the same plane. This symmetry is related to the fact that optical path length is an extremum.

The laws of reflection and refraction can be derived from Fermat's principle, as is done in many books. At a planar interface, the reflection and refraction directions are derived from Maxwell's equations using the boundary conditions. For scalar waves at a plane interface, the directions are related to the fact that the number of oscillation cycles is the same for incident and outgoing waves.

Refraction

At an interface between two homogeneous and isotropic media, described by indices n and n', the incidence angle I and the outgoing angle I' are related by *Snell's law* (Magie 1963[105]):

$$n' \sin I' = n \sin I \tag{78}$$

If $\sin I' > 1$, there is total internal reflection. Another relationship is

$$n' \cos I' = \sqrt{n'^2 - n^2 \sin^2 I} = \sqrt{n'^2 - n^2 - n^2 \cos^2 I} \tag{79}$$

Snell's law can be expressed in a number of ways, one of which is

$$n[\mathbf{r} + (\mathbf{r} \cdot \mathbf{S})\mathbf{S}] = n'[\mathbf{r}' + (\mathbf{r}' \cdot \mathbf{S})\mathbf{S}] \tag{80}$$

Taking the cross product of both sides with **S** gives another form

$$n'(\mathbf{S} \times \mathbf{r}') = n(\mathbf{S} \times \mathbf{r}) \tag{81}$$

A quantity that appears frequently in geometrical optics (but which has no common name or symbol) is

$$\Gamma = n' \cos I' - n \cos I \tag{82}$$

It can be written several ways

$$\Gamma = (n\mathbf{r} - n'\mathbf{r}') \cdot \mathbf{S} = -n \cos I + \sqrt{n'^2 - n^2 \sin^2 I} = -n \cos I + \sqrt{n'^2 - n^2 + n^2 \cos^2 I} \tag{83}$$

In terms of Γ, Snell's law is

$$n'\mathbf{r}' = n\mathbf{r} + \Gamma\mathbf{S} \tag{84}$$

or

$$n'\alpha' = n\alpha + L\Gamma \qquad n'\beta' = n\beta + M\Gamma \qquad n'\gamma' = n\gamma + N\Gamma \tag{85}$$

The outgoing direction is expressed explicitly as a function of incident direction by

$$n'\mathbf{r}' = n\mathbf{r} + \mathbf{S}[n\mathbf{r} \cdot \mathbf{S} - \sqrt{n'^2 - n^2 + (n\mathbf{r} \cdot \mathbf{S})^2}] \tag{86}$$

If the surface normal is in the z direction, the equations simplify to

$$n'\alpha' = n\alpha \qquad n'\beta' = n\beta \qquad n'\gamma' = \sqrt{n'^2 - n^2 + n^2\gamma^2} \tag{87}$$

If $\beta = 0$, this reduces to $n'\alpha' = n\alpha$, the familiar form of Snell's law, written with direction cosines, with $n'\gamma' = (n'^2 - n^2\alpha^2)^{1/2}$, corresponding to Eq. (79). Another relation is

$$\frac{n'\alpha' - n\alpha}{L} = \frac{n'\beta' - n\beta}{M} = \frac{n'\gamma' - n\gamma}{N} = \Gamma \tag{88}$$

All of the above expressions can be formally simplified by using $\mathbf{p} = n\mathbf{r}$ and $\mathbf{p}' = n'\mathbf{r}'$. For a succession of refractions by parallel surfaces,

$$n_1 \sin I_1 = n_2 \sin I_2 = n_3 \sin I_3 = \cdots \tag{89}$$

so the angles within any two media are related by their indices alone, regardless of the intervening layers. Refractive indices vary with wavelength, so the angles of refraction do likewise.

Reflection

The reflection equations can be derived from those for refraction by setting the index of the final medium equal to the negative of that of the incident medium, i.e., $n' = -n$, which gives $\Gamma = -2n \cos I$. The angles of incidence and reflection are equal

$$I' = I \tag{90}$$

The incident and reflected ray directions are related by

$$\mathbf{S} \times \mathbf{r}' = -\mathbf{S} \times \mathbf{r} \tag{91}$$

Another expression is

$$\mathbf{r}' = \mathbf{r} - (2\mathbf{S} \cdot \mathbf{r})\mathbf{S} = \mathbf{r} - (2 \cos I)\mathbf{S} \tag{92}$$

The components are

$$\alpha' = \alpha - 2L \cos I \qquad \beta' = \beta - 2M \cos I \qquad \gamma' = \gamma - 2N \cos I \tag{93}$$

This relationship can be written in terms of dyadics (Silberstein 1918[106]) as $\mathbf{r}' = (\mathbf{I} - \mathbf{SS}) \cdot \mathbf{r}$. This is equivalent to the matrix form (T. Smith 1928,[107] Luneburg 1964,[108] R. E. Hopkins 1965,[109] Levi 1968,[110] Tongshu 1991[111])

$$\begin{pmatrix} \alpha' \\ \beta' \\ \gamma' \end{pmatrix} = \begin{pmatrix} 1-2L^2 & -2LM & -2LN \\ -2LM & 1-2M^2 & -2MN \\ -2LN & -2MN & 1-2N^2 \end{pmatrix} \begin{pmatrix} \alpha \\ \beta \\ \gamma \end{pmatrix} \tag{94}$$

Each column of this matrix is a set of direction cosines and is orthogonal to the others, and likewise for the rows. The matrix associated with a sequence of reflections from plane surfaces is calculated by multiplying the matrices for each reflection. Another relationship is

$$\frac{\alpha' - \alpha}{L} = \frac{\beta' - \beta}{M} = \frac{\gamma' - \gamma}{N} \tag{95}$$

If the surface normal is in the z direction, so $(L, M, N) = (0, 0, 1)$, then

$$\alpha' = \alpha \qquad \beta' = \beta \qquad \gamma' = -\gamma \tag{96}$$

Reflection by a Plane Mirror—Positions of Image Points

If light from a point (x, y, z) is reflected by a plane mirror whose distance from the coordinate origin is d, and whose surface normal has direction (L, M, N), the image point coordinates (x', y', z') are given by

$$\begin{pmatrix} x' \\ y' \\ z' \\ 1 \end{pmatrix} = \begin{pmatrix} 1-2L^2 & -2LM & -2LN & 2dL \\ -2LM & 1-2M^2 & -2MN & 2dM \\ -2LN & -2MN & 1-2N^2 & 2dN \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} \tag{97}$$

This transformation involves both rotation and translation, with only the former effect applying if $d = 0$. It is an affine type of collinear transformation, discussed in the section on collineation. The effect of a series of reflections by plane mirrors is found by a product of such matrices. The transformation can also be formulated in terms of quaternions (Wagner 1951,[112] Levi 1968, p. 367[110]).

Diffractive Elements

The changes in directions produced by gratings or diffractive elements can be handled in an ad hoc geometrical way (Spencer & Murty 1962,[113] di Francia 1950[114])

$$n'\mathbf{r}'_G \times \mathbf{S} = n\mathbf{r} \times \mathbf{S} + G\frac{\lambda}{\mathrm{p}}\mathbf{q} \tag{98}$$

Here λ is the vacuum wavelength, p is the grating period, **q** is a unit vector tangent to the surface and parallel to the rulings, and G is the diffraction order. Equations (81) and (91) are special cases of this equation for the 0th order.

1.9 IMAGING

Introduction

Image formation is the principal use of lenses. Moreover, lenses form images even if this is not their intended purpose. This section provides definitions, and discusses basic concepts and limitations. The purposes of the geometric analysis of imaging include the following: (1) discovering the nominal relationship between an object and its image, principally the size, shape, and location of the image, which is usually done with paraxial optics; (2) determining the deviations from the nominal image, i.e., the aberrations; (3) estimating image irradiance; (4) understanding fundamental limitations—what is inherently possible and impossible; (5) supplying information for diffraction calculations, usually optical path lengths.

Images and Types of Images

A definition of image (Webster 1934[115]) is: “The optical counterpart of an object produced by a lens, mirror, or other optical system. It is a geometrical system made up of foci corresponding to the parts of the object.” The point-by-point correspondence is the key, since a given object can have a variety of different images.

Image irradiance can be found only approximately from geometric optics, the degree of accuracy of the predictions varying from case to case. In many instances wave optics is required, and for objects that are not self-luminous, an analysis involving partial coherence is also needed.

The term *image* is used in a variety of ways, so clarification is useful. The light from an object produces a three-dimensional distribution in image space. The *aerial image* is the distribution on a mathematical surface, often that of best focus, the locus of points of the images of object points. An aerial image is never the final goal; ultimately, the light is to be captured. The *receiving surface* (NS) is that on which the light falls, the distribution of which there can be called the *received image* (NS). This distinction is important in considerations of defocus, which is a relationship, not an absolute. The record thereby produced is the *recorded image* (NS). The recorded image varies with the position of the receiving surface, which is usually intended to correspond with the aerial image surface. In this section, “image” means aerial image, unless otherwise stated.

Object Space and Image Space

The object is said to exist in *object space*; the image, in *image space.* Each space is infinite, with a physically accessible region called *real,* and an inaccessible region, referred to as *virtual.* The two spaces may overlap physically, as with reflective systems. Corresponding quantities and locations associated with the object and image spaces are typically denoted by the same symbol, with a prime indicating image space. Positions are specified by a coordinate system (x, y, z) in object space and (x', y', z') in image space. The refractive indices of the object and image spaces are n and n'.

Image of a Point

An *object point* is thought of as emitting rays in all directions, some of which are captured by the lens, whose internal action converges the rays, more or less, to an *image point,* the term "point" being used even if the ray convergence is imperfect. Object and image points are said to be *conjugate.* Since geometric optics is reversible, if A' is the image of A, then A is the image of A'.

Mapping Object Space to Image Space

If every point were imaged stigmatically, then the entire object space would be mapped into the image space according to a transformation

$$x' = x'(x, y, z) \qquad y' = y'(x, y, z) \qquad z' = z'(x, y, z) \tag{99}$$

The mapping is reciprocal, so the equations can be inverted. If n and n' are constant, then the mapping is a collinear transformation, discussed below.

Images of Extended Objects

An *extended object* can be thought of as a collection of points, a subset of the entire space, and its stigmatic image is the set of conjugate image points. A surface described by $0 = F(x, y, z)$ has an image surface

$$0 = F'(x', y', z') = F(x(x', y', z'), y(x', y', z'), z(x', y', z')) \tag{100}$$

A curve described parametrically by $\mathbf{x}(\sigma) = (x(\sigma), y(\sigma), z(\sigma))$ has an image curve

$$\mathbf{x}'(\sigma) = (x'(x(\sigma), y(\sigma), z(\sigma)), y'(x(\sigma), y(\sigma), z(\sigma)), z'(x(\sigma), y(\sigma), z(\sigma))) \tag{101}$$

Rotationally Symmetric Lenses

Rotationally symmetric lenses have an *axis,* which is a ray path (unless there is an obstruction). All planes through the axis, the *meridians* or *meridional planes,* are planes with respect to which there is bilateral symmetry. An *axial object point* is conjugate to an *axial image point.* An axial image point is located with a single ray in addition to the axial one. Off-axis object and image points are in the same meridian, and may be on the same or opposite sides of the axis. The *object height* is the distance of a point from the axis, and the *image height* is that for its image. It is possible to have rotational symmetry without bilateral symmetry, as in a system made of crystalline quartz (Buchdahl 1970[116]), but such systems are not discussed here. For stigmatic imaging by a lens rotationally symmetric about the z axis, Eq. (99) gives

$$x' = x'(x, z) \qquad y' = y'(y, z) \qquad z' = z'(z) \tag{102}$$

Planes Perpendicular to the Axis

The arrangement most often of interest is that of planar object and receiving surfaces, both perpendicular to the lens axis. When the terms *object plane* and *image plane* are used here without further elaboration, this is the meaning. (This arrangement is more common for manufactured systems with flat detectors, than for natural systems, for instance, eyes, with their curved retinas.)

Magnifications

The term *magnification* is used in a general way to denote the ratio of conjugate object and image dimensions, for example, heights, distances, areas, volumes, and angles. A single number is inadequate when object and image shapes are not geometrically similar. The term magnification implies an increase, but this is not the case in general.

Transverse Magnification

With object and image planes perpendicular to the axis, the relative scale factor of length is the *transverse magnification* or *lateral magnification,* denoted by m, and usually referred to simply as "the magnification." The transverse magnification is the ratio of image height to object height, $m = h'/h$. It can also be written in differential form, e.g., $m = dx'/dx$ or $m = \Delta x'/\Delta x$. The transverse magnification is signed, and it can have any value from $-\infty$ to $+\infty$. Areas in such planes are scaled by m^2. A lens may contain plane mirrors that affect the image parity or it may be accompanied by external plane mirrors that reorient images and change their parity, but these changes are independent of the magnification at which the lens works.

Longitudinal Magnification

Along the rotational axis, the *longitudinal magnification,* m_L, also called *axial magnification,* is the ratio of image length to object length in the limit of small lengths, i.e., $m_L = dz'/dz$.

Visual Magnification

With visual instruments, the perceived size of the image depends on its angular subtense. *Visual magnification* is the ratio of the angular subtense of an image relative to that of the object viewed directly. Other terms are used for this quantity, including "magnification," "power," and "magnifying power." For objects whose positions can be controlled, there is arbitrariness in the subtense without the instrument, which is greatest when the object is located at the near-point of the observer. This distance varies from person to person, but for purposes of standardization the distance is taken to be 250 mm. For instruments that view distant objects there is no arbitrariness of subtense with direct viewing.

Ideal Imaging and Disappointments in Imaging

Terms such as *perfect imaging* and *ideal imaging* are used in various ways. The ideal varies with the circumstances, and there are applications in which imaging is not the purpose, for instance, energy collection and Fourier transformation. The term *desired imaging* might be more appropriate in cases where that which is desired is fundamentally impossible. Some deviations from what is desired are called *aberrations,* whether their avoidance is possible or not. Any ideal that can be approximated must agree in its paraxial limit ideal with what a lens actually does in its paraxial limit.

Maxwellian Ideal for Single-Plane Imaging

The most common meaning of perfect imaging is that elucidated by Maxwell (Maxwell 1858[117]), and referred to here as *maxwellian ideal* or *maxwellian perfection.* This ideal is fundamentally possible. The three conditions for such imaging of points in a plane perpendicular to the lens axis are: (1) Each point is imaged stigmatically. (2) The images of all the points in a plane lie on a plane that is likewise perpendicular to the axis, so the field is flat, or free from field curvature. (3) The ratio of image heights to object heights is the same for all points in the plane. That is, transverse magnification is constant, or there is no distortion.

The Volume Imaging Ideal

A more demanding ideal is that points everywhere in regions of constant index be imaged stigmatically and that the imaging of every plane be flat and free from distortion. For planes perpendicular to the lens axis, such imaging is described mathematically by the collinear transformation, discussed below. It is inherently impossible for a lens to function in this way, but the mathematical apparatus of collineation is useful in obtaining approximate results.

Paraxial, First-Order, and Gaussian Optics

The terms ''paraxial,'' ''first order,'' and ''gaussian'' are often used interchangeably, and their consideration is merged with that of collineation. The distinction is often not made, probably because these descriptions agree in result, although differing in approach. One of the few discussions is that of Southall (Southall 1910[118]). A *paraxial* analysis has to do with the limiting case in which the distances of rays from the axis approach zero, as do the angles of the rays relative to the axis. The term *first order* refers to the associated mathematical approximation in which the positions and directions of such rays are computed with terms to the first order only in height and angle. *Gaussian* refers to certain results of the paraxial optics, where lenses are black boxes whose properties are summarized by the existence and locations of cardinal points. In the limit of small heights and angles, the equations of collineation are identical to those of paraxial optics. Each of these is discussed in greater detail below.

Fundamental Limitations

There are fundamental geometrical limitations on optical systems, relating to the fact that a given ray passes through many points and a given point lies on many rays. So the images of points on the same line or plane, or on different planes, are not independent. A set of rays intersecting at several points in object space cannot be made to satisfy arbitrary requirements in image space. Such limitations are best studied by the methods of hamiltonian optics.

Stigmatic Imaging

If all rays from an object point converge precisely to an image point, the imaging of this point is said to be *stigmatic*. The optical path lengths of all rays between two such points is identical. A stigmatic image point is located by the intersection of any two rays that pass through the points. An *absolute instrument* is one which images all points stigmatically (Born & Wolf 1980[119]). For such imaging

$$n\,\delta x = n'\,\delta x' \qquad n\,\delta y = n'\,\delta y' \qquad n\,\delta z = n'\,\delta z' \tag{103}$$

where conjugate length elements are δx and $\delta x'$, δy and $\delta y'$, δz and $\delta z'$.

Path Lengths and Conjugate Points

All the rays from an object point to its stigmatic image point have the same optical path length. For focal lenses, the paths lengths for different pairs of conjugate points in a plane perpendicular to the axis are different, except for points on circles centered on the axis. For afocal lenses path lengths are nominally the same for all points in planes perpendicular to the axis. For afocal lenses with transverse magnification $\pm n/n'$, path lengths can be the same for all points. In general, the path lengths between different points on an object and image surface are equal only if the shape of the image surface is that of a wavefront that has propagated from a wavefront whose shape is that of the object surface.

The Cosine Condition

The *cosine condition* relates object space and image space ray angles, if the imaging is stigmatic over some area (T. Smith 1922,[120] Steward 1928,[121] Buchdahl 1970[116]). Let the x-y plane lie in the object surface and the x'-y' plane in the conjugate surface (Fig. 2). Two

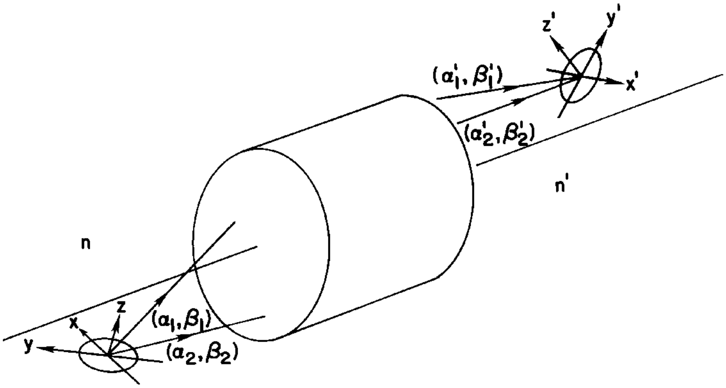

FIGURE 2 The cosine condition. A small area in object space about the origin in the x-y plane is imaged to the region around the origin of the x'-y' plane in image space. A pair of rays from the origin with direction cosines (α_1, β_1) and (α_2, β_2) arrive with (α_1', β_1') and (α_2', β_2'). The direction cosines and the transverse magnification in the planes are related by Eq. (104).

rays leaving a point in the object region have direction cosines (α_1, β_1) and (α_2, β_2), and the rays on the image side have (α_1', β_1') and (α_2', β_2'). If the imaging is stigmatic, with local transverse magnification m on the surface, then

$$m = \frac{n(\alpha_1 - \alpha_2)}{n'(\alpha_1' - \alpha_2')} = \frac{n(\beta_1 - \beta_2)}{n'(\beta_1' - \beta_2')} \tag{104}$$

In the limit as $\alpha_1 \rightarrow \alpha_2$ and $\beta_1 \rightarrow \beta_2$, the cosine condition gives

$$m = \frac{n\, d\alpha}{n'\, d\alpha'} = \frac{n\, d\beta}{n'\, d\beta'} \tag{105}$$

This condition also holds in the more general case of *isoplanatic* imaging, where there is aberration that is locally constant across the region in question (Welford 1976,[122] Welford 1986, sec. 94[123]).

The Abbe Sine Condition

The *sine condition* or *Abbe sine condition* (Abbe 1879,[124] Born & Wolf 1980[119]) is a special case of the cosine condition for object and image planes perpendicular to the axis in regions about the axis. For a plane with transverse magnification m, let θ be the angle relative to the axis made by a ray from an axial object point, and θ' be that in image space. If the lens is free of coma

$$m = \frac{n \sin\theta}{n' \sin\theta'} = \frac{n\alpha}{n'\alpha'} = \frac{n\beta}{n'\beta'} \tag{106}$$

for all θ and θ'. There are signs associated with θ and θ', so that $m > 0$ if they have the same sign, and $m < 0$ if the signs are opposite. This equation is sometimes written with m replaced by the ratio of paraxial angles. There is sometimes the implication that θ and θ' refer only to the extreme angles passing through the lens, when in fact the sine condition dictates that the ratio of the sines is the constant for all angles. For an object at infinity, the sine condition is

$$\sin\theta' = -\frac{y}{f'} \qquad \text{or} \qquad n'\beta' = -y\phi \tag{107}$$

where y is the height of a ray parallel to the axis, ϕ is the power of the lens, and f' is the rear focal length. These relationships hold to a good approximation in most lenses, since small deviations are associated with large aberrations. A deviation from this relationship is called *offense against the sine condition,* and is associated with coma (Conrady 1992,[125] H. Hopkins 1946,[126] T. Smith 1948,[127] H. Hopkins 1950,[128] Welford 1986[123]). The sine condition does not apply where there are discontinuities in ray behavior, for example, in devices like Fresnel lenses, or to diffraction-based devices like zone plates.

The Herschel Condition

The *Herschel condition* is a relationship that holds if the imaging is stigmatic for nearby points along the axis (Herschel 1821,[129] H. Hopkins 1946,[130] Born & Wolf 1980[119]). The two equivalent relations are

$$m = \frac{n \sin(\frac{1}{2}\theta)}{n' \sin(\frac{1}{2}\theta')} \qquad \text{and} \qquad m_L = \frac{n \sin^2(\frac{1}{2}\theta)}{n' \sin^2(\frac{1}{2}\theta')} = \frac{n(1-\gamma)}{n'(1-\gamma')} \tag{108}$$

The Herschel condition is inconsistent with the sine condition unless $m \pm n/n'$. So, in general, stigmatic imaging in one plane precludes that in others.

Sine and Herschel Conditions for Afocal Systems

For afocal systems the sine condition and Herschel condition are identical. For rays entering parallel to the axis at y and leaving at y' they are

$$m = \frac{y'}{y} \tag{109}$$

That is, the ratio of incoming and outgoing heights is independent of the incoming height. (H. Hopkins,[128] Chap. III "The Sine Condition and Herschel's Condition.")

Stigmatic Imaging Possibilities

For object and image spaces with constant refractive indices, stigmatic imaging is only possible for the entire spaces for afocal lenses with identical transverse and longitudinal magnifications $m = \pm n/n'$ and $|m_L| = |m|$. Such lenses re-create not only the intersection points, but the wavefronts, since the corresponding optical path lengths are the same in both spaces, Eq. (103). For other lenses with constant object and image space indices, the maxwellian ideal can be met for only a single surface. In addition, a single point elsewhere can be imaged stigmatically (T. Smith 1948,[127] Velzel 1991[131]). Nonplanar surfaces can be imaged stigmatically, a well-known example being the imaging of spherical surfaces by a spherical refracting surface, for a particular magnification (Born & Wolf 1980, sec. 4.2.3[119]). For systems with spherical symmetry, it is possible that two nonplanar surfaces be stigmatically imaged (T. Smith 1927[132]). In addition, various systems with heterogeneous indices can image stigmatically over a volume.

1.10 DESCRIPTION OF SYSTEMS OF REVOLUTION

Introduction

This section is concerned with the optical description of lens and mirror systems that are figures of revolution.[133–145] From a mechanical viewpoint, optical systems are comprised of lenses and mirrors. From the point of view of the light, the system is regions of media with different indices, separated by interfaces of various shapes. This section is limited to homogeneous isotropic media. It is further restricted to reflecting and refracting surfaces that are nominally smooth, and to surfaces that are figures of revolution arranged so their axes are collinear, so the entire system is a figure of revolution about the *lens axis*. (The often-used term "optical axis" is also used in crystallography. Moreover, the axis is often mechanical as well as "optical.") The lens axis is the z axis of an orthogonal coordinate system, with the x-y plane perpendicular. The distance from a point to the axis is $\rho = \sqrt{x^2 + y^2}$. Along the axis, the positive direction is from left to right.

Terminology

A *meridian* or *meridional plane* contains the axis, all such planes being equivalent. Meridional planes are planes of bilateral symmetry if the indices are homogeneous and isotropic. Some optical systems are comprised of pieces of surfaces of revolution, in which case it is still useful to discuss the behavior about the axis.

Reflection, Unfolded Diagrams

Light passes through refractive systems more or less in the same direction relative to the axis. In reflective and catadioptric systems, the light may change directions. (It may not, in the case of grazing incidence optics.) In order to consider all types of systems in a unified way, pictorially and algebraically, reflections can often be "unfolded," i.e., represented pictorially as transmission, with mirrors replaced by hypothetical lenses with the same properties, Figs. 3 and 18. Some structures must be taken into account several times in unfolding. For example, a hole may block light at one point along a ray and transmit it at another. (In some considerations, unfolding can be misleading—for instance, those involving stray light.)

Description of Surfaces

A *surface* is an interface between media with different refractive indices—either refracting or reflecting. The surface is the optical element, produced by a lens, which is a mechanical element. Surfaces can be described mathematically in many ways. (For example, conics can be described as loci of points with certain relationships.) In optical instruments, the entire surface is rarely used, and the axial region is usually special, so the description usually begins there and works out. The *vertex* of a figure of revolution intersects with

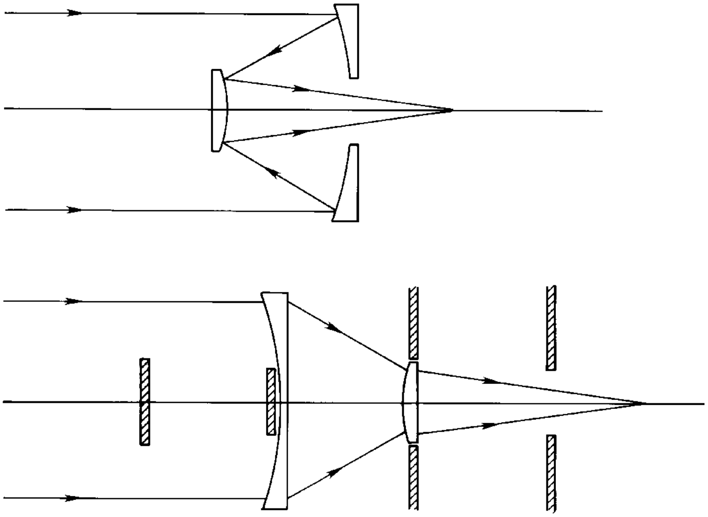

FIGURE 3 Example of an unfolded diagram. The two-mirror system above has an unfolded representation below. The reflective surfaces are replaced by thin lens equivalents. Their obstructions and the finite openings are accounted for by dummy elements.

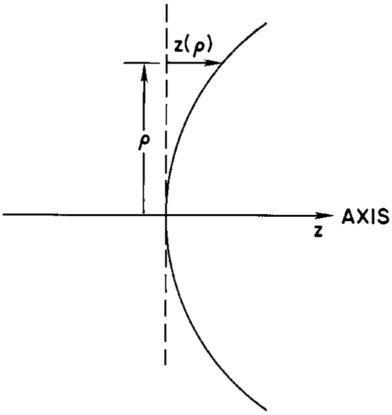

FIGURE 4 Description of a surface of revolution. The distance from the axis is ρ, and the sag $z(\rho)$ is the distance from the vertex tangent plane to the surface.

the axis, and is a local extremum. The plane perpendicular to the axis and tangent to the vertex will be referred to as the *vertex plane* (NS). A surface can be described by its *sag*, the directed distance $z(\rho)$ from the vertex plane to the surface, Fig. 4. The vertex is usually taken to have $z(0) = 0$. The *vertex curvature* or *paraxial curvature* c and radius of curvature r are given by

$$c = \frac{1}{r} = \frac{\partial^2 z(\rho)}{\partial \rho^2}\bigg|_{\rho=0} \tag{110}$$

For an arbitrary surface, this curvature is identical to that of the sphere which is a best fit on axis. The sign convention for curvature and radius is that c and r are positive if the center of curvature is to the right of the vertex, as in the case shown in Fig. 4. In general, the curvature is mathematically more foolproof than radius, since curvature can be zero, but it is never infinite, whereas radius is never zero, but may be infinite.

Spherical Surfaces

The spherical surface is the most common in optics, since it is most naturally produced. Spherical is the default, and is assumed when no other mention is made. Aspheres are thought of as deviating from spheres, rather than spheres as special cases of more general forms. The equation for a sphere with radius r, curvature c, and a vertex at $z = 0$ is

$$\rho^2 + (z - r)^2 = r^2 \tag{111}$$

The sag is given by

$$z(\rho) = r - \sqrt{r^2 - \rho^2} = r(1 - \sqrt{1 - c^2\rho^2}) = \frac{c\rho^2}{1 + \sqrt{1 - c^2\rho^2}} \tag{112}$$

The Taylor expansion is

$$z(\rho) = \tfrac{1}{2}c\rho^2 + \tfrac{1}{8}c^3\rho^4 + \tfrac{1}{16}c^5\rho^6 + \tfrac{5}{128}c^7\rho^8 + \tfrac{7}{256}c^9\rho^{10} + \cdots \tag{113}$$

At the point (x, y, z) on the surface of the sphere, the surface normal has direction cosines

$$(L, M, N) = \left(\frac{x}{r}, \frac{y}{r}, \frac{z-r}{r}\right) = (cx, cy, cz-1) \tag{114}$$

Conics of Rotation

The general form of a conic of rotation about the z axis is

$$z(\rho) = \frac{r}{\varepsilon}(1 - \sqrt{1 - \varepsilon c^2 \rho^2}) = \frac{c\rho^2}{1 + \sqrt{1 - \varepsilon c^2 \rho^2}} \tag{115}$$

The value of ε determines the type of conic, as given in the table below. It is common in optics to use κ, the *conic parameter* or *conic constant,* related by

$$\kappa = \varepsilon - 1 \qquad \text{or} \qquad \varepsilon = 1 + \kappa \tag{116}$$

Another parameter used to describe conics is the *eccentricity* e, used in the polar coordinate form for conics about their focus: $r(\theta) = a/(1 + e \cos \theta)$ where $e^2 = -\kappa$. In the case of paraboloids, the first form of Eq. (115) breaks down. A cone can be approximated by a hyperbola with $\kappa = -\sec^2 \theta$, where θ is the cone half angle.

Conic Type and Value of Parameter

Parameter	ε	κ	e
Oblate ellipsoid	$\varepsilon > 1$	$\kappa > 0$	—
Sphere	$\varepsilon = 1$	$\kappa = 0$	0
Prolate ellipsoid	$0 < \varepsilon < 1$	$-1 < \kappa < 0$	$0 < e < 1$
Paraboloid	$\varepsilon = 0$	$\kappa = -1$	$e = 1$
Hyperboloid	$\varepsilon < 0$	$\kappa < -1$	$e > 1$

The Taylor expansion for the sag is

$$z(\rho) = \tfrac{1}{2}c\rho^2 + \tfrac{1}{8}\varepsilon c^3 \rho^4 + \tfrac{1}{16}\varepsilon^2 c^5 \rho^6 + \tfrac{5}{128}\varepsilon^3 c^7 \rho^8 + \tfrac{7}{256}\varepsilon^5 c^9 \rho^{10} + \cdots \tag{117}$$

The surface normals are

$$(L, M, N) = [1 - 2c(\varepsilon - 1)z + c^2\varepsilon(\varepsilon - 1)z^2]^{-1/2}(cx, cy, cz - 1) \tag{118}$$

The sagittal and tangential curvatures are

$$c_s = \frac{c}{[1 + (1-\varepsilon)c^2\rho^2]^{1/2}} \qquad c_t = \frac{c}{[1 + (1-\varepsilon)c^2\rho^2]^{3/2}} \tag{119}$$

General Asphere of Revolution

For an arbitrary figure of revolution all of whose derivatives are continuous, the Taylor expansion is

$$z(\rho) = \tfrac{1}{2}c\rho^2 + q_4\rho^4 + q_6\rho^6 + \cdots \tag{120}$$

An asphere is often treated as a sphere that matches at the vertex and a deviation therefrom:

$$z(\rho) = z_{\text{sphere}}(\rho) + a_4\rho^4 + a_6\rho^6 + \cdots \tag{121}$$

Alternatively, nonconic aspheres can be treated as conics and a deviation therefrom:

$$z(\rho) = z_{\text{conic}}(\rho) + b_4\rho^4 + b_6\rho^6 + \cdots \tag{122}$$

The expansion coefficients are different in each case. Additional information on the coefficients is given by Malacara (Malacara 1992[144]) and Brueggemann (Brueggemann 1968[135]). The sagittal and tangential curvatures are given in general by

$$c_s = \frac{\dot{z}(\rho)}{\rho[1 + \dot{z}(\rho)^2]^{1/2}} \qquad c_t = \frac{\ddot{z}(\rho)}{[1 + \dot{z}(\rho)^2]^{3/2}} \tag{123}$$

Here $\dot{z}(\rho) = dz(\rho)/d\rho$ and $\ddot{z}(\rho) = d^2z(\rho)/d\rho^2$.

1.11 TRACING RAYS IN CENTERED SYSTEMS OF SPHERICAL SURFACES

Introduction

Ray tracing is the process of calculating the paths of rays through optical systems. Two operations are involved, propagation from one surface to the next and refraction or reflection at the surfaces. Exact equations can be written for spherical surfaces and conics of revolution with homogeneous media (Spencer & Murty 1962,[146] Welford 1974, chap. 4,[147] Kingslake 1978,[148] Kinglake 1983,[149] Slyusarev 1984,[150] Klein & Furtak 1986, sec. 3.1,[151] Welford 1986, chap. 4,[152] W. J. Smith 1992, chap. 10[153]). Conics are discussed by Welford (Welford 1986, sec. 4.7[152]). For general aspheres, the intersection position is found by iterating (Nussbaum & Phillips, p. 95,[154] W. J. Smith 1992, sec. 10.5[153]). Nonsymmetric systems are discussed by Welford (Welford 1986, chap. 5[152]).

Description and Classification of Rays in a Lens

For optical systems with rotational symmetry, rays are typically described in terms of the axial parameter z. A ray crosses each constant z plane at a point (x, y) with direction cosines (α, β, γ), where γ is not independent. Thus a ray is described by $(x(z), y(z))$ and $(\alpha(z), \beta(z))$.

For systems that are figures of revolution, *meridional rays* are those lying in a meridional plane, a plane that includes the axis, and other rays are *skew rays.* The *axial ray* corresponds to the axis of revolution. Rays are also classified according to their proximity to the axis. *Paraxial rays* are those in the limit of having small angles and small distances from the axis. Nonparaxial rays are sometimes referred to as *finite rays* or *real rays. Ray fans* are groups of rays lying in a plane. A *tangential fan* lies in a meridian, and intersects at a *tangential focus.* A *sagittal fan* lies in a plane perpendicular to a meridian, and intersects at a *sagittal focus.*

Transfer

In propagating through a homogeneous medium, a ray originating at (x_1, y_1, z_1) with directions (α, β, γ) intersects a z_2 plane at

$$x_2 = x_1 + \frac{\alpha}{\gamma}(z_2 - z_1) \qquad \text{and} \qquad y_2 = y_1 + \frac{\beta}{\gamma}(z_2 - z_1) \tag{124}$$

Intersection Points

Let the intersection points of the ray with the vertex plane at $z = 0$ be $(x_0, y_0, 0)$, Fig. 5. Define auxiliary functions

$$A(x_0, y_0; \alpha, \beta; c) = \gamma - c(\alpha x_0 + \beta y_0) \qquad \text{and} \qquad B(x_0, y_0, c) = c^2(x_0^2 + y_0^2) \tag{125}$$

The distance D along the ray from this point to the surface is given by

$$cD = A - \sqrt{A^2 - B} = \frac{B}{A + \sqrt{A^2 - B}} \tag{126}$$

The intersection point has the coordinates

$$x = x_0 + \alpha D \qquad y = y_0 + \beta D \qquad z = \gamma D \tag{127}$$

The incidence angle I at the intersection point is given by

$$\cos I = \sqrt{A^2 - B} \tag{128}$$

so

$$\Gamma = -n\sqrt{A^2 - B} + \sqrt{n'^2 - n^2 + n^2(A^2 - B)} \tag{129}$$

Mathematically, double intersection points are possible, so they must be checked for. If

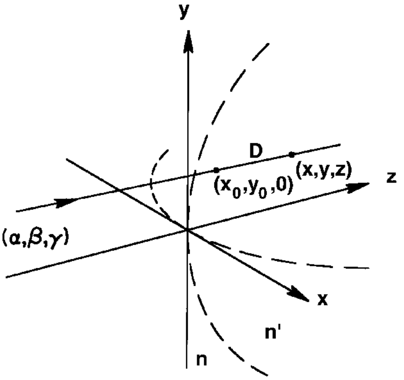

FIGURE 5 Intersection points. A ray with direction cosines (α, β, γ) intersects the vertex tangent plane at $(x_0, y_0, 0)$ and the optical surface at (x, y, z). The distance between these points is D, given by Eq. (126).

the ray misses the surface, then $A^2 < B$. If there is total internal reflection, the second square root in Eq. (129) is imaginary.

Refraction and Reflection by Spherical Surfaces

Rays refract or reflect at surfaces with reference to the local normal at the intersection point. The surface normal given by Eq. (114) is substituted in the general form for refraction, Eq. (85), to give

$$n'\alpha' = n\alpha - \Gamma cx \qquad n'\beta' = n\beta - \Gamma cy \qquad n'\gamma' = ny - \Gamma(1 - cz) \tag{130}$$

For reflection, the above equations are used, with $n' = -n$, so $\Gamma = 2n \cos I = 2n\sqrt{A^2 - B}$.

Meridianal Rays

The meridian is customarily taken to be that for which $x = 0$, so the direction cosines are $(0, \beta, \gamma)$. Let U be the angle between the axis and the ray, so $\beta = \sin U$ and $\gamma = \cos U$. The transfer equation, Eq. (124) becomes

$$y_2 = y_1 + \tan U(z_2 - z_1) \tag{131}$$

The second equation of Eq. (130) can be written

$$n' \sin U' - n \sin U = -cy(n' \cos I' - n \cos I) \tag{132}$$

If the directed distance from the vertex to the intersection point of the incident ray with the axis is l, the outgoing angle is

$$U' = U + \arcsin\,[(lc - 1)\sin U] - \arcsin\left[\frac{n}{n'}(lc - 1)\sin U\right] \tag{133}$$

The directed distance l' from the vertex to the axial intersection of the refracted ray is given by

$$cl' = 1 + (cl - 1)\frac{n}{n'}\frac{\sin U}{\sin U'} \tag{134}$$

For reflection, setting $n' = -n$ gives

$$U' = U + 2 \arcsin\,[(lc - 1)\sin U] \tag{135}$$

1.12 PARAXIAL OPTICS OF SYSTEMS OF REVOLUTION

Introduction

The term *paraxial* is used in different ways. In one, paraxial rays are those whose distances from the axis and whose angles relative to the axis are small. This leaves questions of how small is small enough and how this varies from system to system. The other interpretation of the term, which is used here, is that paraxial rays represent a limiting case in which the distances from the axis and angles relative to the axis vanish. *Paraxial optics* then describes the behavior of systems in this limit. The ray-tracing equations in the paraxial limit are linear in angle and in distance from the axis, hence the term *first-order optics,* which is often considered equivalent to paraxial. (There are no 0th-order terms since the expansion is taken about the axis, so a ray with an initial height and angle of zero, i.e., a ray along the axis, has the same outgoing height and angle.) The linearity of the paraxial equations makes them simple and understandable, as well as expressible in matrix form. Paraxial ray tracing is discussed to some extent by almost every book that treats geometrical optics.

Paraxial ray tracing is done to determine the gaussian properties of lenses, to locate image positions and magnifications, and to locate pupils and determine their sizes. Another use of paraxial ray tracing, not discussed here, is the computation of third-order aberrations (W. Smith 1992[155]).

Paraxial imaging is perfect in the sense that it agrees with the Maxwell ideal and with that of collineation. Point images everywhere are stigmatic, fields are flat, and there is no distortion. Aberration is often thought of as the difference between the behavior of finite rays and that of paraxial rays. If this approach is taken, then in the process of lens design, finite rays are made to agree, insofar as possible, with the paraxial ones, which cannot be similarly changed. In the paraxial limit, surfaces are described by their vertex curvatures, so conics, aspheres, and spheres are indistinguishable, the difference being in the fourth power and above. Consequently, aberrations can be altered by changing the surface asphericity without changing paraxial properties. A paraxial treatment can be done even if a system is missing the axial region, as in the case with central obstructions and off-axis sections of figures of revolution.

This section is concerned with systems of mirrors and lenses with rotational symmetry and homogeneous refractive indices. In this case, it suffices to work in a single meridian. Generalizations are found in the sections in this chapter on images about known rays and rays in heterogeneous media. Other generalizations involve expansions about given rays in systems that are not rotationally symmetric.

The Paraxial Limit

The lens axis is the z axis, and rays in the $x = 0$ meridian are considered. Ray heights are y, and angles relative to the axis are u. In the paraxial limit, the quantities u, $\tan u$, and $\sin u = \beta$ are indistinguishable. The z-direction cosine is $\gamma = \cos u \simeq 1$. Since the ray angles and heights are small, incidence angles are likewise, so $i \simeq \sin i$, $\cos I \simeq 1$, $\cos I' \simeq 1$, and $\Gamma = n' \cos I' - n \cos I \simeq n' - n$.

Transfer

In traversing a distance t between two planes, the height of a meridional ray changes from y to y' according to Eq. (124), $y' = y + t\beta/\gamma$. In the paraxial limit, this equation becomes

$$y' = y + tu \tag{136}$$

If a ray travels from one curved surface to the next, the distance t equals the vertex separation to first order, since the correction for the surface sag is of second order in height and angle. This term is given above in Eq. (127).

Refraction

The paraxial form of Snell's law, Eq. (78), is

$$n'i' = ni \tag{137}$$

Reflection

The law of reflection is the same for paraxial as for finite rays,

$$i' = -i \tag{138}$$

Angle of Incidence at a Surface

A ray with an angle u, which intersects a surface of curvature c at height y, makes an angle i with the local surface normal of the surface given by

$$i = u + yc \tag{139}$$

This equation is easily remembered from two special cases. When $y = 0$, the intersection is at the vertex, so $i = u$. When $u = -cy$, the ray is directed through the center of curvature, so $i = 0$.

Refraction at a Surface

The above equation combined with that for Snell's law gives

$$n'u' = nu - yc(n' - n) \tag{140}$$

This equation can also be obtained from the exact equation, $n'\beta' = n\beta - \Gamma cy$, Eq. (125). In the paraxial limit, $\Gamma = n' - n$, and the intersection height y is that in the vertex plane.

Reflection at a Surface

The relationship between incident and outgoing angles at a reflecting surface is found by combining Eqs. (138) and (139), to be

$$u' = -u - 2cy \tag{141}$$

Refraction and Reflection United—Surface Power

Reflection and refraction can be treated the same way mathematically by thinking of reflection as refraction with $n' = -n$, in which case Eq. (140) gives Eq. (141). A reflecting surface can be represented graphically as a thin convex-plano or concave-plano thin lens with index $-n$, where n is the index of the medium, Fig. 18. For both refraction and reflection,

$$n'u' = nu - y\phi \tag{142}$$

where the surface *power* ϕ is

$$\phi = c(n' - n) \tag{143}$$

If the surface is approached from the opposite direction, then n and n' are switched, as is the sign of c, so ϕ is the same in both directions. Thus ϕ is a scalar property of the interface, which can be positive, negative, or zero. The power is zero if $n' = n$ or $c = 0$. If $n' = n$, the surface is "invisible," and the rays are not bent. If $c = 0$, the rays are bent. For a planar refracting surface $n'u' = nu$, and a planar reflecting surface gives $u' = -u$.

Principal Focal Lengths of a Surface

A ray approaching a surface parallel to the axis ($u = 0$) with a height y has an outgoing angle given by

$$n'u' = -y\phi \tag{144}$$

This ray intercepts the axis at the *rear focal point,* whose directed distance from the vertex is $f' = y/u' = n'/\phi$. This directed distance is the *rear focal length.* Similarly, a ray entering from the right with $u' = 0$ intercepts the axis at the *front focal point,* a directed distance from the vertex of $f = y/u = -n/\phi$, the *front focal length.* Thus, a surface has a single power and two focal lengths, among which the following relationships hold:

$$f' = \frac{n}{\phi} \qquad f = -\frac{n}{\phi} \qquad \phi = -\frac{n}{f} = \frac{n'}{f'} \qquad \frac{f'}{f} = -\frac{n'}{n} \tag{145}$$

For a refracting surface, the signs of f' and f are opposite. For a reflecting surface $f' = f$.

Axial Object and Image Locations for a Single Surface

A ray from an axial point a directed distance l from the vertex of a surface that makes an angle u with the axis intersects the surface at height $y = -l/u$. After refraction or reflection, the ray angle is u', and the ray intersects the axis at a distance $l' = -y/u'$ from the vertex, Fig. 6. Substituting for u and u' in Eq. (142), the relationship between axial object and image distances is

$$\frac{n'}{l'} = \frac{n}{l} + \phi \tag{146}$$

This can also be written

$$n\left(\frac{1}{r} - \frac{1}{l}\right) = n'\left(\frac{1}{r} - \frac{1}{l'}\right) \tag{147}$$

This is a special case of the equations below for imaging about a given ray. The transverse magnification is $m = l'/l$.

Paraxial Ray Tracing

Paraxial rays are traced through an arbitrary lens by a sequence of transfers between surfaces and power operations at surfaces. Each transfer changes height but not angle, and each power operation changes angle but not height. An image can be found by applying Eq. (136) and Eq. (142) successively. Alternatively, matrix methods described below can be used.

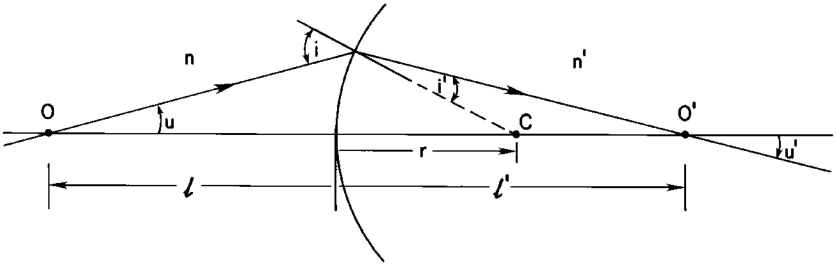

FIGURE 6 Refraction at a single spherical surface with center C and radius r. Axial object point O is imaged at O'.

Linearity of Paraxial Optics

For both the transfer and power operations, the outgoing heights and angles depend linearly on the incoming heights and angles. So a system described by a sequence of such operations is also linear. Therefore, a ray that enters with height y and angle u leaves with $y'(y, u)$ and $u'(y, u)$ given by

$$y' = \left(\frac{\partial y'}{\partial y}\right)y + \left(\frac{\partial y'}{\partial u}\right)u \qquad \text{and} \qquad u' = \left(\frac{\partial u'}{\partial y}\right)y + \left(\frac{\partial u'}{\partial u}\right)u \tag{148}$$

These equations can also be thought of as the first terms of Taylor expansions of exact expressions for $y'(y, u)$ and $u'(y, u)$. These partial derivatives depend on the structure of the system, and they can be determined by tracing two rays through the system. The partial derivatives, other than $\partial u'/\partial y$, also depend on the axial locations of the input and output surfaces. The changes with respect to these locations are treated easily by matrix methods.

The Two-Ray Paraxial Invariant

The various rays that pass through a lens are not acted upon independently, so there are several invariants that involve groups of rays. Consider two meridional paraxial rays that pass through a lens. At a given plane, where the medium has an index n, one ray has height y_1 and angle u_1, and the other has y_2 and u_2. The quantity

$$L = ny_1u_2 - ny_2u_1 = n(y_1u_2 - y_2u_1) \tag{149}$$

which we refer to as the *paraxial invariant* (NS), is unchanged as the rays pass through the system. Applying Eq. (136) and Eq. (142) to the above expression shows that this quantity does not change upon transfer or upon refraction and reflection. The invariant is also related to the general skew invariant, Eq. (73), since a paraxial skew ray can be decomposed into two meridional rays.

Another version of the invariance relationship is as follows. Two objects with heights y_1 and y_2 are separated axially by d_{12}. If their image heights are y_1' and y_2', and the image separation is d_{12}', then

$$n\frac{y_1 y_2}{d_{12}} = n'\frac{y_1' y_2'}{d_{12}'} \tag{150}$$

An additional version of the invariance relationship is

$$\left(\frac{\partial y'}{\partial y}\right)\left(\frac{\partial u'}{\partial u}\right) - \left(\frac{\partial y'}{\partial u}\right)\left(\frac{\partial u'}{\partial y}\right) = \frac{n}{n'} \tag{151}$$

where the partial derivatives, Eq. (148), describe the action of any system.

The invariant applies *regardless* of the system. Thus, for example, if the lens changes, as with a zoom system, so that both of the outgoing rays change, their invariant remains. The invariant arises from basic physical principles that are manifested in a variety of ways, for example, as conservation of brightness and Liouville's theorem, discussed above in the section on conservation of etendue. This invariance shows that there are fundamental limits on what optical systems can do. Given the paraxial heights and angles of two input rays, only three of the four output heights and angles can be chosen arbitrarily. Likewise, only three of the four partial derivatives above can be freely chosen. The invariant is not useful if it vanishes identically. This occurs if the two rays are scaled versions of one another, which happens if both $u_1 = 0$ and $u_2 = 0$ for some z, or if both rays pass through the same axial object point, in which case $y_1 = 0$ and $y_2 = 0$. The invariant also vanishes if one of the rays lies along the axis, so that $y_1 = 0$ and $u_1 = 0$.

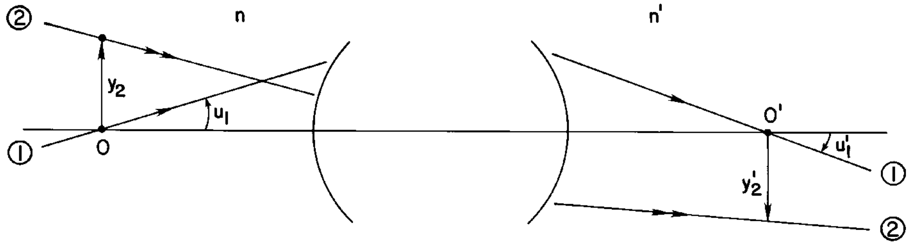

FIGURE 7 An object and image plane with ray 1 through the axial points and ray 2 through off-axis points. The location and magnification of an image plane can be found by tracing a ray from the axial object point O to axial image point O'. The magnification is given by Eq. (153). In the case pictured, u_1 and u_1' have opposite signs, so the transverse magnification is negative.

Image Location and Magnification

To locate an image plane, any ray originating at the axial object point can be traced through the system to determine where it again intersects the axis, Fig. 7. The magnification for these conjugates can be found in two ways. One is to trace an arbitrary ray from any off-axis point in the object plane. The ratio of its height in the image plane to that in the object plane is the transverse magnification.

Alternately, the magnification can be found from the initial and final angles of the ray through the axial points. Let ray 1 leave the axial object point, so $y_1 = 0$. Let ray 2 originate in the object plane some distance from the axis. At the object plane $L = ny_2u_1$, and at the image plane $y_2' = 0$, so $L = n'y_2'u_1'$. Therefore,

$$L = ny_2u_1 = n'y_2'u_1' \tag{152}$$

So the magnification is

$$m = \frac{y_2'}{y_2} = \frac{nu_1}{n'u_1'} \tag{153}$$

The relative signs of u and u' determine that of the magnification. Equation (153) is a paraxial form of the sine condition Eq. (106). Squaring this equation gives $L^2 = n^2y_2^2u_1^2$, which is proportional to a paraxial form of the etendue. These matters are discussed further in the sections on conservation of etendue and on apertures. The quantity ny_2u_1 is sometimes referred to as *the* invariant, but it is not the most general form.

Three-Ray Rule

A further consequence of the paraxial invariant and of the linearity of paraxial optics, is that once the paths of two paraxial meridional rays has been found, that of any third ray is determined. Its heights and angles are a linear combination of those of the other two rays. Given three rays, each pair has an invariant: $L_{12} = n(y_1u_2 - y_2u_1)$, $L_{23} = n(y_2u_3 - y_3u_2)$, and $L_{31} = n(y_3u_1 - y_1u_3)$. Therefore, in every plane

$$y_3 = -\frac{L_{23}}{L_{12}}y_1 + \frac{L_{31}}{L_{12}}y_2 \qquad \text{and} \qquad u_3 = -\frac{L_{23}}{L_{12}}u_1 + \frac{L_{31}}{L_{12}}u_2 \tag{154}$$

This assumes that no pair of the three rays are simply scaled versions of one another, i.e. that both $L_{23} \neq 0$ and $L_{31} \neq 0$.

Switching Axial Object and Viewing Positions

If an axial object and axial viewing position are switched, the apparent size of the image is unchanged. Put more precisely, let an object lie in a plane intersecting the axial point A and let its image be viewed from an axial point B' in image space that is not conjugate to

A. If the object and viewing positions are switched, so the eye is at A and the object plane is at B', the subtense of the object as seen by the eye is unchanged. (Rayleigh 1886,[156] Southall 1910,[157] Herzberg 1935,[158] Brouwer 1967[159]).

1.13 IMAGES ABOUT KNOWN RAYS

Given a ray, referred to here as the *central ray* (also "base ray"), other rays from a point on the central ray making a small angle with respect to it are focused at or near other points on the central ray. These foci can be determined if the path of a central ray is known, as well as the indices of the media through which it passes, and the principal curvatures at the surfaces where it intersects. Here indices are constant. At each intersection point with an optical surface, the wavefront has two principal curvatures, as does the surface. After refraction or reflection, the wavefront has two different principal curvatures. Accordingly, if a single point is imaged, there are two astigmatic focal lines at some orientation. These foci are perpendicular, but they do not necessarily lie in planes perpendicular to that of the central ray. The imaging of a small extended region is generally skewed, so, for example, a small square in a plane perpendicular to the central ray can be imaged as a rectangle, parallelogram, or trapezoid.

This is a generalization of paraxial optics, in which the central ray is the axis of a system of revolution. While not difficult conceptually, the general case of an arbitrary central ray and an arbitrary optical system is algebraically complicated. This case can also be analyzed with a hamiltonian optics approach, using an expansion of a characteristic function about the central ray, like that of Eq. (28). The subject is sometimes referred to as *parabasal optics,* and the central ray as the *base ray.* This subject has been discussed by numerous authors[160–186] under various names, e.g., "narrow beams," "narrow pencils," "first order."

The following is limited to the case of meridional central rays and surfaces that are figures of revolution. The surface, at the point of intersection, has two principal curvatures c_s and c_t. [See Eqs. (119), (123).] For spherical surfaces, $c_s = c_t = c$, and for planar surfaces $c = 0$. There is a focus for the sagittal fan and one for the tangential one, Fig. 8, the two

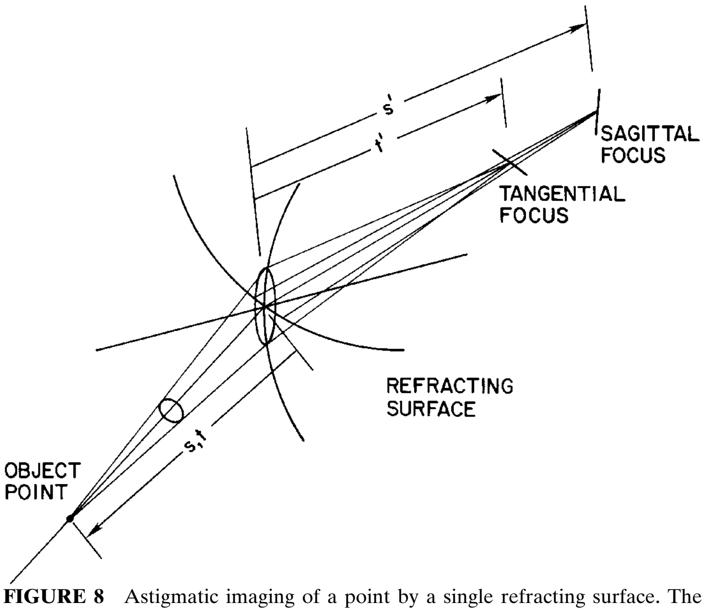

FIGURE 8 Astigmatic imaging of a point by a single refracting surface. The distance from the surface to the object point along the central ray of the bundle is $s = t$. The distances from the surface to the sagittal focus is s', and that to the tangential focus is t', as given by Eq. (155).

foci coinciding if the imaging is stigmatic. After one or more surfaces are encountered, the separated foci are the sources for subsequent imaging. Let s and t be the directed distances from the intersection point of the central ray and the surface to the object point, and s' and t' be the distances from intersection point to the foci. The separation $|s' - t'|$ is known as the *astigmatic difference.*

For refraction

$$\frac{n'}{s'} = \frac{n}{s} + c_s\Gamma \qquad \text{and} \qquad \frac{n'\cos^2 I'}{t'} = \frac{n\cos^2 I}{t} + c_t\Gamma \tag{155}$$

where $\Gamma = n'\cos I' - n\cos I$, Eq. (82). The sagittal equation is simpler, providing a mnemonic for remembering which equation is which: "S" = sagittal = simpler. If the surface is spherical, and the ray fan makes an arbitrary angle of ψ with the meridian, then (H. Hopkins 1950[175])

$$\frac{n'}{d'}(1 - \cos^2\psi\sin^2 I') = \frac{n}{d}(1 - \cos^2\psi\sin^2 I) + c\Gamma \tag{156}$$

where d and d' are the distances along the central ray from the surface to the object and image points. For normal incidence at a spherical surface $\Gamma = n' - n$, so both equations become

$$\frac{n'}{d'} = \frac{n}{d} + c(n' - n) \tag{157}$$

This also applies to surfaces of revolution if the central ray lies along the axis. This equation is identical to the paraxial equation, Eq. (146).

The corresponding relations for reflection are obtained by setting $n' = -n$ and $I' = I$ in the refraction equations, giving

$$\frac{1}{s'} = -\frac{1}{s} + 2c_s\cos I \qquad \text{and} \qquad \frac{1}{t'} = -\frac{1}{t} + \frac{2c_t}{\cos I} \tag{158}$$

For stigmatic imaging between the foci of reflective conics, $s = t$ is the distance from one focus to a point on the surface, and $s' = t'$ is that from the surface to the other focus. Therefore, $c_t = c_s\cos^2 I$. The reflection analogue to Eq. (156), for a spherical surface is

$$\frac{1}{d'} = -\frac{1}{d} + \frac{2c\cos I}{1 - \cos^2\psi\sin^2 I} \tag{159}$$

These equations are known by several names, including *Coddington's equations, Young's astigmatic formulae,* and the *s*- and *t-trace formulae.*

1.14 GAUSSIAN LENS PROPERTIES

Introduction

The meaning of the term *gaussian optics* is not universally agreed upon, and it is often taken to be indistinguishable from paraxial optics or first-order optics, as well as collineation. Here the term is considered to apply to those aspects of paraxial optics discovered by Gauss (Gauss 1840[187]), who recognized that all rotationally symmetric systems of lens elements can be described paraxially by certain system properties. In particular, lenses can be treated as black boxes described by two axial length parameters and the locations of special points, called *cardinal points,* also called *Gauss points.* Once a lens is so characterized, knowledge of its actual makeup is unnecessary for many purposes, and repeated ray traces need not be performed. For example, given the object location, the image location and magnification are determined from the gaussian parameters. From the gaussian description of two or more lenses, that of a coaxial combination can be found. Another consequence of Gauss's discovery is that there is an infinity of specific embodiments for any external prescription.

The lenses considered in this section are figures of revolution with uniform object space and image space indices n and n'. All quantities discussed in this section are paraxial, so the prefix "paraxial" is not repeated. For the purposes of this section, no distinction is made between real and virtual rays. Those in each space are considered to extend infinitely, and intersection points may be either accessible or inaccessible. The quantities used in this section are found in Table 1.

Power, Focal Lenses, and Afocal Lenses

A paraxial ray entering a lens parallel to the axis height y leaves with some angle u', Fig. 9. Likewise, a ray entering from the opposite side with height y' leaves with angle u. The *power* of the lens is defined by

$$\phi = -n'\frac{u'}{y} = n\frac{u}{y'} \tag{160}$$

The outgoing ray can have any angle, and the power can be positive, negative, or zero. If $u' = 0$, then $\phi = 0$ and the lens is *afocal* or *telescopic.* Lenses for which $\phi \neq 0$ are referred to here as *focal,* although the term "nonafocal" is more common. Afocal lenses are fundamentally different from focal ones, and are treated separately below. Power is the same in both directions, i.e. whether the ray enters from left to right or from right to left. The lens in Fig. 9 has $\phi > 0$, and that in Fig. 10 has $\phi < 0$. Diagrams such as Fig. 11 show the location of the principal focal point, but not the sign of the power; two rays enter and two leave, but there is no indication of which is which. (Note that some negative lenses have accessible rear focal points.) Another expression for power involves two rays at arbitrary angles and heights. If two incident rays have (y_1, u_1) and (y_2, u_2), and a nonzero invariant $L = n(y_1u_2 - y_2u_1)$, and the outgoing ray angles are u_1' and u_2', then

$$\phi = -\frac{nn'}{L}(u_1'u_2 - u_2'u_1) \tag{161}$$

Focal Lenses

Focal lenses are those for which $\phi \neq 0$. Their cardinal points are the principal focal points, the principal points, and the nodal points. These points may be located anywhere on axis relative to the physical lens system. If they are inside a lens, then the intersection points referred to below are virtual. The cardinal points are pairs consisting of a member in object space and one in image space. The one in object space is often referred to as *front,* and the one in image space as *rear,* but this terminology may be misleading, since the points can be any sequence along the axis.

Principal Focal Points. Rays entering a lens parallel to its axis cross the axis at the *principal focal points* or *focal points.* Rays parallel to the axis in object space intersect the axis at the *rear focal point F'* in image space and those parallel in image space intersect at the *front focal point F* in object space, Fig. 9. The *principal focal planes* or *focal planes* are the planes perpendicular to the axis at the focal points. The terms *focal point* and *focal plane* are often used to refer to the images of any point or plane. In this chapter, *image point* is used for other points where rays are focused and *image plane* for other planes.

Principal Planes. The *principal planes* are the conjugate planes for which the transverse

TABLE 1 Gaussian Notation and Definitions

By convention, in the diagrams the object space is to the left of the lens, image space is to the right, and rays go left to right. Object space quantities are unprimed, and image space quantities are primed, and quantities or positions that correspond in some way have same symbol, primed and unprimed. This correspondence can have several forms, e.g., the same type of thing or conjugate. The term *front* refers to object space, or left side, and *rear* to image space, or right side. A "front" entity may actually be behind a "rear" one. For example, a negative singlet has its object space focal point behind lens.

Scalars

n and n' object and image space refractive indices
ϕ power
m transverse magnification
m_N nodal point magnification $= n/n'$
m_L longitudinal magnification
m_α angular magnification
u and u' paraxial ray angles (the positive direction is counterclockwise from the axis)
y and y' paraxial ray heights
y_P paraxial ray height at the principal planes $= y'_P$

Axial points

Cardinal points:
Focal points F and F', not conjugate
Principal points P and P', conjugate $m = +1$
Nodal points N and N', conjugate $m_N = n/n'$
Other points:
Axial object and image points O and O', conjugate
Arbitrary object and image points A and A', B and B'
Vertices V and V', not conjugate, in general

Directed axial distances

These distances here are between axial points and are directed.
Their signs are positive if from left to right and vice versa.
Types of distances: entirely in object or image space, between spaces
Principal focal lengths: $f = PF$ and $f' = P'F'$
Principal points to object and image axial points: $l = PO$ and $l' = P'O'$
Front and rear focal points to object and image axial points: $z = FO$ and $z' = F'O'$
Relations: $l = f + z$ and $l' = f' + z'$
Arbitrary point to conjugate object and image points: $d = AO$ and $d' = A'O'$

Distances between object space and image space points involve distances within both spaces, as well as a distance *between* the spaces, e.g., PP', FF', VV', and OO'. The distances between spaces depend on the particular structure of the lens. They can be found by paraxial ray tracing.

magnification is unity, Fig. 12. The intersections of the principal planes and the axis are the *principal points,* denoted by P and P'. The *rear principal plane* is the locus of intersections between $u = 0$ rays incident from the left and their outgoing portions, Fig. 9. Likewise, the *front principal plane* is the intersection so formed with the rays for which $u' = 0$. A ray intersecting the first principal plane with height y_P and angle u leaves the second principal plane with height $y' = y_P$ and an angle given by

$$n'u' = nu - y_P\phi \tag{162}$$

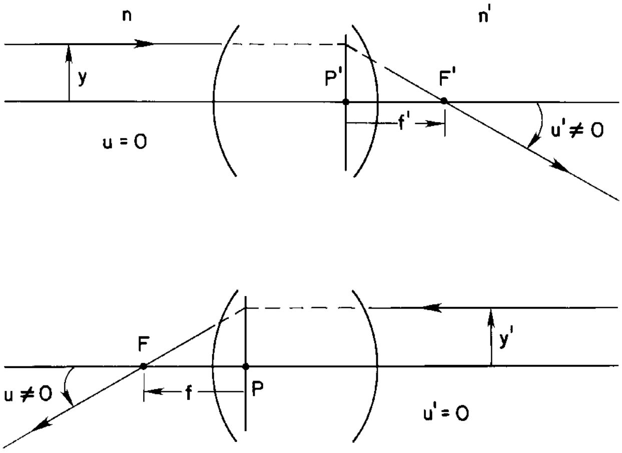

FIGURE 9 Diagrams for determining power, focal points, and focal lengths. Rays parallel to the axis in one space cross the axis in the other space at the focal points. The principal planes are at the intersections of entering and leaving rays. The power is given by Eq. (159). The lens in this diagram has positive power, a positive rear focal length, and a negative front focal length.

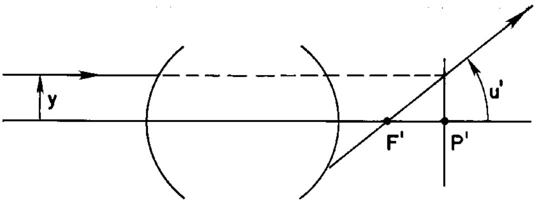

FIGURE 10 A lens with negative power and negative rear focal length. An incoming ray parallel to the axis with a positive height leaves the lens with a positive angle. The rear focal plane precedes the rear principal plane.

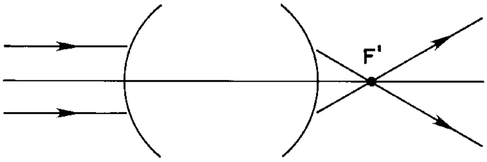

FIGURE 11 An ambiguous diagram. Two rays that enter a lens parallel to its axis converge at the rear focal point F'. Without specifying which ray is which, the sign of the power is not known.

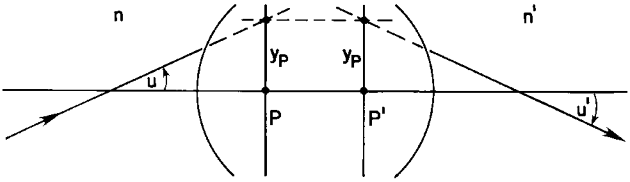

FIGURE 12 Principal planes as effective ray-bending surfaces. Incoming and outgoing paraxial rays intersect the object and image space principal planes at the same height y_P. The angles are related by Eq. (161).

The lens behaves as if the incoming ray intercepts the front principal plane, is transferred to the second with its height unchanged, and is bent at the second by an amount proportional to its height and to the power of lens. The power of the lens determines the amount of bending. For rays passing through the principal points, $y_p = 0$, so $u'/u = n/n'$.

Principal Focal Lengths. The *focal lengths,* also called *effective focal lengths,* are the directed distances from the principal points to the focal points. The front and rear focal lengths are

$$PF = f = -\frac{n}{\phi} \quad \text{and} \quad P'F' = f' = \frac{n'}{\phi} \tag{163}$$

The two focal lengths are related by

$$\phi = -\frac{n}{f} = \frac{n'}{f'} \quad \text{and} \quad \frac{f}{f'} = -\frac{n}{n'} \tag{164}$$

This ratio is required by the paraxial invariant (Kingslake 1965, p. 214[188]). If $n = n'$, then $f' = -f$. If $n = n' = 1$, then

$$f' = -f = \frac{1}{\phi} \tag{165}$$

The focal lengths are the axial scaling factors for the lens, so axial distances in all equations can be scaled to them.

Nodal Points. The *nodal points* are points of unit angular magnification. A paraxial ray entering the *object space nodal point N* leaves the *image space point N'* at the same angle, Fig. 13. The planes containing the nodal points are called *nodal planes.* A *nodal ray* is one that passes through the nodal points. Such a ray must cross the axis, and the point where it does so physically is sometimes called the *lens center.* In general, this point has no special properties. (Gauss suggested an alternate "lens center," the point midway between the

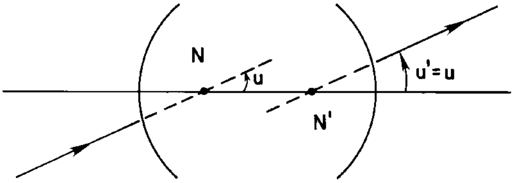

FIGURE 13 Nodal points. A paraxial ray through the object space nodal point N passes through image space nodal point N' with the same angle.

principal points. Rotating a lens front to rear about this point would leave object and image positions and magnifications unchanged.)

If the refractive indices of the object space and image space are the same, the nodal points correspond to the principal points. If not, both nodal points are shifted according to

$$PN = P'N' = \frac{n' - n}{\phi} = f + f' \tag{166}$$

The distances from the nodal points to the focal points are

$$N'F' = -f \qquad \text{and} \qquad NF = -f' \tag{167}$$

The nodal points are conjugate, and the transverse magnification of the nodal planes is

$$m_{\mathrm{N}} = \frac{n}{n'} \tag{168}$$

These equations can be recalled by the simple example of the single refracting surface, for which both nodal points correspond to the center of curvature.

Conjugate Equations. For an object plane perpendicular to the axis at point O, there is an image plane perpendicular to the axis at O', in which the transverse magnification is m. Note that specifying magnification implies both object and image positions. There is a variety of *conjugate equations* (NS) that relate their positions and magnifications. The equations differ in which object space and image space reference points are used from which to measure the directed distances to the object and image. These equations can be written in several ways, as given below, and with reference to Fig. 14. Axial distances can be scaled to the focal lengths, or the distances can be scaled to the indices, with a common power term remaining.

The simplest conjugate equation is *Newton's equation,* for which the reference points are the focal points and the lengths therefrom are $z = FO$ and $z' = F'O'$. The equation can be written in several forms:

$$zz' = ff' \qquad \text{or} \qquad \frac{z'}{f'}\frac{z}{f} = 1 \qquad \text{or} \qquad \frac{z'}{n'}\frac{z}{n} = \frac{1}{\phi^2} \tag{169}$$

More generally, if A and A' are any pair of axial conjugate points, as are B and B', then

$$FA \times F'A' = FB \times F'B' \tag{170}$$

Another form is that for which the reference points are the principal points and the

If the reference points are arbitrary conjugates with magnification m_A and the axial distances are $d = AO$ and $d' = A'O'$, then

$$m_A \frac{n'}{d'} = \frac{1}{m_A} \frac{n}{d} + \phi \qquad \text{or} \qquad \frac{d'}{f'} = \frac{m_A^2 \dfrac{d}{f}}{1 - m_A \dfrac{d}{f}} \tag{172}$$

This equation also relates the curvatures of a wavefront at conjugate points. For a point source at A the radius of the wavefront at O is d, so at O' the radius is d'.

If the reference points are the nodal points, $m_A = m_N = n/n'$, and the axial distances are $d = NO$ and $d' = N'O'$, then

$$1 = \frac{f}{d'} + \frac{f'}{d} \qquad \text{or} \qquad \frac{n}{d'} = \frac{n'}{d} + \phi \tag{173}$$

The most general equation relating conjugate points is obtained when both reference points are arbitrary. Let the reference point in object space be a point A, at which the magnification is m_A, and that in image space be B', associated with magnification m_B'. If $d = AO$ and $d' = B'O'$, then

$$\frac{1}{\phi}\left(1 - \frac{m_B'}{m_A}\right) = \frac{1}{m_A} d - m_B' d' + \phi\, d\, d' \qquad \text{or}$$

$$d' = \frac{\dfrac{1}{m_A} d + \left(\dfrac{m_B'}{m_A} - 1\right) \dfrac{1}{\phi}}{\phi\, d - m_B'} \tag{174}$$

All the other conjugate equations are special cases of this one with the appropriate choice of m_A and m_B'.

If the reference point in object space is the focal point, and that in image space is the principal plane, then $m_A = \infty$ and $m_B' = 1$, giving

$$\frac{n'}{z'\phi} = \frac{l\phi}{n} + 1 \qquad \text{or} \qquad \frac{f'}{z'} = \frac{l}{f} + 1 \tag{175}$$

Likewise, if the object space reference point is P and the image space reference is F', then

$$\frac{n'}{l'\phi} = \frac{z\phi}{n} + 1 \qquad \text{or} \qquad \frac{f'}{l'} = \frac{z}{f} + 1 \tag{176}$$

A relationship between distances to the object and image from the principal points and those from the focal points is

$$1 = \frac{z'}{l'} + \frac{z}{l} = \frac{F'O'}{P'O'} + \frac{FO}{PO} \tag{177}$$

Transverse Magnification. In planes perpendicular to the axis, the *transverse magnification,* usually referred to simply as the *magnification,* is

$$m = \frac{x'}{x} = \frac{y'}{y} = \frac{dx'}{dx} = \frac{dy'}{dy} \tag{178}$$

There are several equations for magnification as a function of object position or image position, or as a relationship between the two. Newton's equations are

$$m = -\frac{f}{z} = -\frac{z'}{f'} = \frac{f}{f - l} = \frac{f' - l'}{f'} \tag{179}$$

Other relationships are

$$m = \frac{n}{n'}\frac{l'}{l} = -\frac{f}{f'}\frac{l'}{l} = \frac{z'}{l'}\frac{l}{z} \tag{180}$$

If $n = n'$, then $m = l'/l$. Another form, with respect to conjugate planes of magnification m_A is

$$mm_A = \frac{n}{d}\frac{d'}{n'} = \frac{f}{d}\frac{d'}{f'} \tag{181}$$

If d and d' are distances from the nodal points, $m = d'/d$. The change of magnification with respect to object or image positions with conjugacy maintained is

$$\frac{dm}{dz'} = -\frac{1}{f'} = \frac{m}{z'} \qquad \text{and} \qquad \frac{dm}{dz} = \frac{f}{z^2} = \frac{m^2}{f} = \frac{m}{z} \tag{182}$$

Images of Distant Objects. If an object at a great distance from the lens subtends an angle ψ from the axis at the lens, then its paraxial linear extent is $y = z\psi$. The image height is

$$y' = my = \frac{-f}{z}y = -f\psi = \frac{n}{n'}f'\psi \qquad \text{and} \qquad \frac{dy'}{d\psi} = \frac{n}{n'}f' \tag{183}$$

If a distant object moves perpendicularly to the axis, then its image moves in the opposite direction if $f' > 0$ and in the same direction if $f' < 0$, so long as n and n' have the same sign.

Distance Between Object and Image. The directed distance from an axial object point to its image contains three terms, one in object space, one in image space, and one relating the two spaces. The first two depend on the magnification and focal lengths. The interspace term depends on the particular structure of the lens, and is found by paraxial ray tracing. The most commonly used interspace distance is PP', since it equals zero for a thin lens, but the equations using FF' are simpler. Newton's equations give $z = -f/m$ and $z' = -mf'$, so the object-to-image distance is

$$OO' = FF' - z + z' = FF' - f'm + \frac{f}{m} = FF' - \frac{1}{\phi}\left(n'm + \frac{n}{m}\right) \tag{184}$$

This is the basic equation from which all others are derived. If the reference points are the principal points, then

$$OO' = PP' + f'(1-m) - f\left(1 - \frac{1}{m}\right) = PP' + \frac{1}{\phi}\left[n'(1-m) + n\left(1 - \frac{1}{m}\right)\right] \tag{185}$$

If the object-to-image distance is given, the magnification is

$$m = \frac{1}{2n'}(-q \pm \sqrt{q^2 - 4nn'})$$

where $q = \phi(OO' - PP') - n - n'$. (186)

There are two magnifications for which OO' is the same. The magnitude of their product is n/n'. The derivative of the object-to-image distance with respect to the magnification is

$$\frac{d}{dm}OO' = -f' - \frac{f}{m^2} = -f' - \frac{z^2}{f} = \frac{1}{\phi}\left(\frac{n}{m^2} - n'\right) \tag{187}$$

Extrema occur at $m \pm \sqrt{n/n'}$, giving $m = \pm 1$ if $n = n'$. The extrema are

$$OO' - FF' = \pm \frac{2}{\phi}\sqrt{nn'} = \pm 2\sqrt{-ff'} \tag{188}$$

or

$$OO' - PP' = \frac{1}{\phi}(n + n' \pm 2\sqrt{nn'}) = f' - f \pm 2\sqrt{-ff'} \tag{189}$$

For the common case of $n' = n$, the object-to-image distance is

$$OO' = PP' + f'\left(2 - m - \frac{1}{m}\right) \tag{190}$$

OO' is the same for magnifications m and $1/m$. For a lens with $f' > 0$, the extremum object-to-image distances are $OO' - PP' = 4f'$ with $m = -1$ and $OO' - PP' = 0$ for $m = +1$. If the object-to-image distance and the focal length are given, then the magnification is

$$m = -\tfrac{1}{2}s \pm \sqrt{\tfrac{1}{4}s^2 - 1}$$

where $s = \dfrac{1}{f'}(OO' - PP') - 2$. (191)

The two values of m are reciprocal.

Axial Separations and Longitudinal Magnification. Two axial points A and B are imaged at A' and B' with magnifications m_A and m_B. Newton's equations give the object separation

$$\Delta z = z_A - z_B = \frac{m_A m_B}{m_B - m_A} f \tag{192}$$

The separation of their images is

$$\Delta z' = z'_A - z'_B = (m_B - m_A)f' \tag{193}$$

The ratio of the image and object separations is

$$\frac{\Delta z'}{\Delta z} = \frac{z'_A - z'_B}{z_A - z_B} = \frac{A'B'}{AB} = \frac{n'}{n} m_A m_B = -\frac{f'}{f} m_A m_B \tag{194}$$

If m_A and m_B have different signs, then the direction of $A'B'$ is opposite that of AB. This occurs when A and B are on opposite sides of the front focal point. In the limit as the separation between A and B vanishes, m_A and m_B both approach the same magnification m. The *longitudinal magnification* m_L is the ratio of axial separations in the limit of small separations

$$m_L = \underset{A \to B}{\mathit{LIMIT}} \frac{A'B'}{AB} = \frac{dz'}{dz} = \frac{n'}{n} m^2 = -\frac{z'}{z} \tag{195}$$

This quantity is also called the *axial magnification.* Since m^2 is always positive, as an object moves axially in a given direction, its image moves in a constant direction. There is a discontinuity in image position when the object crosses the focal point, but the direction of motion stays the same. At the nodal points, the transverse and longitudinal magnifications are equal.

Angular Magnification. The ratio of the outgoing to incoming ray angles, u'/u is sometimes called the *angular magnification* m_α. If the ray passes through conjugate axial points with magnification m, then the angular magnification is

$$m_\alpha = \frac{u'}{u} = \frac{n}{n'}\frac{1}{m} \tag{196}$$

If the ray leaves an object point with height y in a plane for which the magnification is m, the outgoing ray angle is given by

$$n'u' = \frac{1}{m}nu - y\phi = \frac{1}{m}(nu - y'\phi) \tag{197}$$

The ratio u'/u is not constant unless $y = 0$ or $\phi = 0$.

Relationship Between Magnifications. The transverse, angular, and longitudinal magnifications are related by

$$m_\alpha m_L = m \tag{198}$$

This relationship is connected to the paraxial invariant and also holds for afocal lenses.

Reduced Coordinates. Many relationships are formally simplified by using reduced axial distances $\tau = z/n$ and $\tau' = z'/n'$ and reduced angles $\omega = nu$, $\omega' = n'u'$, which are paraxial optical direction cosines. For example, the angular magnification is $\omega'/\omega = 1/m$, and the longitudinal magnification is $d\tau'/d\tau = m^2$.

Mechanical Distances. The cardinal points can be located anywhere on axis relative to the physical structure of the lens. The *vertex* of a lens is its extreme physical point on axis. The object space vertex is denoted by V and the image space vertex by V'. The two vertices are not, in general, conjugate. The *front focal distance FV* is that from the vertex to the front focal point, and the *rear focal distance V'F'* is that from the rear vertex to the rear focal point. Likewise, the *front working distance OV* is the distance from the object to the vertex, and the *rear working distance V'O'* is that from the vertex to the image. These lengths have no significance to the gaussian description of a lens. For example, a lens of a given focal length can have any focal distance and vice versa. For a *telephoto* lens the focal length is greater than the focal distance, and for a *retrofocus* lens the focal distance is greater than the focal length.

Afocal Lenses

An *afocal* or *telescopic* lens (Wetherell 1987,[189] Wetherell 1994,[190] Goodman 1988[191]) is one for which $\phi = 0$. A ray entering with $u = 0$ leaves with $u' = 0$, Fig. 15. There are no

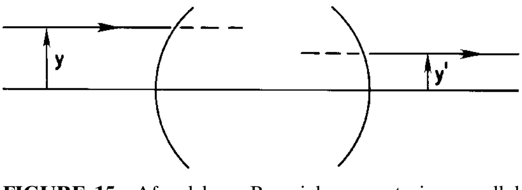

FIGURE 15 Afocal lens. Paraxial rays entering parallel to the axis leave parallel, in general at a different height. The ratio of the heights is the transverse magnification, which is constant.

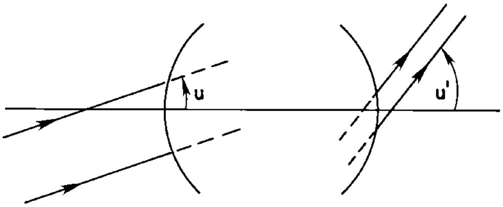

FIGURE 16 Afocal lens. Groups of paraxial rays entering parallel leave parallel, in general at a different angle. The ratio of the angles is the angular magnification, which is constant.

principal focal points or focal lengths. In general, the $u = 0$ ray leaves at a different height than that at which it enters. The ratio y'/y is the same for all such rays, so the transverse magnification m is constant. Likewise, the longitudinal magnification is constant, equaling $m_L = (n'/n)m^2$, as is the angular magnification $u'/u = m_\alpha = n/(n'm)$. A parallel bundle of rays entering at angle u leaves as a parallel bundle at $u' = m_\alpha u$, Fig. 16. Summarizing:

$$m = \text{const} \qquad m_L = \frac{n'}{n}m^2 = \text{const} \qquad m_\alpha = \frac{n}{n'}\frac{1}{m} = \text{const} \qquad m = m_L m_\alpha \tag{199}$$

Any two of these magnifications provide the two scaling factors that describe the system. If $m = n/n'$, then $m_L = m$ and $m_\alpha = 1$, so image space is a scaled version of object space.

Afocal lenses differ fundamentally from focal lenses. Objects at infinity are imaged by afocal lenses at infinity, and objects at finite distances are imaged at finite distances. An afocal lens has no cardinal points and the focal length is undefined. Afocal lenses have no principal planes. If $m \neq 1$ there are no unit magnification conjugates, and if $m = 1$ there is only unit magnification. Likewise, there are no nodal points; the angular magnification is either always unity or always differs from unity. It is sometimes stated or implied that an afocal lens is a focal one with an infinite focal length, but this description is dubious. For example, the above equations relating magnification and conjugate positions to focal length are meaningless for afocal lenses, and they cannot be made useful by substituting $f = \infty$. The equations for the afocal lenses can be obtained from those for focal lenses with a limiting process, but for most purposes this approach is not helpful.

If the positions for a single axial conjugate pair A and A' are known, other pairs are located from the property of constant longitudinal magnification. If O and O' are another pair of conjugates, then

$$A'O' = m_L AO \tag{200}$$

As a function of distance AO, the object-to-image distance OO' is

$$OO' = AA' + (m_L - 1)AO \tag{201}$$

where AA' is the separation between the initially known conjugates. If $m_L = 1$, the object-to-image distance is constant. Otherwise, it can take any value. For all afocal lenses, except those for which $m_L = 1$, there is a position, sometimes called the *center,* at which $OO' = 0$, so the object and image planes coincide.

A principal use of afocal lenses is in viewing distant objects, as with binoculars. An object of height h a great distance d from the lens subtends an angle $\psi \simeq h/d$. The image height is $h' = mh$, and the image distance is approximately $d' = m^2 d$. So the image subtends an angle $\psi' \simeq m\psi = \psi/m_\alpha$. Thus a telescope used visually produces an image which is actually smaller, but which is closer by a greater factor, so the subtense increases.

Determination of Gaussian Parameters

If a lens prescription is given, its gaussian properties can be obtained by paraxially tracing any two meridional rays whose invariant is not zero. A common choice for focal lenses is the rays with $u = 0$ and $u' = 0$, which give F, P, F', and P'. If a lens is known to be afocal, a single ray not parallel to the axis suffices, since such a ray gives a pair of conjugates and the angular magnification. If it is not known that the lens is afocal, two rays show that it is, as well as giving the required information about conjugates. Alternately, a matrix representation of the lens can be determined, from which the cardinal points are found, as described in the matrix section. The gaussian properties can also be determined experimentally in a number of ways.

Basic Systems

Single Refracting Surface. Media of indices n and n' are separated by a surface of curvature c and radius r. The power is $\phi = (n' - n)c$. The principal points coincide at the vertex. The nodal points coincide at the center of curvature. The distance from principal points to nodal points is r.

Thick Lens. The term *thick lens* usually denotes a singlet whose vertex-to-vertex distant is not negligible, where negligibility depends on the application. For a singlet of index n in vacuum with curvatures c_1 and c_2 and thickness t, measured from vertex to vertex

$$\phi = \frac{1}{f'} = (n-1)\left[c_1 - c_2 - \frac{n-1}{n} t c_1 c_2\right] \tag{202}$$

A given power may be obtained with a variety of curvatures and indices. For a given power, higher refractive index gives lower curvatures. The principal planes are located relative to the vertices by

$$VP = \frac{n-1}{n}\frac{tc_2}{\phi} \qquad \text{and} \qquad V'P' = -\frac{n-1}{n}\frac{tc_1}{\phi} \tag{203}$$

These equations can be derived by treating the lens as the combination of two refracting surfaces. Two additional relationships are

$$PP' = VV' - \frac{n-1}{n}\frac{t(c_1 + c_2)}{\phi} \qquad \text{and} \qquad \frac{V'P'}{VP} = \frac{r_2}{r_1} = \frac{c_1}{c_2} \tag{204}$$

Thin Lens. A *thin lens* is the limiting case of a refracting element whose thickness is negligible, so the principal planes coincide, and the ray bending occurs at a single surface, Fig. 17. In the limit as $t \to 0$, for a lens in vacuum the thick lens expressions give

$$\phi = \frac{1}{f'} = (n-1)(c_1 - c_2) \qquad VP = V'P' = 0 \qquad PP' = 0 \tag{205}$$

Single Reflecting Surface. A reflecting surface has power $\phi = 2n/r = 2nc$. The principal points are located at the vertex. The nodal points are at the center of curvature.

Mirror as a Thin Lens. In unfolding systems, a mirror can be thought of as a convex or

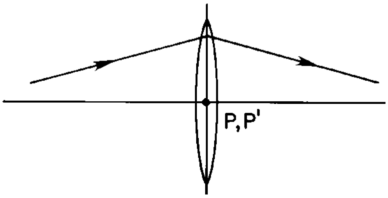

FIGURE 17 The thin lens approximation. The thickness of the lens is negligible, and the principal planes are coincident, so rays bend at the common plane.

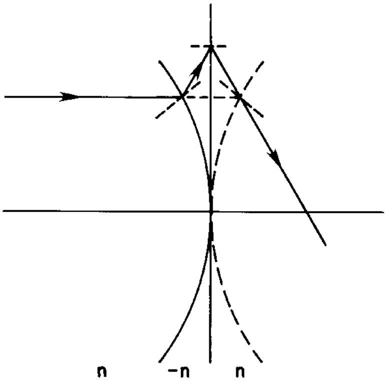

FIGURE 18 Reflecting surface represented unfolded. A convex mirror is represented as a convex-plano thin lens with index $n' = -n$, where n is the index of the medium. Snell's law gives $I' = -I$.

concave plano thin lens, with an index $-n$, where n is the index of the medium in which it works, Fig. 18. All the thin lens equations apply, as well as those for third-order aberration equations, which are not discussed here.

1.15 COLLINEATION

Introduction

Collineation is a mathematical transformation that approximates the imaging action of a lens with homogeneous refractive indices in both spaces. This transformation takes points to points, lines to lines, and planes to planes. With an actual lens, incoming rays become outgoing rays, so lines go exactly to lines. In general, however, rays that interest in object space do not intersect in image space, so points do not go to points, nor planes to planes. The collinear transformation is an approximate description of image geometry with the intervening optical system treated as a black box, not a theory that describes the process of image formation. Collineation is also referred to as *projective transformation.* The historical development of this approach, which was first applied to optics by Möbius (Möbius 1855[192]), is discussed by Southall (Southall, 1910[193]). Several authors give extensive discussions (Czapski 1893,[194] Drude 1901[195] Southall 1910,[193] Wandersleb 1920,[196] Chrétien 1980[197]). Projective transformation is used in computer graphics, and is discussed in this context in a number of recent books and papers.

The imaging described by collineation is, by definition, stigmatic everywhere, and planes are imaged without curvature. And for rotationally symmetric lenses, planes perpendicular to the axis are imaged without distortion. So the three conditions of maxwellian perfection are satisfied for all conjugates. Consequently, collineation is often taken as describing ideal imaging of the entire object space. However, it is physically impossible for a lens to image as described by collineation, except for the special case of an afocal lens with $m = m_L = n/n'$. The putative ray intersections of collineation violate the equality of optical path lengths for the rays involved in the imaging of each point. The intrinsic impossibility manifests itself in a variety of ways. As an example, for axial points in a plane with transverse magnification m and ray angles θ and θ' relative to the axis, collineation gives $m \propto \tan\theta/\tan\theta'$, but optical path length considerations require that $m \propto \sin\theta/\sin\theta'$. Another violation is that of the skew invariant $\mathcal{S} = n(\alpha y - \beta x)$. The ratio of this quantity before and after collineation is not unity, but $\mathcal{S}'/\mathcal{S} = \gamma'/\gamma$, where γ is the axial direction cosine in object space and γ' is that in image space.

The expressions for collineation do not contain refractive indices, another manifestation of their not accounting for optical path length. Rather than the refractive index ratio n'/n, which occurs in many imaging equations, the expressions of collineation involve ratios of focal lengths. For afocal lenses there are ratios of transverse and longitudinal magnifications or ratios of the focal lengths of the lenses making up the afocal system.

The expressions for actual ray behavior take the form of collineation in the paraxial, and, more generally, parabasal limits. So paraxial calculations provide the coefficients of the transformation for any particular system.

Collineation is most often treated by starting with the general form, and then reducing its complexity by applying the symmetries of a rotationally symmetric system, to give familiar simple equations such as Newton's (Born & Wolf 1980[198]). Alternatively, it is possible to begin with the simple forms and to derive the general ones therefrom with a succession of images, along with translations and rotations. However, the more important use of these properties is in treating lenses lacking rotational symmetry. This includes those comprised of elements that are arbitrarily oriented, that is, tilted or decentered—either intentionally or unintentionally. Other examples are nonplanar objects, tilted object planes, and arbitrary three-dimensional object surfaces.

Lenses, along with plane mirror systems, can form a succession of images and can produce translations and rotations. Correspondingly, a succession of collinear transformations is a collinear transformation, and these transformations form a group. It is associative, corresponding to the fact that a series of imaging operations can be associated pairwise in any way. There is a unit transformation, correspondingly physically to nothing or to a unit magnification afocal lens. There is an inverse, so an image distorted as a result of object or lens tilt can be rectified by an appropriately designed system—to the extent that collineation validly describes the effects.

General Equations

The general form of the collinear transformation is

$$x' = \frac{a_1 x + b_1 y + c_1 z + d_1}{ax + by + cz + d} \qquad y' = \frac{a_2 x + b_2 y + c_2 z + d_2}{ax + by + cz + d} \qquad z' = \frac{a_3 x + b_3 y + c_3 z + d_3}{ax + by + cz + d} \tag{206}$$

At least one of the denominator coefficients, a, b, c, d, is not zero. The equations can be inverted, so there is a one-to-one correspondence between a point (x, y, z) in object space and a point (x', y', z') in image space. The inverted equations are formally identical, and can be written by replacing unprimed quantities with primed ones and vice versa in the above equation. It is seen that a plane is transformed to a plane, since $a'x' + b'y' + c'z' + d' = 0$ has the same form as a function of (x, y, z). An intersection of two planes gives a line. It can also be shown that a line transforms to a line by writing the equation for a line in parametric form, with parameter σ, $x(\sigma) = x_0 + \alpha\sigma$, $y(\sigma) = y_0 + \beta\sigma$, $z(\sigma) = z_0 + \gamma\sigma$. Substituting in the transformation equations, it is found that $dx'/dy' = (dx'/d\sigma)/(dy'/d\sigma)$ is constant, as are other such ratios.

These equations contain 16 coefficients, but it is possible to divide all three equations through by one of the coefficients, so there are 15 independent coefficients in general. Since the location of an image point is described by three coordinates, five points that are not coplanar determine the transformation.

The ratios of the coefficient dimensions are determined by the fact that x, y, z and x', y', z' are lengths. A variety of schemes can be used and, in the expressions below, a given symbol may have different dimensions.

There are two major categories of the transformation, according to whether the denominator varies or is constant. That with a varying denominator corresponds to focal lenses. For afocal lenses, the demonimator is constant, and the general form of the transformation is

$$x' = a_1x + b_1y + c_1z + d_1 \qquad y' = a_2x + b_2y + c_2z + d_2 \qquad z' = a_3x + b_3y + c_3z + d_3 \tag{207}$$

Here coefficient d has been normalized to unity. Such a transformation is called *affine* or *telescopic.*

Coordinate Systems and Degrees of Freedom

The transformation involves two coordinate systems. The origin of each is located by three parameters, as is the orientation of each. This leaves three parameters that describe the other aspects of the transformation for the most general case of no symmetry. The number is reduced to two if there is rotational symmetry.

In addition to considering the transformation of the entire space, there are other cases, especially the imaging of planes. In each situation, there are specific coordinate systems in which the aspects of the relationship, other than position and orientation, are most simply expressed. Accordingly, different coordinate systems are used in the following sections. Thus, for example, the z axis in one expression may not be the same as that for another.

Simplest Form of the General Transformation

For focal lenses, the denominators are constant for a set of parallel planes

$$ax + by + cz + d = \text{constant} \tag{208}$$

Each such plane is conjugate to one of a set of parallel planes in the other space. Within each of these planes, the quantities $\partial x'/\partial x$, $\partial x'/\partial y$, $\partial x'/\partial z$ are constant, as are the other such derivatives. Therefore, magnifications do not vary with position over these planes, although they do vary with direction. There is one line that is perpendicular to these planes in one space whose conjugate is perpendicular to the conjugate planes in the other space. It can be taken to be the z axis in one space and the z' axis in the other. The aximuths of the x-y and x'-y' axes are found by imaging a circle in each space, which gives an ellipse in the other. The directions of the major and minor axes determine the orientations of these coordinate axes. The *principal focal planes,* are the members of this family of planes for which

$$0 = ax + by + cz + d \tag{209}$$

Lines that are parallel in one space have conjugates that intersect at the principal focal plane in the other. The *principal focal points* are the intersection of the axes with the focal planes.

Using these simplifying coordinate systems, the general transformation is

$$x' = \frac{a_1 x}{cz + d} \qquad y' = \frac{b_1 y}{cz + d} \qquad z' = \frac{c_3 z + d_3}{cz + d} \tag{210}$$

One of the six coefficients can be eliminated, and two of the others are determined by the choice of origins for the z axis and z' axis. If the origins are taken to be at the principal focal points, the transformation equations are

$$x' = \frac{e_x x}{z} \qquad y' = \frac{e_y y}{z} \qquad z' = \frac{e_z}{z} \tag{211}$$

where e_x, e_y, e_z are constants. Unless $e_x = e_y$, the images of shapes in constant z planes vary with their orientations. Squares in one orientation are imaged as rectangles, and in others as parallelograms. Squares in planes not perpendicular to the axes are imaged, in general, with four unequal sides.

For afocal lenses, the simplest form is

$$x' = m_x x \qquad y' = m_y y \qquad z' = m_z z \tag{212}$$

Spheres in one space are imaged as ellipsoids in the other. The principal axes of the ellipsoids give the directions of the axes for which the imaging equations are simplest.

Conjugate Planes

A pair of conjugate planes can be taken to have $x = 0$ and $x' = 0$, so the general transformation between such planes is

$$y' = \frac{b_2 y + c_2 z + d_2}{by + cz + d} \qquad z' = \frac{b_3 y + c_3 z + d_3}{by + cz + d} \tag{213}$$

There are eight independent coefficients, so four points that are not in a line define the transformation. In each space, two parameters specify the coordinate origins and one the orientation. Two parameters describe the other aspects of the transformation.

The simplest set of coordinates is found by a process like that described above. For focal lenses, constant denominators define a line set of parallel lines

$$by + cz + d = \text{constant} \tag{214}$$

with similar conjugate lines in the other space. There is a line that is perpendicular to this family in one space, whose conjugate is perpendicular in the other, which can be taken as the z axis on one side and the z' axis on the other. There is a *principal focal line* in the plane in each space, and a *principal focal point,* at its intersection with the axis. In this coordinate system the transformation is

$$y' = \frac{b_2 y}{cz + d} \qquad z' = \frac{c_3 z + d_3}{cz + d} \tag{215}$$

Of the five coefficients, four are independent and two are fixed by the choice of origins. If $z = 0$ and $z' = 0$ are at the principal focal points, then

$$y' = \frac{e_y y}{z} \qquad z' = \frac{e_z}{z} \tag{216}$$

where e_y and e_z are constants.

For afocal lenses, the general transformation between conjugate planes is

$$y' = b_2 y + c_2 z + d_2 \qquad z' = b_3 y + c_3 z + d_3 \tag{217}$$

The simplest form of the transformation is

$$y' = m_y y \qquad z' = m_z z \tag{218}$$

where m_y and m_z are constants.

Conjugate Lines

A line can be taken to have $x = 0$, $y = 0$, $x' = 0$, $y' = 0$, so its transformation is

$$z' = \frac{c_3 z + d_3}{cz + d} \tag{219}$$

There are three independent coefficients, so three points determine them. The origins in the two spaces account for two of the parameters, leaving one to describe the relative scaling. The simplest forms are

$$\text{Focal:} \quad z' = \frac{e_z}{z} \qquad \text{Afocal:} \quad z' = m_z z \tag{220}$$

There is a relationship between distances along a line (or ray) that is unchanged in collineation (Southall 1910,[193] Southall 1933[199]). If four points on a line A, B, C, D have images A', B', C', D', the *double ratio* or *cross ratio* is invariant under projective transformation, that is,

$$\frac{AC}{BC}\frac{BD}{AD} = \frac{A'C'}{B'C'}\frac{B'D}{A'D} \tag{221}$$

where AC is the distance from A to C, and likewise for other pairs.

Matrix Representation of the Transformation

The transformation can be expressed in linear form by using the variables (u_1, u_2, u_3, u_4) and (u_1', u_2', u_3', u_4'), where $x = u_1/u_4$, $y = u_2/u_4$, $z = u_3/u_4$ and $x' = u_1'/u_4'$, $y' = u_2'/u_4'$, $z' = u_3'/u_4'$. These are referred to as *homogeneous coordinates*. The transformation can be written

$$\begin{pmatrix} u_1' \\ u_2' \\ u_3' \\ u_4' \end{pmatrix} = \begin{pmatrix} a_1 & b_1 & c_1 & d_1 \\ a_2 & b_2 & c_2 & d_2 \\ a_3 & b_3 & c_3 & d_3 \\ a & b & c & d \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{pmatrix} \tag{222}$$

In terms of the cartesian coordinates and an additional pair of terms q and q', the transformation can be expressed as

$$\begin{pmatrix} q'x' \\ q'y' \\ q'z' \\ q' \end{pmatrix} = \begin{pmatrix} a_1 & b_1 & c_1 & d_1 \\ a_2 & b_2 & c_2 & d_2 \\ a_3 & b_3 & c_3 & d_3 \\ a & b & c & d \end{pmatrix} \begin{pmatrix} qx \\ qy \\ qz \\ q \end{pmatrix} \tag{223}$$

The dimensions of q and q' depend on the choice of coefficient dimensions. Here $q'/q = ax + by + cz + d$, the equation for the special set of planes.

Certain sections of the matrix are associated with various aspects the transformation (Penna & Patterson 1986[200]). The first three elements in the rightmost column have to do with translation. This is shown by setting $(x, y, z) = (0, 0, 0)$ to locate the conjugate in the other space. The first three elements in the bottom row are related to perspective transformation. The upper left-hand 3×3 array expresses rotation, skew, and local magnification variation.

For the simple form of the transformation expressed in Eq. (211), $a_1 = e_x$, $b_2 = e_y$, $d_3 = e_z$, $c = 1$, and the rest of the coefficients vanish. The general matrix representation for the afocal transformation is

$$\begin{pmatrix} x' \\ y' \\ z' \\ 1 \end{pmatrix} = \begin{pmatrix} a_1 & b_1 & c_1 & d_1 \\ a_2 & b_2 & c_2 & d_2 \\ a_3 & b_3 & c_3 & d_3 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} \tag{224}$$

The quantities q and q' can also be included, in which case $q' = q$. In the simplest afocal form, Eq. (212), the matrix is diagonal with $a_1 = m_x$, $b_2 = m_y$, $d_3 = m_z$, and the rest of the nondiagonal coefficients vanishing. A succession of collineations can be treated by multiplying the matrices that describe them (Chastang 1990[201]). To combine lenses with arbitrary orientations and to change coordinate systems, compatible rotation and translation matrices are required. The transformation for a pure rotation with direction cosines (L, M, N) is

$$\begin{pmatrix} x' \\ y' \\ z' \\ 1 \end{pmatrix} = \begin{pmatrix} 1 - 2L^2 & -2LM & -2LN & 0 \\ -2LM & 1 - 2M^2 & -2MN & 0 \\ -2LN & -2MN & 1 - 2N^2 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} \tag{225}$$

The transformation for translation by $(\Delta x, \Delta y, \Delta z)$ is

$$\begin{pmatrix} x' \\ y' \\ z' \\ 1 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 & \Delta x \\ 0 & 1 & 0 & \Delta y \\ 0 & 0 & 1 & \Delta z \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} \tag{226}$$

The quantities q and q' can be included if necessary. The transformations associated with conjugate planes can likewise be expressed with 3×3 matrices, and the transformations of lines with 2×2 matrices.

Rotationally Symmetric Lenses

For rotationally symmetric lenses, the simplest forms are obtained with the z and z' axes corresponding to the lens axis in the two spaces, and the x and x' meridians corresponding. There is one less degree of freedom than in the general case, and $a_1 = b_2$ in Eq. (210). The general transformation is thus

$$x' = \frac{a_1 x}{cz + d} \qquad y' = \frac{a_1 y}{cz + d} \qquad z' = \frac{c_3 z + d_3}{cz + d} \tag{227}$$

There are four degrees of freedom, two associated with the lens and two with the choice of coordinate origins. For focal lenses, the two axial length parameters are f and f'. If the coordinate origins are at the focal points,

$$x' = -\frac{fx}{z} \qquad y' = -\frac{fy}{z} \qquad z' = \frac{f'f}{z} \tag{228}$$

If the coordinate origins are conjugate and related by magnification m_0, then

$$x' = \frac{m_0 x}{1 + z/f} \qquad y' = \frac{m_0 y}{1 + z/f} \qquad z' = \frac{(f'/f)m_0^2 z}{1 + z/f} \tag{229}$$

The constant term in the numerator of the z' expression is the longitudinal magnification for $z = 0$, for which point $dz'/dz = (f'/f)m_0^2$. A special case of these equations is that for which the principal points are the origins, so $m_0 = 1$.

For rotationally symmetric afocal lenses, the two degrees of freedom are the transverse magnification $m_x = m_y = m$, and the longitudinal magnification $m_z = m_L$. The simplest set of transformation equations is

$$x' = mx \qquad y' = my \qquad z' = m_L z \tag{230}$$

where $z = 0$ and $z' = 0$ are conjugate. If $m = \pm 1$ and $m_L = \pm 1$ the image space replicates object space, except possibly for orientation. If $m_L = m$, the spaces are identical except for overall scaling and orientation. The m and m_L appear as functions of ratios of focal lengths of the lenses that make up the afocal system.

Rays for Rotationally Symmetric Lenses

A skew ray with direction cosines (α, β, γ) in object space is described in parametric form with parameter z as follows

$$x(z) = x_0 + \frac{\alpha}{\gamma} z \qquad y(z) = x_0 + \frac{\beta}{\gamma} z \tag{231}$$

For a focal lens, if $z = 0$ is taken to be the front focal plane, and $z' = 0$ is the rear focal plane, the parametric form of the ray in image space is

$$x'(z') = \left(-f\frac{\alpha}{\gamma}\right) + \left(-\frac{x_0}{f'}\right)z' \qquad y'(z') = \left(-f\frac{\beta}{\gamma}\right) + \left(-\frac{y_0}{f'}\right)z' \tag{232}$$

So $x_0' = -f\alpha/\gamma$, $y_0' = -f\beta/\gamma$, $\alpha'/\gamma' = -x_0/f'$, $\beta'/\gamma' = -y_0/f'$. For meridional rays with $x = 0$, if θ and θ' are the ray angles in the two spaces, then $\tan\theta = \beta/\gamma$, $\tan\theta' = -y_0/f'$, and

$$\frac{\tan\theta}{\tan\theta'} = \frac{f'}{f} m \tag{233}$$

where m is the transverse magnification in a plane where the meridional ray crosses the axis.

For afocal lenses, if $z = 0$ and $z' = 0$ are conjugate planes, the ray in image space is given by

$$x'(z') = mx_0 + \left(\frac{m}{m_L}\frac{\alpha}{\gamma}\right)z' \qquad y'(z') = my_0 + \left(\frac{m}{m_L}\frac{\beta}{\gamma}\right)z' \tag{234}$$

For meridianal rays with $x = 0$,

$$\frac{\tan\theta}{\tan\theta'} = \frac{m_L}{m} \tag{235}$$

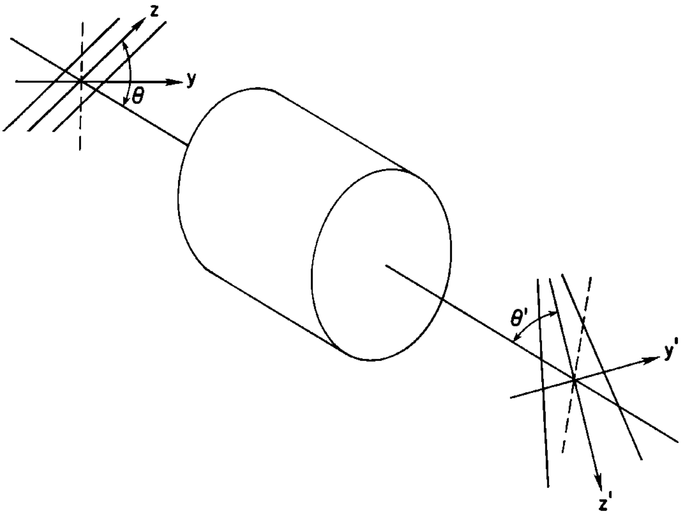

FIGURE 19 The image plane for a tilted object plane. The y-z plane is the object plane and the y'-z' plane is the image plane. The angles between the planes and the lens axis are θ and θ', which are related by Eq. (232). The conjugate points in these planes are related by Eq. (235).

Tilted Planes with Rotationally Symmetric Lenses

A plane making an angle θ with the lens axis in object space has an image plane that makes an angle θ', given by Eq. (233), the so-called *Scheimpflug condition* (Scheimpflug 1907,[202] Sasian 1992[203]). A tilted plane and its image are perpendicular to a meridian of the lens, Fig. 19. There is bilateral symmetry on these planes about the intersection line with the meridian, which is taken to be the z axis in object space and the z' axis in image space. The perpendicular, coordinates are y and y'. Letting m_0 be the transverse magnification for the axial point crossed by the planes, the transform equations are

$$y' = \frac{m_0 y}{1 + z/g} \qquad z' = \frac{(g'/g)m_0^2 z}{1 + z/g} \tag{236}$$

Here g and g' are the focal lengths in the tilted planes, the distances from the principal planes to the focal planes of the lens, measured along the symmetry line, so

$$g = \frac{f}{\cos\theta} \qquad g' = \frac{f'}{\cos\theta'} \qquad \text{and} \qquad \frac{g'}{g} = \sqrt{\left(\frac{f'}{f}\right)^2 \cos^2\theta + \frac{1}{m_0^2}\sin^2\theta} \tag{237}$$

As $\theta \rightarrow 90°$, g and g' become infinite, and $(g'/g)m_0 \rightarrow 1$, giving $y' \rightarrow m_0 y$ and $z' \rightarrow m_0 z$. (Forms like Newton's equations may be less convenient here, since the distances from the axes to the focal points may be large.)

For an afocal lens with transverse magnification m and longitudinal magnification m_L, the object and image plane angles are related by Eq. (235). The conjugate equations for points in the planes are

$$y' = my \qquad z' = (m_L^2 \cos^2\theta + m^2 \sin^2\theta)^{1/2} z \tag{238}$$

Here the origins may be the axial intersection point, or any other conjugate points.

Some General Properties

For all collinear transformations, points go to points, lines to lines, and planes to planes. In general, angles at intersections, areas, and volumes are changed. The degree of a curve is unchanged, so, for example, a conic is transformed into a conic. For focal systems, a "closed" conic, an ellipse or circle, may be imaged as either a closed or an "open" one, a parabola or hyperbola. For afocal systems, the closedness and openness are preserved. With focal systems, the imaging of a shape varies with its location, but for afocal systems it does not. For afocal systems parallelness of lines is maintained, but for focal systems the images of parallel lines intersect. For afocal systems, equal distances along lines are imaged as equal distances, but are different unless the magnification is unity.

1.16 SYSTEM COMBINATIONS—GAUSSIAN PROPERTIES

Introduction

This section deals with combinations of systems, each of which is of arbitrary complexity. From a gaussian description of each lens and the geometry of the combination, the gaussian description of the net system can be found. If two rotationally symmetric lenses are put in series with a common axis, the resultant system is also rotationally symmetric. Its gaussian description is found from that of the two constituent lenses and their separations. The net magnification is the product of the two contributions, i.e., $m = m_1 \times m_2$. Matrix methods are particularly convenient for handling such combinations, and the results below can be demonstrated easily thereby. If two rotationally symmetric lenses are combined so their axes do not coincide, the combination can be handled with appropriate coordinate translations and rotations in the intermediate space, or by means of collineation. In the most general case, where subsystems without rotational symmetry are combined, the general machinery of collineation can be applied. There are three classes of combinations: focal-focal, focal-afocal, and afocal-afocal.

Focal-Focal Combination—Coaxial

The first lens has power ϕ_1 and principal points at P_1 and P_1', Fig. 20. The index preceding the lens is n and that following it is n_{12}. The second lens has power ϕ_2 and principal points at P_2 and P_2', with preceding index n_{12} and following index n'. The directed distance from the rear principal point of the first lens to the first principal point of the second lens is

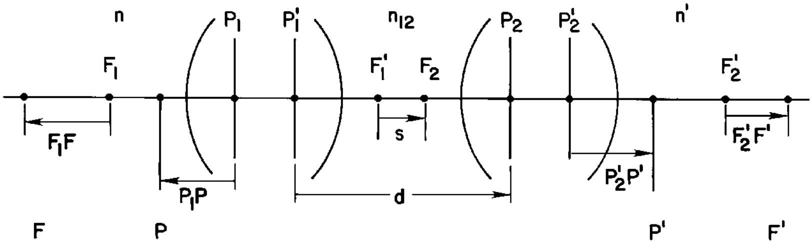

FIGURE 20 Coaxial combination of two focal lenses. The cardinal points of the two lenses are shown above the axis and those of the system below. The directions in this drawing are only one possible case.

$d = P_1'P_2'$, which may be positive or negative, since the lenses may have external principal planes. The power of the combination is

$$\phi = \phi_1 + \phi_2 - \frac{1}{n_{12}} d\phi_1\phi_2 \tag{239}$$

The two principal planes of the combination are located relative to those of the contributing lenses by directed distances

$$P_1P = +\frac{n}{n_{12}} d\frac{\phi_2}{\phi} \qquad P_2'P' = -\frac{n'}{n_{12}} d\frac{\phi_1}{\phi} \tag{240}$$

If $\phi = 0$, the combination is afocal and there are no principal planes. In applying these equations, the inner-space index n_{12} must be the same as that for which the two lenses are characterized. For example, if two thick lenses are characterized in air and combined with water between them, these equations cannot be used by simply changing n_{12}. It would be necessary to characterize the first lens with water following it and the second lens with water preceding it.

Another set of equations involves the directed distance from the rear focal point of the first lens to the front focal point of the second, $s = F_1'F_2$. The power and focal lengths of the combination are

$$\phi = -\frac{1}{n_{12}} s\phi_1\phi_2 \qquad f = +\frac{f_1f_2}{s} \qquad f' = -\frac{f_1'f_2'}{s} \tag{241}$$

The focal points are located with respect to those of the contributing lenses by

$$F_1F = +\frac{nn_{12}}{s\phi_1^2} = \frac{n_{12}f_1^2}{n\ \ s} \qquad F_2'F' = -\frac{n'n_{12}}{s\phi_2^2} = -\frac{n_{12}f_2'^2}{n'\ \ s} \tag{242}$$

Another relationship is $(F_1F)(F_2'F') = ff'$. The system is afocal if $s = 0$. There are many special cases of such combinations. Another case is that when the first principal point of the second lens is at the rear focal point of the first, in which case the system focal length is that of the first. These relationships are proven by Welford (Welford 1986, p. 35[204]).

Focal-Afocal—Coaxial

A focal lens combined with an afocal lens is focal, Fig. 21. Here we take the afocal lens to be to the left, with magnification m_1. The focal lens to the right has power ϕ_2 and rear

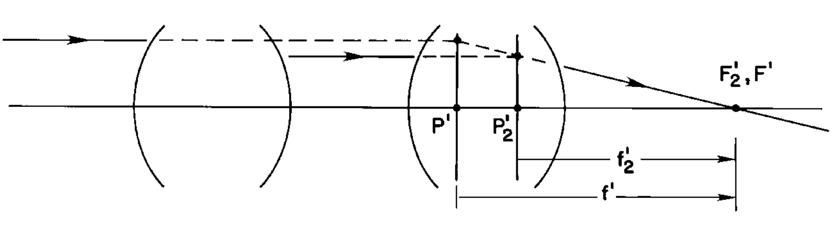

FIGURE 21 Coaxial combination of a focal lens and an afocal lens. In this drawing the afocal lens has a transverse magnification $0 < m_1 < 1$ and the focal lens has a positive power. The combination is a focal lens with focal length $f' = f_2'/m_1$. The focal point on the side of the focal lens is at the focal point of that lens alone.

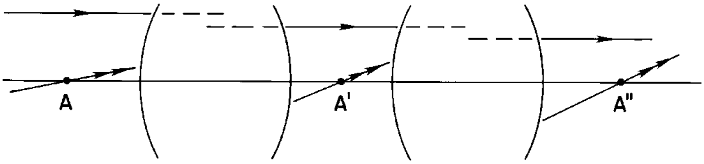

FIGURE 22 Coaxial combination of two afocal lenses. An internal point A' has an object space conjugate A and an image space conjugate A''. These two points can be used for position references in the overall object and image spaces.

focal length f_2'. The power of the combination is $\phi_2 m_1$, and the rear focal length of the combination is $f' = f_2'/m_1$. On the side of the focal lens, the location of the principal focal point is unchanged. On the side of the afocal lens, the system focal point is located at the image of the focal point of the focal lens in the space between the two. Changing the separation between the lenses does not change the power or the position of the principal focal point relative to that of the focal lens. The principal focal point on the afocal lens side does move.

Afocal-Afocal—Coaxial

The combination of two afocal lenses is itself afocal, Fig. 22. If the two lenses have transverse magnifications m_1 and m_2, the combination has $m = m_1 m_2$. A pair of conjugate reference positions is found from the conjugates in the outer regions to any axial point in the inner space. If the separation between the two lenses changes, the combination remains afocal and the magnification is fixed, but the conjugate positions change. This result extends to a combination of any number of afocal lenses.

Noncoaxial Combinations—General

The most general combinations can be handled by the machinery of collineation. The net collineation can be found by multiplying the matrices that describe the constituents, with additional rotation and translation matrices to account for their relative positions. After obtaining the overall matrix, object and image space coordinate systems can be found in which the transformation is simplest. This approach can also be used to demonstrate general properties of system combinations. For example, by multiplying matrices for afocal systems, it is seen that a succession of afocal lenses with any orientation is afocal.

1.17 PARAXIAL MATRIX METHODS

Introduction

Matrix methods provide a simple way of representing and calculating the paraxial properties of lenses and their actions on rays. These methods contain no physics beyond that contained in the paraxial power and transfer equations, Eq. (136) and Eq. (142), but they permit many useful results to be derived mechanically, and are especially useful for lens combinations. The matrix description of systems is also useful in elucidating fundamental paraxial properties. With the symbolic manipulation programs now available, matrix methods also provide a means of obtaining useful expressions.

The optical system is treated as a black box represented by a matrix. The axial positions of the input and output planes are arbitrary. The matrix describes the relationship between what enters and what leaves, but contains no information about the specifics of the system within, and there is an infinity of systems with the same matrix representation.

The origin of matrix methods in optics is not clear. Matrices were used by Samson (Samson 1897[205]) who referred to them as "schemes." Matrices appear without comment in a 1908 book (Leathem 1908[206]). Matrix methods are treated in papers (Halbach 1964,[207] Sinclair 1973[208]) and in many books (O'Neil 1963,[209] Brouwer 1964,[210] Blaker 1971,[211] Longhurst 1973,[212] Gerrard & Burch 1974,[213] Naussbaum & Phillips 1976,[214] Kogelnik 1979,[215] Klein & Furtak 1986,[216] Moller 1988,[217] Guenther 1990[218]). Notation is not standardized, and many treatments are complicated by notation that conceals the basic structures.

This section is limited to rotationally symmetric lenses with homogeneous media. References are provided for systems with cylindrical elements. This treatment is monochromatic, with the wavelength dependence of index not made explicit.

The matrices are simplified by using *reduced axial distances* $\tau = t/n$ and *reduced angles* $\omega = nu$. The paraxial angles u are equivalent to direction cosines, and the reduced angles are optical direction cosines in the paraxial limit. For brevity, ω and τ are usually referred to in this section simply as "angle" and "distance."

Basic Idea—Linearity

Paraxial optics is concerned with the paraxial heights and paraxial angles of rays. A meridional ray entering a system has a given height y and angle ω and leaves with another height y' and angle ω'. Paraxial optics is linear, as discussed above, in the sense that both the outgoing height and angle depend linearly on the incoming height and angle. Writing Eq. (148) in terms of ω's gives

$$y' = \left(\frac{\partial y'}{\partial y}\right)y + \left(\frac{\partial y'}{\partial \omega}\right)\omega \qquad \text{and} \qquad \omega' = \left(\frac{\partial \omega'}{\partial y}\right)y + \left(\frac{\partial \omega'}{\partial \omega}\right)\omega \tag{243}$$

The partial derivatives are constant for a given system. This linearity is the basis of the matrix treatment, since these equations can be written in matrix form:

$$\begin{pmatrix} y' \\ \\ \omega' \end{pmatrix} = \begin{pmatrix} \dfrac{\partial y'}{\partial y} & \dfrac{\partial y'}{\partial \omega} \\ \dfrac{\partial \omega'}{\partial y} & \dfrac{\partial \omega'}{\partial \omega} \end{pmatrix} \begin{pmatrix} y \\ \\ \omega \end{pmatrix} \tag{244}$$

Basic Operations

The basic operations in paraxial ray tracing are transfer, Eq. (136), between surfaces and refraction or reflection at surfaces, Eq. (142).

Transfer Matrix

Transfer changes the height of a ray, in general, leaving the angle unchanged. In terms of reduced quantities, the relationships are:

$$y' = y + tu = y + \frac{t}{n}un = y + \tau\omega \qquad \text{and} \qquad \omega' = \omega \tag{245}$$

The transfer matrix is:

$$\begin{pmatrix} 1 & \tau \\ 0 & 1 \end{pmatrix} \tag{246}$$

For left-to-right transfer, $\tau > 0$. This gives a difference in signs between some of the terms in expressions here and those in the gaussian section, where directed distances are measured from a reference point related to the lens to the object.

Power Matrix

Refraction or reflection changes the angle of a ray, but not its height. The equations for reduced quantities are

$$n'u' = nu - y\phi = \omega' = \omega - y\phi \qquad \text{and} \qquad y' = y \tag{247}$$

Here $\phi = c(n' - n)$ for refraction and $\phi = -2nc$ for reflection, where c is the surface curvature, Eq. (143). The power matrix is:

$$\begin{pmatrix} 1 & 0 \\ -\phi & 1 \end{pmatrix} \tag{248}$$

A planar reflecting or refracting surface has $\phi = 0$, so it is represented by the unit matrix.

Arbitrary System

A general system consists of a series of surfaces with powers $\phi_1, \phi_2, \ldots$ that are separated from one another by distances $\tau_1, \tau_2, \ldots$. Its matrix is the product

$$\begin{pmatrix} 1 & \tau_N \\ 0 & 1 \end{pmatrix} \cdots \begin{pmatrix} 1 & 0 \\ -\phi_2 & 1 \end{pmatrix} \begin{pmatrix} 1 & \tau_2 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -\phi_1 & 1 \end{pmatrix} \begin{pmatrix} 1 & \tau_1 \\ 0 & 1 \end{pmatrix} \tag{249}$$

By convention, the successive matrices are concatenated from right to left, whereas ray tracing is done left to right.

A special case is a succession of transfers, itself a transfer.

$$\text{Succession of transfers:} \quad \begin{pmatrix} 1 & \tau_1 + \tau_2 + \cdots \\ 0 & 1 \end{pmatrix} \tag{250}$$

Another is a series of refractions with no intervening transfer, itself a power operation.

$$\text{Succession of powers:} \quad \begin{pmatrix} 1 & 0 \\ -(\phi_1 + \phi_2 + \cdots) & 1 \end{pmatrix} \tag{251}$$

Matrix Elements

Each matrix element has a physical significance, and the terms can be given mnemonic symbols associated with the conditions under which they are zero. (This practice is not standard.) If the initial ray angle is zero, the outgoing angles depend on the incident ray heights and the power of the system, according to $\omega' = -\phi y$, so $\partial\omega'/\partial y = -\phi$. If the initial surface is at the front focal plane, the outgoing ray angles depend only on the incident height, so $\partial\omega'/\partial\omega = 0$. This term is denoted by F for "front." Similarly, if the final surface is at the real focal plane, the outgoing ray heights depend only on the incoming angles, so $\partial y'/\partial y = R$ for "rear." If the initial and final planes are conjugate, then all incoming rays at a given height y have the outgoing height $y' = my$, regardless of their angle, so $\partial y'/\partial\omega = 0$ for conjugate planes. Since this term is related to the condition of conjugacy, $\partial y'/\partial\omega = C$ for "conjugate." With this notation, the general matrix is

$$\begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} \tag{252}$$

Dimensions

The terms R and F are dimensionless. C has the dimensions of length, and those of ϕ are inverse length. Dimensional analysis, as well as the consideration of Eq. (248), shows that the F and R terms will always contain products of equal numbers of ϕ_l's and τ_k's, such as $\phi_k\tau_l$. The ϕ expression contains terms like ϕ_k and $\tau_k\phi_l\phi_m$, with one more power term than distance terms. Similarly, C has terms like τ_k and $\tau_k\tau_l\phi_m$.

Determinant

Both the transfer and power matrices have unit determinants. Therefore, any product of such matrices has a unit determinant, a fact that is related to the two-ray paraxial invariant.

$$\begin{vmatrix} R & C \\ -\phi & F \end{vmatrix} = FR + C\phi = 1 \tag{253}$$

This provides an algebraic check. For afocal lenses and conjugate arrangements, $FR = 1$.

Possible Zeros

The possible arrangements of zeros in a system matrix is limited by the unit determinant restriction. There can be a single zero anywhere. In this case, either $C = 1/\phi$ or $F = 1/R$, and the remaining nonzero term can have any value. There can be two zeros on either diagonal. No row or column can contain two zeros, since a system represented by such a matrix would violate conservation of brightness. A matrix with double zeros in the bottom row would collimate all rays, regardless of their incoming position and direction. A matrix with all zeros in the top row represents a system that would bring all incoming light to a single point. A system whose matrix has double zeros in the first column would bring all incoming light to a focus on the axis. For double zeros in the second row, the system would concentrate all light diverging from an input point in a single output point with a single direction.

Operation on Two Rays

Instead of considering a single input and output ray, the matrix formalism can be used to treat a pair of rays, represented by a 2 × 2 matrix. In this case

$$\begin{pmatrix} y_1' & y_2' \\ \omega_1' & \omega_2' \end{pmatrix} = \begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} \begin{pmatrix} y_1 & y_2 \\ \omega_1 & \omega_2 \end{pmatrix} \tag{254}$$

Since the system matrix has a unit determinant, the determinants of the incoming and outgoing ray matrices are identical:

$$L_{12} = y_1'\omega_2' - y_2'\omega_1' = y_1\omega_2 - y_2\omega_1 \tag{255}$$

This is the paraxial invariant, Eq. (149). It is possible to operate on more than two rays, but never necessary, since any third ray is a linear combination of two, Eq. (154). Operations on two rays can also be handled with a complex notation in which two ray heights and two angles are each represented by a complex number (Marechal 1956,[219] Marechal 1961[220]).

Conjugate Matrix

For conjugate planes, $y' = my$, so $C = 0$, $R = m$, and $F = 1/m$, giving

$$\begin{pmatrix} m & 0 \\ -\phi & 1/m \end{pmatrix} \tag{256}$$

The $1/m$ term gives the angular magnification, $u'/u = n/n'm$, Eq. (196). This matrix also holds for afocal lenses, in which case $\phi = 0$.

Translated Input and Output Planes

For a given system, the locations of the input and output planes are arbitrary. If the input plane is translated by τ and the output plane by τ', the resultant matrix is

$$\begin{pmatrix} R - \tau'\phi & C + \tau R + \tau' F - \tau\tau'\phi \\ -\phi & F - \tau\phi \end{pmatrix} \tag{257}$$

Note that the object-space translation term τ is grouped with F and the image-space term τ' with R. The equation $C = 0 = \tau R - \tau' F - \tau\tau'\phi$ gives all pairs of τ and τ' for which the input and output surfaces are conjugate.

Principal Plane-to-Principal Plane

If the input and output planes are the principal planes, then the matrix is a conjugate one, for which $m = +1$.

$$\begin{pmatrix} 1 & 0 \\ -\phi & 1 \end{pmatrix} \tag{258}$$

This is also the matrix representing a thin lens.

Nodal Plane-to-Nodal Plane

The nodal points are conjugate, with unit angular magnification, so $u' = u$ and $\omega' = n'\omega/n$. Thus

$$\begin{pmatrix} n/n' & 0 \\ -\phi & n'/n \end{pmatrix} \tag{259}$$

The transverse magnification $m_N = n/n'$ equals unity when $n = n'$. This matrix has no meaning for afocal lenses.

Focal Plane-to-Focal Plane

If the initial surface is at the front principal focal plane and the final surface is at the rear focal plane, the matrix is

$$\begin{pmatrix} 0 & 1/\phi \\ -\phi & 0 \end{pmatrix} \tag{260}$$

This is the "Fourier transform" arrangement, in which incident heights are mapped as angles and vice versa.

Translation from Conjugate Positions

If the input plane is translated τ from a plane associated with magnification m and the output plane is translated a distance τ' from the conjugate plane, the matrix is

$$\begin{pmatrix} m - \tau'\phi & m\tau + \tau'/m - \tau\tau'\phi \\ -\phi & 1/m - \tau\phi \end{pmatrix} \tag{261}$$

Setting $C = 0$ gives an equation that locates all other pairs of conjugate planes relative to the first one, Eq. (172).

Translation from Principal Planes

If the initial conjugate planes are the principal planes, then

$$\begin{pmatrix} 1 - \tau'\phi & \tau + \tau' - \tau\tau'\phi \\ -\phi & 1 - \tau\phi \end{pmatrix} \tag{262}$$

The equation for other conjugates is $C = 0 = \tau + \tau' - \tau\tau'\phi$, corresponding to Eq. (170). It follows that the distance from the input surface to the first principal plane is $\tau = (1 - F)/\phi$ and the distance from the output surface to the second principal plane is $\tau' = (1 - R)/\phi$.

Translation from Focal Planes

If the input plane is a distance τ from the front focal plane and the output plane a distance τ' from the rear focal plane, the matrix is

$$\begin{pmatrix} -\phi\tau' & \dfrac{1}{\phi}(1 - \phi^2\tau\tau') \\ -\phi & -\phi\tau \end{pmatrix} \tag{263}$$

Thus F and R are proportional to the distances of the input and output surfaces from the object space and image space focal planes. Using Newton's formulas, this can also be written

$$\begin{pmatrix} m' & \dfrac{1}{\phi}\left(1-\dfrac{m'}{m}\right) \\ -\phi & \dfrac{1}{m} \end{pmatrix} \tag{264}$$

Here m' is the magnification that would obtain if the image point were as located by R, and m is that if the object point were located by F. The conjugate term vanishes when $m = m'$.

Conjugate Relative to Principal Focal Planes

If Eq. (263) is a conjugate matrix, it becomes

$$\begin{pmatrix} -\phi\tau' & 0 \\ -\phi & -\phi\tau \end{pmatrix} \tag{265}$$

The vanishing C term gives $0 = 1/\phi - \phi\tau\tau'$, which is the Newton equation usually written as $zz' = ff'$. The magnification terms are the other Newton's equations, $m = -\phi\tau'$ and $1/m = -\phi\tau$, which are usually written as $m = -z'/f' = -f/z$.

Afocal Lens

For afocal lenses $\phi = 0$. Since the determinant is unity, $F = 1/R$. And since the transverse magnification is constant, $R = m$, giving

$$\begin{pmatrix} m & C \\ 0 & 1/m \end{pmatrix} \tag{266}$$

A ray with $\omega = 0$ has $y' = my$, and $\omega' = \omega/m$ for all y. At conjugate positions, an afocal lens has the matrix

$$\begin{pmatrix} m & 0 \\ 0 & 1/m \end{pmatrix} \tag{267}$$

Performing a translation in both object and images spaces from the conjugate position gives

$$\begin{pmatrix} m & m\tau + \dfrac{\tau'}{m} \\ 0 & 1/m \end{pmatrix} \tag{268}$$

Setting $C = 0$ gives $\tau' = -m^2\tau$, which relates the location of a single conjugate pair to all others, Eq. (200).

Symmetrical Lenses

For lenses with symmetry about a central plane and symmetrically located input and output surfaces, $F = R$, so the matrix has the form

$$\begin{pmatrix} B & C \\ -\phi & B \end{pmatrix} \tag{269}$$

where $B^2 = 1 - \phi C$. The conjugate matrix has $m = \pm 1$.

Reversing Lenses

When a lens is flipped left to right, the matrix of the reversed system is obtained from that of the original one by switching the F and R terms.

$$\begin{pmatrix} F & C \\ -\phi & R \end{pmatrix} \tag{270}$$

This reversal maintains the exterior references planes, that is, the input surface for the initial system becomes the output surface for the flipped one and vice versa.

Inverse Systems

By the "inverse" of a lens is meant a second system that undoes the effect of a given one. That is, the rays at the output surface of the second system have the same height and angle as those at the input of the first system. The combination of a system and its inverse is afocal with unit magnification. The matrix representing the inverse system is the inverse of that representing the system.

$$\begin{pmatrix} F & -C \\ \phi & R \end{pmatrix} \tag{271}$$

The matrix provides no instruction as to how such a lens is made up. Alternatively, the inverse matrix can be interpreted as that whose input is y' and ω', with outputs y and ω.

Series of Arbitrary Lenses

The matrix for two successive lenses is

$$\begin{pmatrix} R_1 R_2 - C_2 \phi_1 & C_1 R_2 + C_2 F_1 \\ -\phi_1 F_2 - \phi_2 R_1 & F_1 F_2 - C_1 \phi_2 \end{pmatrix} = \begin{pmatrix} R_2 & C_2 \\ -\phi_2 & F_2 \end{pmatrix} \begin{pmatrix} R_1 & C_1 \\ -\phi_1 & F_1 \end{pmatrix} \tag{272}$$

For example, two given lenses separated by some distance have the matrix

$$\begin{pmatrix} R_2 & C_2 \\ -\phi_2 & F_2 \end{pmatrix} \begin{pmatrix} 1 & \tau \\ 0 & 1 \end{pmatrix} \begin{pmatrix} R_1 & C_1 \\ -\phi_1 & F_1 \end{pmatrix} \tag{273}$$

Multiplying from right to left gives a running product or "cumulative matrix," that shows the effect of the system up to a given plane.

Decomposition

Matrix multiplication is associative, so the system representation can be broken up in a number of ways. For example, the portion of a lens before and after the aperture stop can be used to find the pupil locations and magnifications. An arbitrary lens matrix can be written as a product of three matrices (Macukow & Arsenault 1983[221]):

$$\begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ -\phi/R & 1 \end{pmatrix} \begin{pmatrix} R & 0 \\ 0 & 1/R \end{pmatrix} \begin{pmatrix} 1 & C/R \\ 0 & 1 \end{pmatrix} \tag{274}$$

or

$$\begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} = \begin{pmatrix} 1 & C/F \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1/F & 0 \\ 0 & F \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -\phi/F & 1 \end{pmatrix} \tag{275}$$

Thus a general lens is equivalent to a succession of three systems. One has power and works at unit magnification. The second is a conjugate afocal matrix. The third is a translation. Each of these systems is defined by one of the three terms, either *R*, ϕ/R, C/R or *F*, ϕ/F, C/F. This is another manifestation of the three degrees of freedom of paraxial systems.

Matrix Determination by Two-Ray Specification

If a two-ray input matrix is given along with the desired output, or the two input and output rays are measured to determine the matrix of an unknown lens, Eq. (254) gives

$$\begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} = \begin{pmatrix} y_1' & y_2' \\ \omega_1' & \omega_2' \end{pmatrix} \begin{pmatrix} y_1 & y_2 \\ \omega_1 & \omega_2 \end{pmatrix}^{-1} \tag{276}$$

so

$$\begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} = \frac{1}{y_1\omega_2 - y_2\omega_1} \begin{pmatrix} y_1'\omega_2 - y_2'\omega_1 & y_2'y_1 - y_1'y_2 \\ \omega_1'\omega_2 - \omega_2'\omega_1 & \omega_2'y_1 - y_2\omega_1' \end{pmatrix} \tag{277}$$

The denominator of the multiplicative factor is the paraxial invariant associated with the two rays, Eq. (149). As a special case, the two rays could be the marginal and chief rays. The input and output pairs must have the same invariant, or the matrix thus found will not have a unit determinant.

Experimental Determination of Matrix Elements

The matrix elements for an unknown lens can, in principle, be determined experimentally. One method, as mentioned in the preceding section, is to measure the heights and angles of an arbitrary pair of rays. Another method is as follows. The power term is found in the usual way by sending a ray into the lens parallel to the axis and measuring its outgoing angle. To find $C = \partial y'/\partial\omega$, the input ray angle is varied, while its height is unchanged. If the output height is graphed, its slope is *C*. Likewise, the other partial derivatives in Eq. (243) can be found by changing one of the input parameters while the other is fixed. The four measurements are redundant, the unit determinant providing a check of consistency.

Angle Instead of Reduced Angle

The matrices above can be modified to use the angles u and u', instead of the reduced angles. In terms of matrix theory, this amounts to a change in basis vectors, which is accomplished by multiplying by diagonal vectors with elements 1 and n or 1 and n'. The result is

$$\begin{pmatrix} y \\ u' \end{pmatrix} = \begin{pmatrix} R & nC \\ -\frac{1}{n'}\phi & \frac{n}{n'}F \end{pmatrix} \begin{pmatrix} y \\ u \end{pmatrix} \tag{278}$$

This matrix has a constant determinant n/n'. The form Eq. (252) is simpler.

Other Input-Output Combinations

Referring to Eq. (244), any pair of the four quantities y, ω, y', and ω' can be taken as inputs, with the other two as outputs, and the relationships can be expressed in matrix form. The four matrices in this section cannot be multiplied to account for the concatenation of lenses. If the angles are given, the heights are

$$\begin{pmatrix} y \\ y' \end{pmatrix} = \frac{1}{\phi} \begin{pmatrix} F & -1 \\ 1 & -R \end{pmatrix} \begin{pmatrix} \omega \\ \omega' \end{pmatrix} \tag{279}$$

The matrix is undefined for afocal lenses, for which the relationship of ω and ω' is independent of heights. Similarly, the angles can be expressed as functions of the heights by

$$\begin{pmatrix} \omega \\ \omega' \end{pmatrix} = \frac{1}{C} \begin{pmatrix} -R & 1 \\ -1 & F \end{pmatrix} \begin{pmatrix} y \\ y' \end{pmatrix} \tag{280}$$

For conjugates the expression breaks down, since there is no fixed relationship between heights and angles. If the input is a height on one side and an angle on the other, then

$$\begin{pmatrix} y' \\ \omega \end{pmatrix} = \frac{1}{F} \begin{pmatrix} 1 & C \\ \phi & 1 \end{pmatrix} \begin{pmatrix} y \\ \omega' \end{pmatrix} \tag{281}$$

For the inverse situation,

$$\begin{pmatrix} y \\ \omega' \end{pmatrix} = \frac{1}{R} \begin{pmatrix} 1 & -C \\ -\phi & 1 \end{pmatrix} \begin{pmatrix} y' \\ \omega \end{pmatrix} \tag{282}$$

The determinants of these matrices are, respectively, C, ϕ, R, and F.

Derivative Matrices

If the axial position of the input surface changes, the rate of change of the output quantities is

$$\begin{pmatrix} dy'/dz \\ d\omega'/dz \end{pmatrix} = \begin{pmatrix} 0 & R \\ 0 & -\phi \end{pmatrix} \begin{pmatrix} y \\ \omega \end{pmatrix} \tag{283}$$

If the axial position of the output surface can change, the rate of change of output quantities is

$$\begin{pmatrix} dy'/dz' \\ d\omega'/dz' \end{pmatrix} = \begin{pmatrix} -\phi & F \\ 0 & 0 \end{pmatrix} \begin{pmatrix} y \\ \omega \end{pmatrix} \tag{284}$$

Higher derivatives vanish.

Skew rays

The matrix formalism can be used to treat a paraxial skew ray, represented by a 2×2 matrix of x and y positions and directions α and β. In this case

$$\begin{pmatrix} x' & y' \\ n'\alpha' & n'\beta' \end{pmatrix} = \begin{pmatrix} R & C \\ -\phi & F \end{pmatrix} \begin{pmatrix} x & y \\ n\alpha & n\beta \end{pmatrix} \tag{285}$$

Since the lens matrix has a unit determinant, the determinants of the incoming and outgoing ray matrices are identical:

$$n'(y'\alpha' - x'\beta') = n(y\alpha - x\beta) \tag{286}$$

From Eq. (73), this is the skew invariant.

Relationship to Characteristic Functions

A lens matrix can be related to any one of the four paraxial characteristic functions, Eqs. (34) through (37), each of which has three first coefficients, associated with the three degrees of freedom of the matrix. Brouwer and Walther (Brouwer & Walther 1967[222]) derive the paraxial matrices from more general matrices based on the point angle characteristic function.

Nonrotationally Symmetric Systems

Systems comprised of cylindrical lenses can also be treated paraxially by matrices (Arsenault 1979,[223] Arsenault 1980,[224] Arsenault 1980,[225] Keating 1981,[226] Arsenault & Macukow 1983,[227] Macukow & Arsenault 1983,[221] Attard 1984[228]). The more general case of a treatment around an arbitrary ray is also represented by a 4×4 matrix (Stone & Forbes 1992[229]). This is treated by several of the references to the section ''Images About Known Rays.''

1.18 APERTURES, PUPILS, STOPS, FIELDS, AND RELATED MATTERS

Introduction

This section is concerned with the finite sizes of lens and their fields, as expressed in various limitations of linear dimensions and angles, and with some of the consequences of these limits. (Other consequences, for example, resolution limitations, are in the domain of wave optics.) Terminology in this area is not well defined, and the terms typically used are insufficient for all the aspects of the subject, so this section deals considerably with definitions.

Field Size and Field Stop

The *field* or *field of view* of a lens is the region of object space from which light is captured or the region of image space that is used. The field size may be described in angular, linear, or area units, depending on the circumstances. (It can be described in still other ways, e.g., the number of pixels.) In and of itself, a lens does not have a definite field size, but

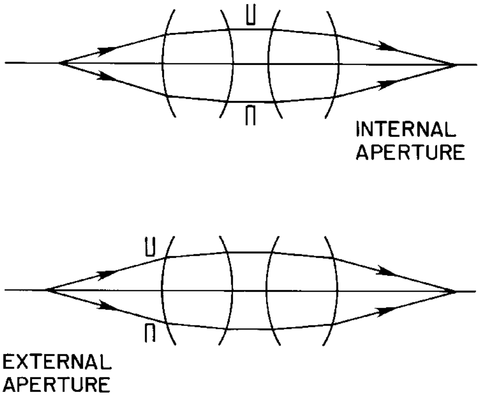

FIGURE 23 Axial ray cone and aperture stop. The upper lens has an internal aperture, and the lower one has an external aperture on the object side.

beyond a certain size, image quality diminishes, both with respect to aberration correction and to light collection. A *field stop* is a physical delimiter of the field, which may be in either object or image space. A detector may be the delimiter.

Aperture Stop

Each object point can be thought of as emitting rays in all directions. Since lenses are finite in size, only some of the rays pass through them. The rays that do pass are referred to as *image-forming rays,* the ensemble of which is the *image-forming bundle,* also called the *image-forming cone,* although the bundle may not be conical. The bundle associated with each object point is delimited by one or more physical structures of the lens. For axial object points, the delimiting structure is called the *aperture,* the *stop,* or the *aperture stop.* The aperture may be either within the lens or outside of it on either side, Fig. 23. The aperture may be a structure whose sole purpose is delimiting the bundle, or it may be the edge of an optical element or a lens mount. The aperture stop may be fixed or adjustable, for instance an iris. Which structure acts as the aperture can change with object position, Fig. 24. The size and position of the aperture do not effect the gaussian properties of the lens, i.e., the cardinal points and the conjugate locations and magnifications. They do

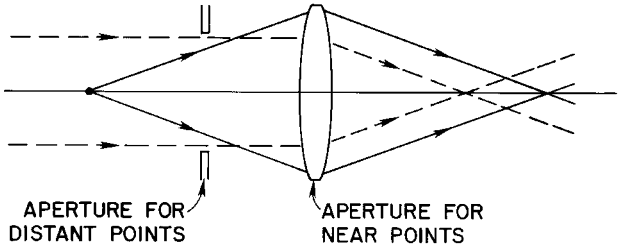

FIGURE 24 An example of change of aperture with axial object position. For distant points the aperture is the nominal stop. For near points the aperture is the rim of the lens.

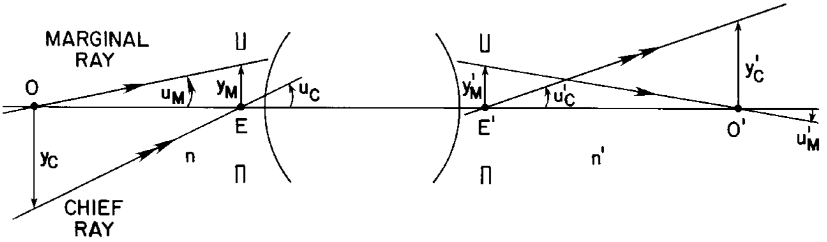

FIGURE 25 Schematic diagram of a lens with object and image planes, entrance and exit pupils, and marginal and chief rays. The entrance pupil is located at *E* and the exit pupil at *E*′. The chief ray passes through the edges of the fields and the centers of the pupils. The marginal ray passes through the axial object and image points and the edges of the pupils.

affect the image irradiance, the aberrations, and the effects of defocus. The aperture is most commonly centered on axis, but this is not always so. With visual instruments, the aperture stop for the entire system may be either an aperture in the optics or the iris of the observer's eye.

Marginal Rays and Chief Rays

Ray bundles are described to a considerable extent by specifying their central and extreme rays. For object planes perpendicular to the lens axis, there are two meridional rays of particular importance, defining the extremities of field and aperture, Fig. 25. These rays are reciprocal in that one is to the pupil what the other is to the field.

The *marginal ray* originates at the axial object point, intersects the conjugate image point, and passes through the edge of the aperture. This term is also used for rays from other field points that pass through the extremes of the aperture. The *paraxial marginal ray* is the marginal ray in the paraxial limit.

The *chief ray* or *principal ray* originates at the edge of the object field, intersects the edge of the image field, and passes approximately through the center of the aperture, and hence approximately through the center of the pupils. (Here we use "chief ray," since the prefix "principal" is so commonly used for other entities.) The term is also used for the central ray of other bundles. The *paraxial chief ray* passes exactly through the centers of the aperture and both paraxial pupils.

Field Angle

The *field angle* is that subtended by the field of view at the lens. This term is ambiguous, since several angles can be used, as well as angles in both object and image space. A nodal ray angle is the same in both spaces. If the nodal points are not at the pupils, the chief ray angle differs on the two sides. The ratio of paraxial chief ray angles is proportional to the paraxial pupil magnification, as discussed later, Eq. (289). If the lens is telecentric, the chief ray angle is zero. An afocal lens has no nodal points, and the paraxial ratio of output angles to input angles is constant. The concept of field angle is most useful with objects and/or images at large distances, in which case on the long conjugate side the various ray angles are nearly identical. On the short conjugate side, ambiguity is removed by giving the focal length, the linear size of the detector, and the principal plane and exit pupil positions. For finite conjugates, such information should be provided for both spaces.

Pupils

The term *pupil* is used in several ways, and care should be taken to distinguish between them. There are paraxial pupils, ''real'' pupils, pupils defined as ranges of angles, and pupil reference spheres used for aberration definition and diffraction calculations. The *entrance pupil* is the aperture as seen from object space—more precisely, as seen from a particular point in object space. If the aperture is physically located in object space, the entrance pupil is identical to the aperture. Otherwise, the entrance pupil is the image of the aperture in object space formed by the portion of the lens on the object side of the aperture. If the aperture is in image space, the entrance pupil is its image formed by the entire lens. Similarly, the *exit pupil* is the aperture as seen from image space. A *real pupil* is a physically accessible image of the aperture or the aperture itself, and a *virtual pupil* is an inaccessible image. Visual instruments often have external pupils, where the user's eye is located. The axial entrance pupil point is denoted here by E and the exit pupil by E'.

The pupils can be located anywhere on axis, except that they cannot coincide with the object or image. It is common to draw pupils as shown in Fig. 25, but they can also be on the side of the object or image away from the lens. The pupils are usually centered on axis, but not necessarily. Aberrations may shift pupils from nominal axial centration.

Both pupils are conjugate to the aperture, so they are conjugate to each other. The term *pupil imaging* refers to the relationship of the pupils with respect to each other and to the aperture. In pupil imaging, the chief ray of the lens is the marginal ray and vice versa. The *pupil magnification* m_P denotes the ratio of exit pupil size to entrance pupil size. The size may be specificed as linear or an angular extent, and the pupil magnification may be a transverse magnification, finite or paraxial, or a ratio of angular subtenses. In general, there is *pupil aberration,* so the image of the aperture in each space is aberrated, as is that of the imaging of one pupil to the other. Pupil imaging is subject to chromatic aberration, so positions, sizes, and shapes of pupils may vary with wavelength.

There is ambiguity about pupil centers and chief rays for several reasons. The center can be taken with respect to linear, angular, or direction cosine dimensions. Because of spherical pupil aberration, a ray through the center of the pupil may not also pass through the center of the aperture, and vice versa. The angular dimensions of pupils may change with field position. Pupil aberrations cause the actual pupil shape to be different from that of the paraxial pupil.

Pupils that are not apertures can have any linear size, since the aperture can be imaged at any magnification. If the aperture is within the lens, there is no particular relationship between the positions and linear sizes of the entrance and exit pupils, since the portions of the lens that precede and follow the aperture have no specific relationship. There is a relationship between the angular subtense of the pupils, as discussed below.

The angular size and shape of the pupils can vary with field position, and the pupils can change position if the aperture changes with object position. If the lens changes internally, as with a zoom, the sizes and positions of the pupils change.

Paraxial Description

The *paraxial pupils* are the paraxial images of the aperture. They are usually planar and perpendicular to the axis and are implicitly free from aberration. The paraxial chief ray passes through the center of both pupils and the aperture, and the paraxial marginal ray through the edges. The object and pupil magnifications and the distances from object to entrance pupil and from exit pupil to image are related by Eq. (194). If the object at O

is imaged at O' with magnification m, and the pupil magnification from entrance pupil at E to exit pupil at E' is m_E, then from Eq. (194)

$$O'E' = \frac{n'}{n} m m_E OE \tag{287}$$

Paraxial Invariant for Full Field and Full Aperture

Let the height of the paraxial marginal ray be y_M at the entrance pupil and y'_M at the exit pupil, and that of the paraxial chief ray by y_C, at the object plane and y'_C at the image plane, Fig. 25. Let the angles of these rays be u_M, u_C, u'_M, u'_C. The two-ray paraxial invariant, Eq. (149), is

$$L = n y_C u_M = n y_M u_C = n' y'_M u'_C = n' y'_C u'_M \tag{288}$$

This relationship was rediscovered several times, so the conserved quantity is referred to by a variety of names, including the *Lagrange invariant,* the *Helmholtz invariant,* the *Smith invariant,* and with various hyphenated combinations of the proper names (Rayleigh 1886,[230] Southall 1910[231]). Further discussions are found in the sections on paraxial optics and on the étendue. The paraxial transverse magnification and paraxial pupil magnifications are related to the paraxial marginal and chief ray angles by

$$m = \frac{y'_C}{y_C} = \frac{n u_M}{n' u'_M} \qquad \text{and} \qquad m_P = \frac{y'_M}{y_M} = \frac{n u_C}{n' u'_C} \tag{289}$$

Pupil Directions

For some purposes, pupils are best described as ranges of directions, specified in direction cosines, rather than by linear extents of aperture images. Here the term *pupil directions* (NS) is used. This is particularly the case when dealing with a given region of the object. The construction for this description is shown in Fig. 26. The x and y axes of the

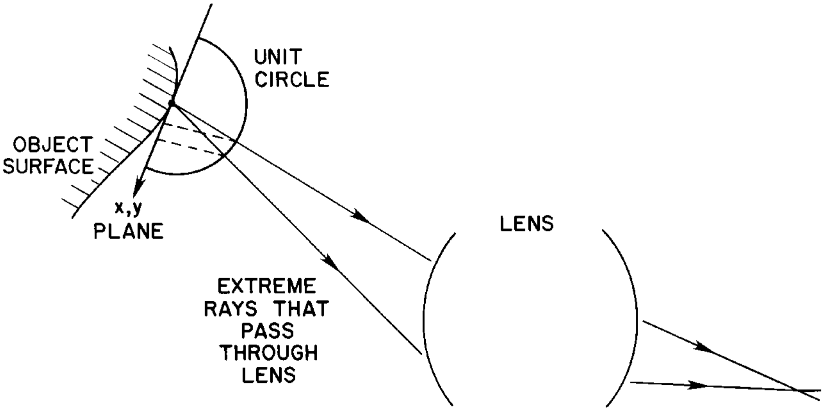

FIGURE 26 Construction for the description of the pupils with direction cosines. An x-y plane is tangent to the object surface at the object point, and a unit sphere is centered on the point. The intersections with the unit sphere of the rays are projected to the tangent plane to give the pupil direction cosines.

object-space coordinate system lie in the object surface, and the x' and y' axes. From a point on the object plane, the extreme set of rays that passes through the lens is found. Its intersection with a unit sphere about the object point is found, and perpendiculars are dropped to the unit circle on (or tangent to) the object plane, giving the extent in direction cosines.

The entrance pupil is delimited by a closed curve described by a relationship $0 = P(\alpha, \beta; x, y)$, and the exit pupil is likewise defined by $0 = P'(\alpha', \beta'; x', y')$. The spatial argument is included to indicate that the shape varies, in general, with the field position. There may be multiple regions, as in the case of central obstructions. It is usually preferable to define the pupils relative to *principal directions* (NS) (α_0, β_0) in object space and (α_0', β_0') in image space, where the two directions are those of the same ray in the two spaces, usually a meridional ray. The principal directions are analogous to the chief rays. The entrance pupil is then given by $0 = Q(\alpha - \alpha_0,\ \beta - \beta_0;\ x, y)$ and the exit pupil by $0 = Q'(\alpha' - \alpha_0',\ \beta' - \beta_0';\ x', y')$. For example, for a field point on the $x = 0$ meridian, the expression for the pupil might be well approximated by an ellipse, $0 = a\alpha^2 + b(\beta - \beta_0)^2$, where $(0, \beta_0)$ is the chief ray direction. If the imaging is stigmatic, the relationship between entrance and exit pupil angular shapes is provided by the cosine condition, Eq. (104).

$$Q'(\alpha', \beta'; x', y') = Q(m_P\alpha' - \alpha_0', m_P\beta' - \beta_0'; x, y) \tag{290}$$

The entrance and exit pupils have the same shapes when described in direction cosine space. They are scaled according to the *pupil angular magnification* (NS) $m_P = n/n'm$. The orientations may be the same or rotated 180°. There is no particular relationship between (α_0, β_0) and (α_0', β_0'), which can, for example, be changed by field lenses. The principal directions are, however, usually in the same meridian as the object and image points, in which case $\alpha_0/\beta_0 = \alpha_0'/\beta_0'$. If the field point is in the x meridian, and the central ray is in this meridian, then $\alpha_0 = 0$ and $\alpha_0' = 0$. Even with aberrations, Eq. (290) usually holds to a good approximation. The aberration *pupil distortion* refers to a deviation from this shape constancy.

Pupil Directional Extent: Numerical Aperture and Its Generalizations

The angular extent of a pupil extent is limited by some extreme directions. In the example above of the elliptical shape, for instance, there are two half widths

$$\tfrac{1}{2}(\alpha_{\max} - \alpha_{\min}) \qquad \text{and} \qquad \tfrac{1}{2}(\beta_{\max} - \beta_{\min}) \tag{291}$$

For a rotationally symmetric lens with a circular aperture, the light from an axial object point in a medium of index n is accepted over a cone whose vertex angle is $\theta_{\max}$. The *object space numerical aperture* is defined as

$$NA = n \sin\theta_{\max} = n\sqrt{(\alpha^2 + \beta^2)_{\max}} = n\alpha_{\max} = n\beta_{\max} \tag{292}$$

Likewise, on the image side, where the index is n' and the maximum angle is $\theta_{\max}'$, the *image space numerical aperture* is

$$NA' = n' \sin\theta_{\max}' = n'\sqrt{(\alpha'^2 + \beta'^2)_{\max}} = n'\alpha_{\max}' = n'\beta_{\max}' \tag{293}$$

If the lens is free of coma, the sine condition, Eq. (106), gives for finite conjugates

$$m = \frac{n \sin \theta_{\max}}{n' \sin \theta'_{\max}} = \frac{NA}{NA'} \tag{294}$$

For infinite conjugates

$$\sin \theta'_{\max} = -\frac{y_{\max}}{f'} \qquad \text{or} \qquad n' \sin \theta'_{\max} = NA' = n\beta_{\max} = -y_{\max}\phi \tag{295}$$

If there is coma, these relationships are still good approximations. For a given lens and a given aperture size, the numerical aperture varies with the axial object position.

F-Number and Its Problems

The *F-number* is written in a variety of ways, including F/no. and F/#. It is denoted here by *FN*. The F-number is not a natural physical quantity, is not defined and used consistently in the literature, and is often used in ways that are both wrong and confusing (Hatch 1980,[232] Goodman 1993[233]). Moreover, there is no need to use the F-number, since everything that it purports to describe or approximately describes is treated properly with direction cosines. The most common definition for F-number, applied to the case of an object at infinity, is

$$FN = \frac{\text{focal length}}{\text{entrance pupil diameter}} = \frac{1}{2 \tan \theta'} \tag{296}$$

where θ' is the outgoing angle of the axial imaging done. In general, the F-number is associated with the tangents of collinear transformations, rather than the sines (or direction cosines) that are physically appropriate. It presumes that a nonparaxial ray entering parallel to the axis at height y leaves the rear principal plane at the same height and intersects the rear focal point, so that $\tan \theta' = y/f'$. However, this particular presumption contradicts Eq. (294), and in general, collineation does not accurately describe lens behavior, as discussed above.

Other problems with F-number, as it is used in the literature, include the following: (1) It is not defined consistently. For example, the literature also contains the definition F-number = (focal length)/(exit pupil diameter). (2) For lenses used at finite conjugates, the F-number is often stated for an object at infinity. In fact, given only the numerical aperture for an object at infinity, that for other conjugates cannot be determined. (3) There are confusing descriptions of variation of F-number with conjugates, for example, the equation $FN_m = (1 + m)FN_\infty$, where FN_m is the F-number for magnification m and FN_∞ is that for an object at infinity. In fact, numerical apertures for various magnification are not so related. (4) The object and image space numerical apertures are related by Eq. (293), but there is no such relationship for tangents of angles, except that predicted by collineation, Eq. (232), which is approximate. (5) With off-axis field points and noncircular pupils, the interpretation of F-number is more ambiguous. (6) Afocal systems have finite numerical apertures when used at finite conjugates, but they have no analogue to Eq. (295). (7) Object and image space refractive indices are not accounted for by the F-number, whereas they are by the numerical aperture. (8) The F-number is often used as a descriptor of radiometric throughput, rather than of ray angles per se.

A related quantity is the *T-number* (W. J. Smith 1992[234]), which accounts for both the convergence angle of the imaging cone and the fraction of power transmitted by the lens.

This is useful as a single-number descriptor, but it is subject to all the confusion associated with the F-number.

Image Irradiance for Lambertian Objects

If the light from a region of an object is lambertian with a power/area M, then the emitted power per angle with angle according to $(M/\pi)\cos\theta\, d\omega = (M/\pi)\, d\alpha\, d\beta$. The power captured by the entrance pupil from a small object area dA is

$$dP = \frac{1}{\pi} M\, dA \int_{\text{entrance pupil}} d\alpha\, d\beta \tag{297}$$

(For a full hemisphere $\int d\alpha\, d\beta = \pi$, giving $dP = M\, dA$.) If there are no losses within the lens, the power reaching the conjugate image region dA' is the same. Using the conservation of étendue equation, Eq. (72), the image irradiance is

$$E = \frac{dP}{dA'} = \frac{1}{\pi} M \frac{n'^2}{n^2} \int_{\text{exit pupil}} d\alpha'\, d\beta' \tag{298}$$

The image irradiance does not depend explicitly on the magnification, but magnification is included implicitly, since, for a given lens, the subtense of the exit pupil varies with conjugates.

This equation obtains everywhere in the field, and it applies to arbitrary object surface positions and orientations, so long as the direction cosines are defined with respect to the local object and image surface normals. These equations apply regardless of the chief ray angles, so they are applicable, for example, with telecentricity. In general, the pupil shape and principal direction vary with field position, so there is a gradation of irradiance in the image of a uniform lambertian object.

These equations do not account for all that influences image irradiance, for example lens absorption and reflection. These effects can be included in the above expressions by adding an appropriate weighting function of angle and field in the above integrals, giving

$$E(x', y') = \frac{dP}{dA'} = \frac{1}{\pi} M(x, y) \frac{n'^2}{n^2} \int \tau(\alpha', \beta'; x', y')\, d\alpha'\, d\beta' \tag{299}$$

where $\tau(\alpha', \beta'; x', y')$ is the lens transmittance as a function of the direction cosines for the image point (x', y'). With externally illuminated objects that are not lambertian scatterers, these relationships do not hold. For example, in optical projectors the illumination is matched to the object and imaging lens to give nominally uniform image irradiance.

Axial Image Irradiance for Lambertian Objects

In the special case of circular pupils and axial object surfaces perpendicular to the axis, the collected power and image irradiance given above are

$$dP = M\, dA \sin^2\theta \qquad \text{and} \qquad E = M \frac{n'^2}{n^2} \sin^2\theta' \tag{300}$$

Power / Pixel

From wave optics, a lens working at the "resolution limit" has an image pixel size $q\lambda/n' \sin\theta'$, where λ is the vacuum wavelength and q is a dimensionless factor, typically of the order of unity. Applying Eq. (300), this gives

$$\text{Power/pixel} = q^2 M\left(\frac{\lambda}{n}\right)^2 \tag{301}$$

$M(\lambda/n)^2$ is the energy emitted per square wavelength of object area. This is a fundamental radiometric quantity. Increasing q gives a greater numerical aperture than is nominally required for resolution, but in practice the aberration correction may be such that the actual resolution is not greater.

Cosine-to-the-Fourth Approximation

For distant, planar, uniform lambertian objects perpendicular to the lens axis, if the entrance pupil is well approximated by a circle, then the image irradiance varies approximately with the object space field angle ψ according to the *cosine-to-the-fourth* relationship

$$E(\psi) = E_0 \cos^4 \psi \tag{302}$$

where E_0 is the axial irradiance. There are three contributions to this dependence. (1) The angular distribution of a lambertian emitter varies as $\cos\psi$. (2) The distance from the field point to the entrance pupil varies as $1/d^2 \propto \cos^2\psi$. (3) Insofar as the pupil behaves as a rigid circle, its projected solid angle varies approximately as $\cos\psi$. The cosine-to-the-fourth relationship should be used only as a guideline, since ray tracing permits more accurate calculations, and because of the ambiguities in the meaning of the field angle, as discussed above, and elsewhere (Kingslake 1945,[235] Reiss 1945,[236] Gardner 1947,[237] Reiss 1948,[238] Kingslake 1965[239]). For example, field angle is meaningless with telecentricity. Some lenses, especially wide-angle ones, are specifically designed so the pupil subtense increases with the field angle in order to compensate for effects (1) and (2) above, to produce a sufficiently uniform image (Slyusarev 1941[240]).

Total Lens Étendue

The total amount of power from a lambertian object that can be transferred through a lens is

$$\frac{1}{\pi} M \int_{\text{field}} dx\, dy \int_{\text{pupil}} d\alpha\, d\beta \tag{303}$$

The pupil integral may vary over the field. If the pupil is round and constant over the field, the étendue is proportional to $\mathrm{A(NA)}^2$, where A is the area of the field. This quantity is also related to the total number of pixels in the field, and the ability of the lens to transfer information (Gabor 1961[241]). The term "area-solid angle product" is sometimes used, but this is an approximation. The total etendue is proportional paraxially to $\sim L^2$, where L is given by Eq. (288).

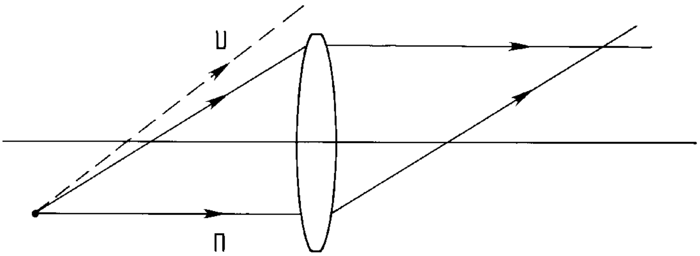

FIGURE 27 Example of vignetting. The dashed ray passes through the aperture, but misses the lens.

Vignetting

Vignetting occurs when an image-forming bundle is truncated by two or more physical structures in different planes, Fig. 27. Typically, one is the nominal aperture and another is the edge of a lens. Another case is that of central obstructions away from the aperture. When vignetting occurs, the image irradiance is changed, and its diminution with field height is faster than it otherwise would be. Aberration properties are also changed, so vignetting is sometimes used to eliminate light that would unacceptably blur the image.

Lens Combinations and Field Lenses

When lenses are used to relay images, the light is transferred without loss only if the exit pupil of one corresponds with the entrance pupil of the next. An example of the failure to meet this requirement is shown in Fig. 28. The axial point is reimaged satisfactorily, but off-axis bundles are vignetted. To transfer the light properly, a *field lens* in the vicinity

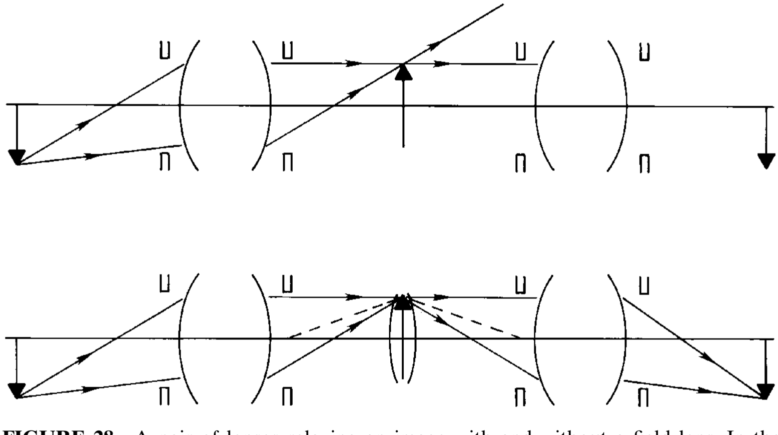

FIGURE 28 A pair of lenses relaying an image with and without a field lens. In the top figure, there is no field lens, and some of the light forming the intermediate image does not pass through the second lens. The amount lost depends on the two numerical apertures and increases with distance from the axis. In the lower figure, a field lens at the intermediate image forms an image of the exit pupil of the first lens into the entrance pupil of the next. No light is lost unless the numerical aperture of the second lens is less than that of the first.

of the intermediate image is used to image the exit pupil of the preceding lens into the entrance pupil of the next one. If the field lens is a thin lens in the image plane, then its magnification with respect to the image is unity. In practice, the field lens is usually shifted axially, so scratches or dust on its surface are out of focus. Its magnification then differs from unity. The focal length of a thin field lens in air is given by $1/f' = 1/a + 1/b$, where a is the distance from exit pupil of first lens to the field lens, and b is that from field lens to the entrance pupil of the second lens. The exit pupil is reimaged with a magnification b/a. If the sizes of the various pupils and their images are not matched, then the aperture of the combination is determined by the smallest. Field lenses affect aberrations.

Defocus

When the object and image-receiving surface are not conjugate there is *defocus*. If either the object or the receiving surface is considered to be correctly positioned, the defocus is associated with the other. Another situation is that in which the object and receiving surfaces are conjugate, but both are wrongly located, so that the image is sharp but the magnification is not what is desired, a condition that might be called *misfocus* (NS).

Defocus has two basic geometric effects, if there are no aberrations, Fig. 29. One is blurring, since the rays from an object point do not converge to a single point on the receiving surface. The blur size varies linearly with the axial defocus in image space and with the cone angle of the image-forming bundle. The shape of the blur is that of the exit pupil, projected on the receiving surface. The other effect of defocus is a lateral shift in position of the blur's centroid relative to that of the correctly focused point. The shift depends on the chief ray angle on the side of the lens where the defocus occurs. In the simplest case, the shift is approximately linear with field height, so acts as a change of magnification. If the object is tilted or is not flat, the effects of defocus vary across the field in a more complicated way. Aberrations affect the nature of the blur. With some aberrations, the blur is different on the two sides of focus. With spherical aberration, the blur changes in quality, and with astigmatism the orientation of the blur changes.

In considering the geometrical imaging of a small region of a lambertian object, there is an implict assumption that the pupil is filled uniformly with light. In imaging an extended object that is externally illuminated, the light from a given region may not fill the pupil uniformly, so the character of the blurring is affected by the angular properties of the illumination and scattering properties of the object.

The amount of defocus can be described in either object or image space, and it can be measured in a variety of ways, for example, axial displacement, displacement along a chief ray, geometrical blur size, and wavefront aberration. The axial displacements in object

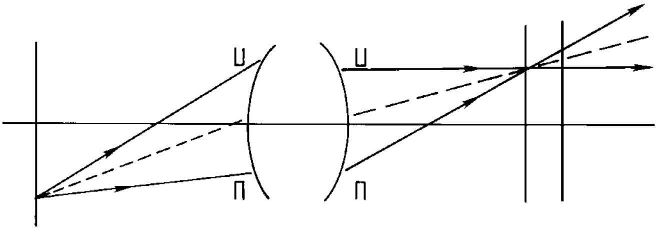

FIGURE 29 Defocus of the receiving surface. A receiving surface is shown in focus and shifted axially. The image of a point on the shifted surface is blurred, and its centroid is translated radially.

and image space differ, in general, and are related by the longitudinal magnification. As expressed in wavefront aberration, i.e., optical path length, defocus is the same in both spaces. There are also various functional measurements of defocus, for example, the sizes of recorded images through focus.

Telecentricity

A lens is *telecentric* if the chief rays are parallel to one another. Most commonly, they are also parallel to the lens axis and perpendicular to the object and/or image planes that are perpendicular to the axis, Fig. 30. Telecentricity is often described by speaking of pupils at infinity, but the consideration of ray angles is more concrete and more directly relevant. A lens is *telecentric in object space* if the chief rays in object space are parallel to the axis, $\alpha_0 = 0$ and $\beta_0 = 0$. In this case the image of the aperture formed by the portion of the lens preceding it is at infinity and the aperture is at the rear focal plane of the portion preceding it. Similarly, a lens is *telecentric in image space* if the aperture is at the front focal point of the subsequent optics, so $\alpha_0' = 0$ and $\beta_0' = 0$. More generally, but less commonly, the chief rays can be parallel to each other, but not necessarily to the axis, and not necessarily perpendicular to a (possibly tilted) object or image plane.

With tilted object and image surfaces and nonaxial pupils, the chief rays are not perpendicular to the object and/or image surfaces, but their angles are everywhere the same, so defocus can result in a rigid shift of the entire image.

A focal lens can be nontelecentric or telecentric on either side, but it cannot be doubly telecentric. An afocal lens can be nontelecentric, or doubly telecentric, but it cannot be telecentric on one side. A doubly telecentric lens must be afocal, and a singly telecentric lens cannot be afocal.

For a lens that is telecentric in image space, if the receiving surface is defocused, the image of a point is blurred, but its centroid is fixed. However, if it is not telecentric in object space, then the scale changes if the object is defocused. The converse holds for object-space telecentricity without image-space telecentricity. For a doubly telecentric lens, an axial shift of either the object or the receiving plane produces blurring without a centroid shift. Although the magnification of an afocal lens does not change with conjugates, there can be an effective change with defocus if it is not telecentric. If the pupil is not on the axis or if the object and image planes are tilted, there can be telecentricity without the chief rays being perpendicular to the object and/or image planes. In these cases, defocus results in a rigid shift of the entire image.

Nominal telecentricity can be negated in several ways. Pupil aberrations may change the chief ray angles across the field. For an extended object that is externally illuminated the pupil may not be filled uniformly by light from a given region, so defocus can product a lateral image shift.

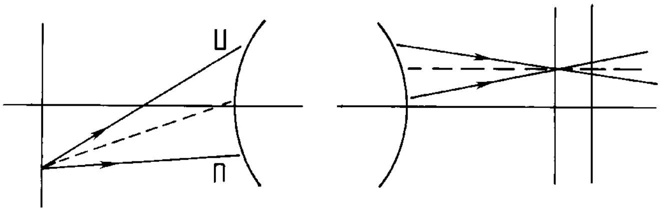

FIGURE 30 Example of telecentricity. The lens shown is telecentric in image space, in which ray bundles are parallel to the axis. An axial shift in the receiving surface results in blurring, but does not translate the centroid, so there is no change in image scale.

Depth of Focus and Depth of Field

The *depth of focus* and *depth of field* are the amounts of defocus that the receiving surface or object may undergo before the recorded image becomes unacceptable. The criterion depends on the application—the nature of the object, the method of image detection, and so on, and there are both ray and wave optics criteria for goodness of focus. For example, a field of separated point objects differs from that of extended objects. Depth of focus is usually discussed in terms of blurring, but there are cases where lateral shifts become unacceptable before blurring. For example, in nature photography blurring is more critical than geometrical deformation, while the opposite may be true in metrology.

Range of Focus and Hyperfocal Distance

In some cases, a geometrical description of defocus is applicable, and the allowable blur is specified as an angle (Ray 1988,[242] Kingslake 1992,[243] W. Smith 1992[234]). The *hyperfocal distance* is

$$\text{Hyperfocal distance} = \frac{\text{diameter of the entrance pupil}}{\text{maximum acceptable angular blur}} = d_H \tag{304}$$

Let the object distance at which the lens is focused be d, the nearest distance at which the image is acceptable be d_N, and the furthest distance be d_F. All of these quantities are positive definite. The following relations obtain:

$$d_F = \frac{d_H d}{d_H - d} \qquad \text{and} \qquad d_N = \frac{d_H d}{d_H + d} \tag{305}$$

The distances to either side of best focus are

$$d_F - d = \frac{d^2}{d_H - d} \qquad \text{and} \qquad d - d_N = \frac{d^2}{d_H + d} \tag{306}$$

The total range of focus is

$$d_F - d_N = \frac{2d^2 d_H}{d_H^2 - d^2} = \frac{2d}{(d_H/d)^2 - 1} \tag{307}$$

For $d > d_H$ the above quantities involving d_F are infinite (not negative). If the lens is focused at the hyperfocal distance or beyond, then everything more distant is adequately focused. If the lens is focused at the hyperfocal distance, i.e., $d = d_H$, the focus is adequate everywhere beyond half this distance, and this setting gives the greatest total range. If the lens is focused at infinity, then objects beyond hyperfocal distance are adequately focused. The hyperfocal distance decreases as the lens is stopped down.

1.19 GEOMETRIC ABERRATIONS OF POINT IMAGES—DESCRIPTION

Introduction

In instrumental optics, the term *aberration* refers to a departure from what is desired, whether or not it is physically possible. Terms such as "perfect system" and "ideal system" indicate what the actual is compared to, and these terms themselves are not absolute, but depend on what is wished for. The ideal may be intrinsically impossible, in which case a deviation therefrom is not a defect. A further distinction is between aberrations inherent in a design and those that result from shortcomings in fabrication.

This section considers only the description of aberrations of point images, with the lens treated as a black box, whose action with respect to aberrations is accounted for by what leaves the exit pupil. A full consideration of aberrations involves, among other things, their causes, their correction, their various manifestations, and their evaluation. Aberrated images of extended objects are formed by overlapping blurs from the individual points. The analysis of such images is object- and application-dependent, and is beyond the scope of this section. Aberrations do vary with wavelength, but most of this discussion involves monochromatic aberrations, those at a single wavelength. In addition, aberrations vary with magnification. Aberrations are discussed to some extent in many books that treat geometric optics (Conrady 1929,[244] H. Hopkins 1950,[245] Buchdahl 1954,[246] Herzberger 1958,[247] Kingslake 1978,[248] Born & Wolf 1980,[249] Slyusarev 1984,[250] Welford 1986,[251] Welford 1986,[252] W. Smith 1992[253]).

Descriptions

Aberration has many manifestations, and can be described in a variety of ways. For example, geometric wavefronts, path lengths, ray angles, and ray intersection points can all differ from the nominal (and in wave optics there are additional manifestations). Terms such as ''wavefront aberration'' and ''ray aberration'' do not refer to fundamentally different things, but to different aspects of the same thing. Often, a single manifestation of the aberration is considered, according to what is measurable, what best describes the degradation in a particular application, or what a lens designer prefers to use for optimization during the design process.

Classification

Aberrations are classified and categorized in a variety of ways. These include pupil dependence, field dependence, order, evenness and oddness, pupil and field symmetry, and the nature of change through focus—symmetrical and unsymmetrical. In addition, there are natural groupings, e.g., astigmatism and field curvature. The classification systems overlap, and the decompositions are not unique. The complete aberration is often described as a series of terms, several schemes being used, as discussed below. The names of aberrations, such as ''spherical,'' ''coma,'' and ''astigmatism,'' are not standardized, and a given name may have different meanings with respect to different expansions. Furthermore, the effects of aberrations are not simply separated. For example, ''pure coma'' can have effects usually associated with distortion. Defocus is sometimes taken to be a type of aberration, and it is useful to think of it in this way, since it is represented by a term in the same expansion and since the effects of aberrations vary with focus. The number of terms in an expansion is infinite, and familiar names are sometimes associated with unfamiliar terms. To improve clarity, it is recommended that all the terms in an expansion be made explicit up to agreed-upon values too small to matter, and that, in addition, the net effect be shown graphically. Further, it is often helpful to show more than one of an aberration's manifestations.

Pupil and Field Coordinates

In this section, all the quantities in the equation are in image space, so primes are omitted. Field coordinates are x and y, with $h^2 = x^2 + y^2$, and (x, y) is the nominal image point in a plane $z = 0$. Direction cosines equally spaced on the exit pupil should be used for pupil coordinates but, in practice, different types of coordinates are used, including linear positions, spatial frequencies, and direction cosines. Here the pupil coordinates are ξ and

η, which are dimensionless, with $\rho^2 = \xi^2 + \eta^2$. The overall direction of the pupil may vary with field. Here the $(\xi, \eta) = (0, 0)$ is always taken at the pupil center, the meaning of which may not be simple, as discussed in the section on pupils above. The angle of a meridian in the pupil is ψ. Entrance and exit pupil coordinates must be distinguished. For diffraction calculations, the exit pupil should be sampled at equal intervals in direction cosines, but a set of rays from an object point that is equally spaced in direction cosines may leave with uneven spacing, as a result of aberrations.

Wavefront Aberration

If an object point is imaged stigmatically, then the optical path lengths of all rays from the object point to its image are identical, and the geometric wavefronts leaving the exit pupil are spherical. In the presence of aberrations, the wavefront is no longer spherical. Rather than describing the wavefront shape, it is usually preferable to consider the difference between the actual wavefront, and a nominal wavefront, often called the *reference sphere,* centered at a *reference point* that is usually the nominal image point. This reference sphere is usually taken to intersect the center of the pupil, since this gives the most accurate diffraction calculations. The *wavefront aberration* W is the optical path length from reference sphere to wavefront, or vice versa, according to the convention used, Fig. 31. Two sign conventions are in use; a positive wavefront aberration may correspond either to a wavefront which lags or leads the reference sphere. For each nominal image point (x, y, z), the wavefront aberration is a function of the pupil coordinates (ξ, η), so the functional form is $W(\xi, \eta; x, y, z)$, with the z usually suppressed, since the image plane is usually taken to be fixed. For a given lens prescription, W is found by tracing a set of rays from each object point to the reference sphere and calculating their path lengths. If the absolute path length is unimportant, the choice of the reference sphere's radius is not critical. Considered from the point of view of wave optics, the image of a point is degraded by phase differences across the reference sphere, so absolute phase is of no consequence, and the zero of the wavefront aberration can be chosen arbitrarily. By convention and convenience, the zero is usually taken at the center of the pupil, so $W(0, 0, x, y) = 0$.

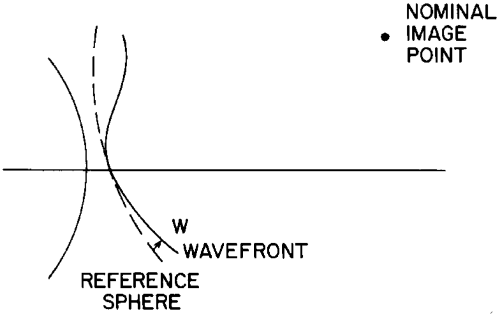

FIGURE 31 Wavefront aberration. The reference sphere is concentric with the nominal image point. The wavefront is taken that is tangent to the reference sphere in the center of the pupil. The wavefront aberration function is the distance from the reference sphere to the wavefront as a function of pupil coordiantes.

Absolute optical path lengths are significant for imaging systems with paths that separate between object and image in cases where there is coherence between the various image contributions. An error in absolute optical path length is called *piston error.* This results in no ray aberrations, so it is omitted from some discussions.

Ray Aberrations

In the presence of aberrations, the rays intersect any surface at different points than they would otherwise. The intersection of the rays with the receiving surface, usually a plane perpendicular to the axis, is most often of interest. The *transverse ray aberration* is the vectorial displacement $(\varepsilon_x, \varepsilon_y)$ between a nominal intersection point and the actual one. The displacement is a function of the position of the nominal image point (x, y) and the position in the pupil through which the ray passes (ξ, η). A complete description of transverse ray aberrations is given by

$$\varepsilon_x(\xi, \eta; x, y) \qquad \text{and} \qquad \varepsilon_y(\xi, \eta; x, y) \tag{308}$$

The *longitudinal aberration* is the axial displacement from nominal of an axial intersection point. This description is useful for points on the axis of rotationally symmetrical systems, in which case all rays intersect the axis. Such aberrations have both transverse and longitudinal aspects. The intersection with a meridian can also be used. The *diapoint* is the point where a ray intersects the same meridian as that containing the object point (Herzberger 1958[247]). For an image nominally located at infinity, aberrations can be described by the slope of the wavefront relative to that of the nominal, that is, by ray angles rather than intersection points. A hypothetical ideal focusing lens can also be imagined to convert to transverse aberrations.

A *ray intercept diagram* shows the intersection points of a group of rays with the receiving surface (O'Shea 1994[254]). The rays are usually taken to arise from a single object point and to uniformly sample the pupil, with square or hexagonal arrays commonly used. The ray intercept diagrams can suffer from artifacts of the sampling array, which can be checked for by using more than one type of array. Other pupil loci, for instance, principal meridians and annuli, can be employed to show particular aspects of the aberration. Intercept diagrams can also be produced for a series of surfaces through focus. Image quality may be better than ray diagrams suggest, since destructive interference can reduce the irradiance in a region relative to that predicted by the ray density.

Relationship of Wavefront and Ray Aberrations

Since rays are normal to geometric wavefronts, Fig. 32, transverse ray aberrations are proportional to the slope of the wavefront aberration function. For systems of rotation

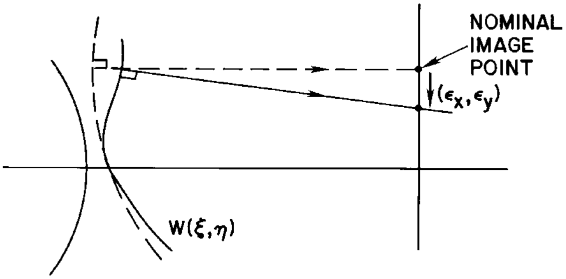

FIGURE 32 Ray aberration. Rays intersect the receiving plane at positions shifted from the nominal.

with image space index n and marginal ray angle θ, the transverse aberrations are to a good approximation (Welford 1986[251])

$$\varepsilon_x = \frac{1}{n \sin \theta} \frac{\partial W}{\partial \xi} \qquad \varepsilon_y = \frac{1}{n \sin \theta} \frac{\partial W}{\partial \eta} \tag{309}$$

The refractive index appears since W is an optical path length. If the rays are nominally parallel, then the partial derivatives give the angular ray errors

$$\Delta\alpha = \frac{1}{np} \frac{\partial W}{\partial \xi} \qquad \Delta\beta = \frac{1}{np} \frac{\partial W}{\partial \eta} \tag{310}$$

where p is the linear radius of the exit pupil, which cannot be infinite if the image is at infinity. These expressions may also have a multiplicative factor of -1, depending on the sign conventions. A sum of wavefront aberrations gives a transverse aberration that is the sum of the contributing ones.

Ray Densities

The density of rays near the nominal image point is (Welford 1986[251])

$$\frac{1}{\text{Density}} \propto \left(\frac{\partial^2 W}{\partial \xi^2}\right)\left(\frac{\partial^2 W}{\partial \eta^2}\right) - 2\left(\frac{\partial^2 W}{\partial \xi \, \partial \eta}\right)^2 \tag{311}$$

Caustics are the surfaces where ray densities are infinite. Here, geometric optics predicts infinite power/area, so the ray model is quantitatively inaccurate in this case.

Change of Reference Points

The center of the reference sphere may be displaced from the nominal image point. If the reference point is changed by linear displacement $(\delta x, \delta y, \delta z)$, then the wavefront aberration function changes from W to W' according to

$$W'(\xi, \eta; x, y; \delta x, \delta y, \delta z) = W(\xi, \eta; x, y) + W_x \xi + W_y \eta + W_z(\xi^2 + \eta^2) \tag{312}$$

where $W_x = n \sin \theta \, \delta x,$

$$W_y = n \sin \theta \, \delta y \qquad W_z = \tfrac{1}{2} n \sin^2 \theta \, \delta z \tag{313}$$

The transverse ray aberration ε'_x and ε'_y with respect to the new reference points are

$$\varepsilon'_x = \varepsilon_x + \delta x + \sin \theta \, \delta z \qquad \varepsilon'_y = \varepsilon_y + \delta y + \sin \theta \, \delta z \tag{314}$$

The change through focus is accounted for by varying δz. Setting $\varepsilon'_x = \varepsilon'_y = 0$ gives the parametric equations $x(\delta z)$ and $y(\delta z)$ for a ray with pupil coordinates (ξ, η), relative to the nominal ray near the nominal image point.

Aberration Symmetries for Systems with Rotational Symmetry

If the lens, including the aperture, is a figure of rotation, only certain aberration forms are possible. For object points on axis, the wavefront aberration and the image blur are figures of revolution. For off-axis points, both wavefront aberration and blur are bilaterally symmetrical about the meridional plane containing the object point. For object points on a circle centered on the axis, the wavefront and ray aberrations are independent of azimuth, relative to the local meridian. In practice, there is always some imperfection, so the symmetries are imperfect and additional aberration forms arise.

Wavefront Aberration Forms for Systems with Rotational Symmetry

Here the pupil is taken to be circular, with the coordinate zero taken at the center. The field coordinates are normalized so $x^2 + y^2 = h^2 = 1$ at the edge of the field. The pupil coordinates are normalized, so that $\xi^2 + \eta^2 = \rho^2 = 1$ on the rim of the pupil. The algebra is simplified by using dimensionless coordinates. To add dimensions and actual sizes, replace the ξ by $\xi/\xi_{\max}$, and likewise for other variables. The simplest combinations of pupil and field coordinates with rotational symmetry are

$$x^2 + y^2 = h^2 \qquad \xi^2 + \eta^2 = \rho^2 \qquad \xi x + \eta y \tag{315}$$

The general wavefront aberration function can be expressed as a series of such terms raised to integral powers,

$$W(x, y; \xi, \eta) = \sum_{L,M,N=0} W_{LMN}(x^2 + y^2)^L(\xi^2 + \eta^2)^M(x\xi + y\eta)^N \tag{316}$$

where L, M, N are positive integers. The terms can be grouped in *orders* according to the sum $L + M + N$, where, by convention, the order equals $2(L + M + N) - 1$. The order number refers more directly to ray aberration forms than to wavefront forms, and it is always odd. The first-order terms are those for which $L + M + N = 1$, for the third-order terms the sum is two, and so on. The number of terms in the Qth order is $1 + (Q + 1)(Q + 7)/8$. For orders 1, 3, 5, 7, 9 the number of terms is 3, 6, 10, 15, 21. For each order, one contribution is a piston error, which is sometimes excluded from the count.

The expression of Eq. (316) is related to the characteristic function for a rotationally symmetrical system, Eq. (32). If the spatial coordinates are taken to be those of the object point, this is the point-angle characteristic function. In the hamiltonian optics viewpoint, the characteristic function is a sum of two parts. The first-order terms specify the nominal properties, and those of higher orders the deviation therefrom. This is discussed in the references given in that section. The term for which $L = M = N = 0$ has to do with absolute optical path length.

Since there is bilateral symmetry about all meridians, the expansion can be simplified by considering object points in a single meridian, customarily taken to be that for which $x = 0$. Doing so and letting the fractional field height be $y = h$ gives the wavefront aberration function

$$W(h; \rho, \eta) = \sum_{L,M,N=0} W_{LMN}h^{2L+N}\rho^{2M}\eta^N = \sum_{A,B,C} W'_{ABC}h^A\rho^B\eta^C \tag{317}$$

where $A = 2L + N$, $B = 2M$, $C = N$, and the order equals $(A + B + C) - 1$. Another form is obtained with the fractional pupil radius ρ and the pupil azimuth ψ, the angle from the $x = 0$ meridian, so $\eta = \rho \cos \psi$. With these pupil variables the wavefront aberration function is

$$W(h; \rho, \psi) = \sum_{L,M,N=0} W_{LMN} h^{2L+N} \rho^{2M+N} \cos^N \psi = \sum_{A,B,C} W''_{ABC} h^A \rho^B \cos^C \psi \tag{318}$$

where $A = 2L + N$, $B = 2M + N$, $C = N$, and the order is $A + B - 1$. For orders above the first, the W_{LMN}, W'_{ABC}, and W''_{ABC} are the *wavefront aberration coefficients.*

For a given field position, the wavefront aberration function for circular pupils can also be decomposed into the *Zernike polynomials,* also called *circle polynomials,* a set of functions complete and orthonormal on a circle (Zernike 1934,[255] Kim & Shannon 1987,[256] Malacara 1978,[257] Born & Wolf 1980[249]).

Third-Order Aberrations and Their Near Relatives

There are six third-order terms. The *Seidel aberrations* are spherical, coma, astigmatism, field curvature, distortion, and there is also a piston-error term. Expressions for these aberrations are given below, along with some higher-order ones that fall in the same classification. The terminology of higher-order aberrations is not standardized, and there are forms that do not have third-order analogues. This section uses the notation of the second expression of Eq. (318), without the primes on the coefficients.

It is useful to include *defocus* as a term in aberration expansions. Its wavefront aberration and transverse ray aberrations are

$$W = W_{020}\rho^2 \qquad \varepsilon_x \propto 2W_{020}\xi \qquad \varepsilon_y \propto 2W_{020}\eta \tag{319}$$

Coefficient W_{020} is identical to W_z, Eq. (313).

In *spherical aberration* the wavefront error is a figure of revolution in the pupil. The individual terms of the expansion have the form ρ^{2N}. The form that appears on axis, and which is independent of field position is

$$W = W_{020}\rho^2 + W_{040}\rho^4 + W_{060}\rho^6 + \cdots \tag{320}$$

where defocus has been included. The W_{040} term is the third-order term, the W_{060} is the fifth-order term, etc. The ray aberrations are

$$\begin{aligned} \varepsilon_x &\propto 2W_{020}\xi + 4W_{040}\rho^2\xi + 6W_{060}\rho^4\xi + \cdots \\ \varepsilon_y &\propto 2W_{020}\eta + 4W_{040}\rho^2\eta + 6W_{060}\rho^4\eta + \cdots \end{aligned} \tag{321}$$

There are also higher-order off-axis terms, called *oblique spherical aberration,* with forms $h^{2L}\rho^{2M}$. Spherical is an even aberration.

In *coma,* the wavefront aberration varies linearly with field height, so the general form is $h\rho^{2M}\eta = h\rho^{2M+1} \cos \psi$. Coma is an odd aberration. The wavefront expansion is

$$W = (W_{131}\rho^2 + W_{151}\rho^4 + \cdots)\eta h = (W_{131}\rho^3 + W_{151}\rho^5 + \cdots) \cos \psi h \tag{322}$$

The ray aberrations are

$$\begin{aligned} \varepsilon_x &\propto [W_{131}(2\xi\eta) + 4W_{151}(\xi^2 + \eta^2)\xi\eta + \cdots]h \\ \varepsilon_y &\propto [W_{131}(\xi^2 + 3\eta^2) + W_{151}(\xi^4 + 5\xi^2\eta^2 + 6\eta^4) + \cdots]h \end{aligned} \tag{323}$$

In *astigmatism* the wavefront aberration is cylindrical. The third-order term is

$$W = W_{222}h^2\eta^2 = W_{222}h^2\rho^2 \cos^2 \psi \tag{324}$$

with ray aberration

$$\varepsilon_x = 0 \qquad \varepsilon_y \propto 2W_{222}h^2\eta \tag{325}$$

Field curvature, also known as *Petzval curvature,* is a variation of focal position in the axial direction with field height. In its presence, the best image of a planar object lies on a nonplanar surface. Its absence is called *field flatness.* The wavefront aberration form is

$$W = (W_{220}h^2 + W_{420}h^4 + W_{620}h^6 + \cdots)\rho^2 \tag{326}$$

with symmetrical blurs given by

$$\begin{aligned}\varepsilon_x &\propto (W_{220}h^2 + W_{420}h^4 + W_{620}h^6 + \cdots)\xi \\ \varepsilon_y &\propto (W_{220}h^2 + W_{420}h^4 + W_{620}h^6 + \cdots)\eta\end{aligned} \tag{327}$$

The curvature of the best focus surface may have the same sign across the field, or there may be curvatures of both signs.

Astigmatism and field curvature are often grouped together. Combining defocus, third-order astigmatism, and third-order field curvature, the wavefront aberration can be written

$$W = W_{020}(\xi^2 + \eta^2) + [W_{220}\xi^2 + (W_{220} + W_{222})\eta^2]h^2 \tag{328}$$

The resultant ray aberration is

$$\varepsilon_x \propto [W_{020} + W_{220}h^2]\xi \qquad \varepsilon_y \propto [W_{020} + (W_{222} + W_{220})h^2]\eta \tag{329}$$

A tangential fan of rays, one that lies in the $x = 0$ meridian, has $\xi = 0$, so $\varepsilon_x = 0$. The *tangential focus* occurs where $\varepsilon_y = 0$, which occurs for a defocus of $W_{020} = -(W_{220} + W_{222})h^2$. Combining this result with Eq. (314) gives $\delta z \propto h^2$, the equation for the tangential focal surface. A sagittal fan of rays crosses the pupil in the $\eta = 0$ meridian, so $\varepsilon_y = 0$. The *sagittal focus* occurs where $\varepsilon_x = 0$, i.e., on the surface given by $W_{020} = -W_{220}h^2$.

In general, *distortion* is a deviation from geometric similarity between object and image. For rotationally symmetrical lenses and object and image planes perpendicular to the axis, the error is purely radial, and can be thought of as a variation of magnification with field height. The aberration forms are

$$W = (W_{111}h + W_{311}h^3 + W_{511}h^5 + \cdots)\eta \tag{330}$$

with

$$\varepsilon_x = 0 \qquad \varepsilon_y \propto W_{111}h + W_{311}h^3 + W_{511}h^5 + \cdots \tag{331}$$

In *pincushion* distortion the magnitude of magnification increases monotonically with field height, so the image is stretched radially. In *barrel distortion* the magnitude decreases, so the image is squeezed. In general, the aberration coefficients can be both positive and negative, so the direction of distortion can change as a function of field height and the distortion may vanish for one or more field heights.

For *piston error* the wavefront differs uniformly across the pupil from its nominal in a way that varies with field height.

$$W = W_{000} + W_{200}h^2 + W_{400}h^4 + W_{600}h^6 + \cdots \qquad \varepsilon_x = \varepsilon_y = 0 \tag{332}$$

There are no transverse ray aberrations.

Chromatic Aberrations

In general, the properties of optical systems vary with wavelength. The term *chromatic aberration* often refers to the variation in paraxial properties as a function of wavelength. Thus, *axial color* is related to differences of focal length and principal plane location with wavelength, and *lateral color* is related to variations of magnification with wavelength. Also, the monochromatic aberrations vary in magnitude with wavelength. Reflective systems have identical ray properties at all wavelengths, but their wave properties vary with color, since a given variation in path length has an effect on phase that varies with wavelength.

Stop Size and Aberration Variation

For a given system, if the size of the aperture is changed, the marginal ray is changed, but not the chief ray. If the aperture is reduced, depth of focus and depth of field increase and image irradiance decreases. The rays from axial object points are more nearly paraxial, so the imaging tends to be better corrected. For off-axis points, some aberrations are changed and others are not. Distortion, as defined with respect to the chief ray, is not changed. Field curvature per se does not change, since the aperture size does not change the location of the best image surface (if there are no other aberrations), but the depth of focus does change, so a flat detector can cover a larger field.

Stop Position and Aberration Variation

For a given system, if the aperture is moved axially, the image-forming bundle passes through different portions of the lens elements. Accordingly, some aberrations vary with the position of the stop. Lens design involves an operation called the *stop shift,* in which the aperture is moved axially while its size is adjusted to keep the numerical apertures constant. In this operation, the marginal ray is fixed, while the chief ray is changed. This does not change the aberrations on axis. Most of those for off-axis points are changed, but third-order field curvature is unchanged.

2.1 GLOSSARY

A	amplitude
$\mathbf{E}$	electric field vector
$\mathbf{r}$	position vector
x, y, z	rectangular coordinates
ϕ	phase

2.2 INTRODUCTION

Interference results from the superposition of two or more electromagnetic waves. From a classical optics perspective, interference is the mechanism by which light interacts with light. Other phenomena, such as refraction, scattering, and diffraction, describe how light interacts with its physical environment. Historically, interference was instrumental in establishing the wave nature of light. The earliest observations were of colored fringe patterns in thin films. Using the wavelength of light as a scale, interference continues to be of great practical importance in areas such as spectroscopy and metrology.

2.3 WAVES AND WAVEFRONTS

The *electric field vector* due to an electromagnetic field at a point in space is composed of an amplitude and a phase

$$\mathbf{E}(x, y, z, t) = \mathbf{A}(x, y, z, t)e^{i\phi(x,y,z,t)} \tag{1}$$

or

$$\mathbf{E}(\mathbf{r}, t) = \mathbf{A}(\mathbf{r}, t)e^{i\phi(\mathbf{r},t)} \tag{2}$$

where $\mathbf{r}$ is the position vector and both the amplitude $\mathbf{A}$ and phase ϕ are functions of the spatial coordinate and time. As described in Chap. 5, "Polarization," the polarization state of the field is contained in the temporal variations in the amplitude vector.

This expression can be simplified if a linearly polarized monochromatic wave is assumed:

$$\mathbf{E}(x, y, z, t) = \mathbf{A}(x, y, z)e^{i[\omega t - \phi(x,y,z)]} \tag{3}$$

where ω is the angular frequency in radians per second and is related to the frequency ν by

$$\omega = 2\pi\nu \tag{4}$$

Some typical values for the optical frequency are 5×10^{14} Hz for the visible, 10^{13} Hz for the infrared, and 10^{16} Hz for the ultraviolet. Note that in the expression for the electric field vector, the time dependence has been eliminated from the amplitude term to indicate a constant linear polarization. The phase term has been split into spatial and temporal terms. At all locations in space, the field varies harmonically at the frequency ω.

Plane Wave

The simplest example of an electromagnetic wave is the *plane wave.* The plane wave is produced by a monochromatic point source at infinity and is approximated by a collimated light source. The complex amplitude of a linearly polarized plane wave is

$$\mathbf{E}(x, y, z, t) = \mathbf{E}(\mathbf{r}, t) = \mathbf{A}e^{i[\omega t - \mathbf{k}\cdot\mathbf{r}]} \tag{5}$$

where $\mathbf{k}$ is the wave vector. The wave vector points in the direction of propagation, and its magnitude is the wave number $k = 2\pi/\lambda$, where λ is the wavelength. The wavelength is related to the temporal frequency by the speed of light v in the medium:

$$\lambda = \frac{v}{\nu} = 2\pi\frac{v}{\omega} = \frac{c}{n\nu} = 2\pi\frac{c}{n\omega} \tag{6}$$

where n is the index of refraction, and c is the speed of light in a vacuum. The amplitude $\mathbf{A}$ of a plane wave is a constant over all space, and the plane wave is clearly an idealization.

If the direction of propagation is parallel to the z axis, the expression for the complex amplitude of the plane wave simplifies to

$$\mathbf{E}(x, y, z, t) = \mathbf{A}e^{i[\omega t - kz]} \tag{7}$$

We see that the plane wave is periodic in both space and time. The spatial period equals the wavelength in the medium, and the temporal period equals $1/\nu$. Note that the wavelength changes with index of refraction, and the frequency is independent of the medium.

Spherical Wave

The second special case of an electromagnetic wave is the spherical wave which radiates from an isotropic point source. If the source is located at the origin, the complex amplitude is

$$E(r, t) = (A/r)e^{i[\omega t - kr]} \tag{8}$$

where $r = (x^2 + y^2 + z^2)^{1/2}$. The field is spherically symmetric and varies harmonically with time and the radial distance. The radial period is the wavelength in the medium. The amplitude of the field decreases as $1/r$ for energy conservation. At a large distance from the source, the spherical wave can be approximated by a plane wave. Note that the vector characteristics of the field (its polarization) are not considered here as it is not possible to describe a linear polarization pattern of constant amplitude that is consistent over the

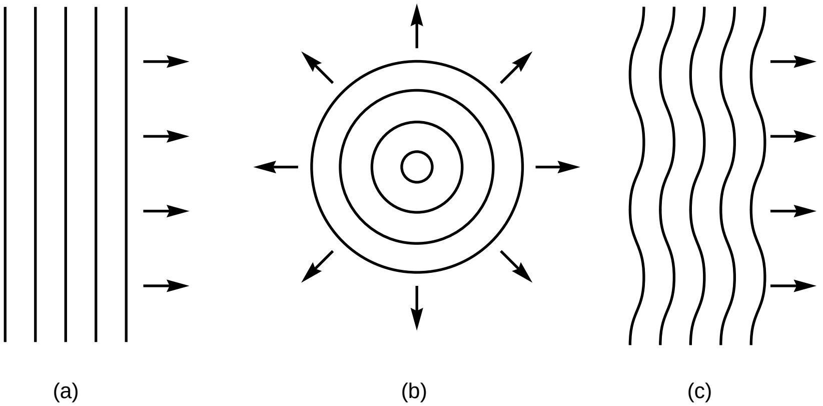

FIGURE 1 Examples of wavefronts: (*a*) plane wave; (*b*) spherical wave; and (*c*) aberrated plane wave.

entire surface of a sphere. In practice, we only need to consider an angular segment of a spherical wave, in which case this polarization concern disappears.

Wavefronts

Wavefronts represent surfaces of constant phase for the electromagnetic field. Since they are normally used to show the spatial variations of the field, they are drawn or computed at a fixed time. Wavefronts for plane and spherical waves are shown in Fig. 1*a* and *b*. The field is periodic, and a given value of phase will result in multiple surfaces. These surfaces are separated by the wavelength. A given wavefront also represents a surface of constant optical path length (OPL) from the source. The OPL is defined by the following path integral:

$$\text{OPL} = \int_S^P n(s)\, ds \tag{9}$$

where the integral goes from the source S to the observation point P, and $n(s)$ is the index of refraction along the path. Variations in the index or path can result in irregularities or aberrations in the wavefront. An aberrated plane wavefront is shown in Fig. 1*c*. Note that the wavefronts are still separated by the wavelength.

The local normal to the wavefront defines the propagation direction of the field. This fact provides the connection between wave optics and ray or geometrical optics. For a given wavefront, a set of rays can be defined using the local surface normals. In a similar manner, a set of rays can be used to construct the equivalent wavefront.

2.4 INTERFERENCE

The net complex amplitude is the sum of all of the component fields,

$$\mathbf{E}(x, y, z, t) = \sum_i \mathbf{E}_i(x, y, z, t) \tag{10}$$

and the resulting field intensity is the time average of the modulus squared of the total complex amplitude

$$I(x, y, z, t) = \langle |\mathbf{E}(x, y, z, t)|^2 \rangle \tag{11}$$

where $\langle\ \rangle$ indicates a time average over a period much longer than $1/\nu$. If we restrict ourselves to two interfering waves $\mathbf{E}_1$ and $\mathbf{E}_2$, this result simplifies to

$$I(x, y, z, t) = \langle|\mathbf{E}_1|^2\rangle + \langle|\mathbf{E}_2|^2\rangle + \langle\mathbf{E}_1 \cdot \mathbf{E}_2^*\rangle + \langle\mathbf{E}_1^* \cdot \mathbf{E}_2\rangle \tag{12}$$

or

$$I(x, y, z, t) = I_1 + I_2 + \langle\mathbf{E}_1 \cdot \mathbf{E}_2^*\rangle + \langle\mathbf{E}_1^* \cdot \mathbf{E}_2\rangle \tag{13}$$

where I_1 and I_2 are the intensities due to the two beams individually, and the (x, y, z, t) dependence is now implied for the various terms.

This general result can be greatly simplified if we assume linearly polarized monochromatic waves of the form in Eq. (3):

$$\mathbf{E}_i(x, y, z, t) = \mathbf{A}_i(x, y, z)e^{i[\omega_i t - \phi_i(x,y,z)]} \tag{14}$$

The resulting field intensity is

$$I(x, y, z, t) = I_1 + I_2 + 2(\mathbf{A}_1 \cdot \mathbf{A}_2) \cos[(\omega_1 - \omega_2)t - (\phi_1(x, y, z) - \phi_2(x, y, z))] \tag{15}$$

The interference effects are contained in the third term, and we can draw two important conclusions from this result. First, if the two interfering waves are orthogonally polarized, there will be no visible interference effects, as the dot product will produce a zero coefficient. Second, if the frequencies of the two waves are different, the interference effects will be modulated at a temporal beat frequency equal to the difference frequency.

Interference Fringes

We will now add the additional restrictions that the two linear polarizations are parallel and that the two waves are at the same optical frequency. The expression for the intensity pattern now becomes

$$I(x, y, z) = I_1 + I_2 + 2\sqrt{I_1 I_2} \cos[\Delta\phi(x, y, z)] \tag{16}$$

where $\Delta\phi = \phi_1 - \phi_2$ is the phase difference. This is the basic equation describing interference. The detected intensity varies cosinusoidally with the phase difference between the two waves as shown in Fig. 2. These alternating bright and dark bands in the

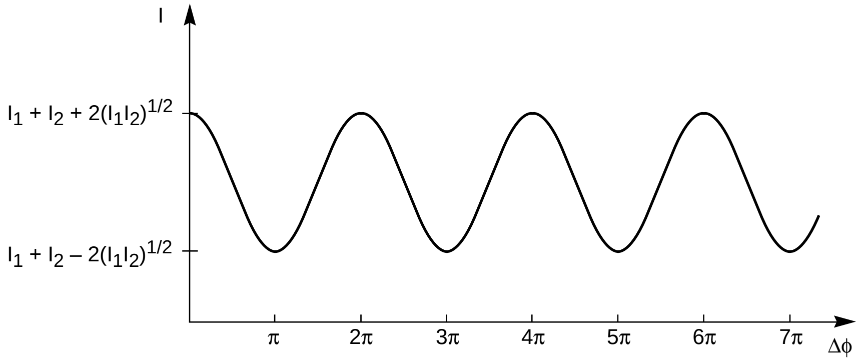

FIGURE 2 The variation in intensity as a function of the phase difference between two interfering waves.

TABLE 1 The Phase Difference and OPD for Bright and Dark Fringes (*m* an Integer)

	$\Delta\phi$	OPD
Bright fringe	$2m\pi$	$m\lambda$
Dark fringe	$2(m+1)\pi$	$(m+1/2)\lambda$

intensity pattern are referred to as *interference fringes,* and along a particular fringe, the phase difference is constant.

The phase difference is related to the difference in the optical path lengths between the source and the observation point for the two waves. This is the *optical path difference* (OPD):

$$\text{OPD} = \text{OPL}_1 - \text{OPL}_2 = \left(\frac{\lambda}{2\pi}\right)\Delta\phi \tag{17}$$

or

$$\Delta\phi = \left(\frac{2\pi}{\lambda}\right)\text{OPD} \tag{18}$$

The phase difference changes by 2π every time the OPD increases by a wavelength. The OPD is therefore constant along a fringe.

Constructive interference occurs when the two waves are in phase, and a bright fringe or maximum in the intensity pattern results. This corresponds to a phase difference of an integral number of 2π's or an OPD that is a multiple of the wavelength. A dark fringe or minimum in the intensity pattern results from *destructive interference* when the two waves are out of phase by π or the OPD is an odd number of half wavelengths. These results are summarized in Table 1. For conditions between these values, an intermediate value of the intensity results. Since both the OPD and the phase difference increase with the integer *m,* the absolute value of *m* is called the *order of interference.*

As we move from one bright fringe to an adjacent bright fringe, the phase difference changes by 2π. Each fringe period corresponds to a change in the OPD of a single wavelength. It is this inherent precision that makes interferometry such a valuable metrology tool. The wavelength of light is used as the unit of measurement. Interferometers can be configured to measure small variations in distance, index, or wavelength.

When two monochromatic waves are interfered, the interference fringes exist not only in the plane of observation, but throughout all space. This can easily be seen from Eq. (16) where the phase difference can be evaluated at any z position. In many cases, the observation of interference is confined to a plane, and this plane is usually assumed to be perpendicular to the z axis. The z dependence in Eq. (16) is therefore often not stated explicitly, but it is important to remember that interference effects will exist in other planes.

Fringe Visibility

It is often more convenient to rewrite Eq. (16) as

$$I(x, y) = I_0(x, y)\{1 + \gamma(x, y)\cos[\Delta\phi(x, y, z)]\} \tag{19}$$

or

$$I(x, y) = I_0(x, y)\{1 + \gamma(x, y)\cos[2\pi\text{OPD}(x, y)/\lambda]\} \tag{20}$$

where $I_0(x, y) = I_1(x, y) + I_2(x, y)$, and

$$\gamma(x, y) = \frac{2[I_1(x, y)I_2(x, y)]^{1/2}}{I_1(x, y) + I_2(x, y)} \tag{21}$$

Since the cosine averages to zero, $I_0(x, y)$ represents the average intensity, and $\gamma(x, y)$ is the local *fringe contrast* or *visibility*. The fringe visibility can also be equivalently calculated using the standard formula for modulation:

$$\gamma(x, y) = \frac{I_{\max}(x, y) - I_{\min}(x, y)}{I_{\max}(x, y) + I_{\min}(x, y)} \tag{22}$$

where $I_{\max}$ and $I_{\min}$ are the maximum and minimum intensities in the fringe pattern.

The fringe visibility will have a value between 0 and 1. The maximum visibility will occur when the two waves have equal intensity. Not surprisingly, the visibility will drop to zero when one of the waves has zero intensity. In general, the intensities of the two waves can vary with position, so that the average intensity and fringe visibility can also vary across the fringe pattern. The average intensity in the observation plane equals the sum of the individual intensities of the two interfering waves. The interference term redistributes this energy into bright and dark fringes.

Two Plane Waves

The first special case to consider is the interference of two plane waves of equal intensity, polarization and frequency. They are incident at angles θ_1 and θ_2 on the observation plane, as shown in Fig. 3. The plane of incidence is the x-z plane (the two k-vectors are contained in this plane). According to Eq. (5), the complex amplitude for each of these plane waves is

$$\mathbf{E}_i(x, y, z, t) = \mathbf{A}e^{i[\omega t - kz\cos(\theta_i) - kx\sin(\theta_i)]} \tag{23}$$

where the dot product has been evaluated. For simplicity we will place the observation plane at $z = 0$, and the phase difference between the two waves is

$$\Delta\phi(x, y) = kx(\sin\theta_1 - \sin\theta_2) = (2\pi x/\lambda)(\sin\theta_1 - \sin\theta_2) \tag{24}$$

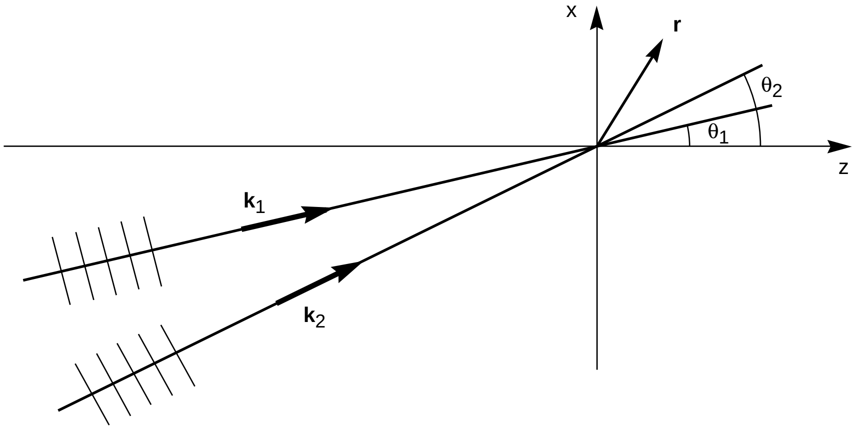

FIGURE 3 The geometry for the interference of two plane waves.

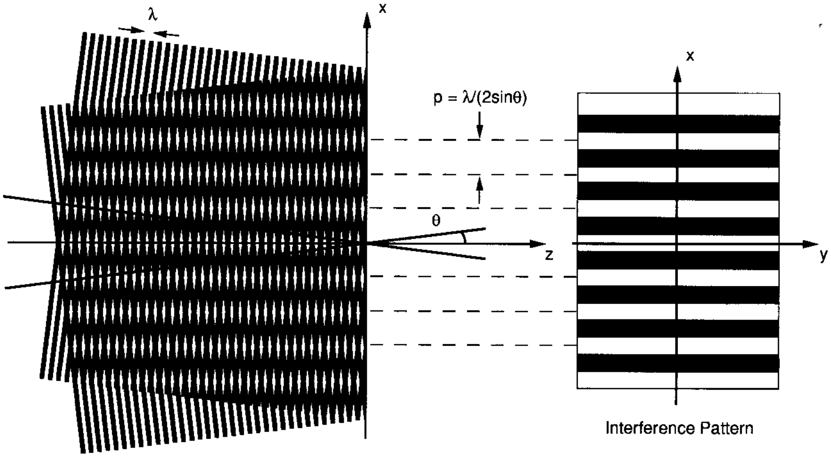

FIGURE 4 The interference of plane waves incident at ±θ resulting in straight fringes.

The resulting intensity from Eq. (19) is

$$I(x, y) = I_0\{1 + \cos [(2\pi x/\lambda)(\sin \theta_1 - \sin \theta_2)]\} \tag{25}$$

where $I_0 = 2A^2$ is twice the intensity of each of the individual waves. Straight equispaced fringes are produced. The fringes are parallel to the y axis, and the fringe period depends on the angle between the two interfering beams.

The fringe period p is

$$p = \frac{\lambda}{\sin \theta_1 - \sin \theta_2} \tag{26}$$

and this result can also be obtained by noting that a bright fringe will occur whenever the phase difference equals a multiple of 2π. A typical situation for interference is that the two angles of incidence are equal and opposite, $\theta_1 = -\theta_2 = \theta$. The angle between the two beams is 2θ. Under this condition, the period is

$$p = \frac{\lambda}{2 \sin \theta} \approx \frac{\lambda}{2\theta} \tag{27}$$

and the small-angle approximation is given. As the angle between the beams gets larger, the period decreases. For example, the period is 3.8λ at 15° (full angle of 30°) and is λ at 30° (full angle of 60°). The interference of two plane waves can be visualized by looking at the overlap or moiré of two wavefront patterns (Fig. 4). Whenever the lines representing the wavefronts overlap, a fringe will result. This description also clearly shows that the fringes extend parallel to the z axis and exist everywhere the two beams overlap.

Plane Wave and Spherical Wave

A second useful example to consider is the interference of a plane wave and a spherical wave. Once again the two waves have the same frequency. The plane wave is at normal incidence, the spherical wave is due to a source at the origin, and the observation plane is located at $z = R$. The wavefront shape at the observation plane will be a spherical shell of radius R. Starting with Eq. (8), the complex amplitude of the spherical wave in the observation plane is

$$E(\rho, t) = (A/R)e^{i[\omega t - k(R^2+\rho^2)^{1/2}]} \approx (A/R)e^{i[\omega t - k(R+\rho^2/2R)]} \tag{28}$$

where $\rho = (x^2 + y^2)^{1/2}$, and the square root has been expanded in the second expression. This expansion approximates the spherical wave by a parabolic wave with the same vertex radius. An additional assumption is that the amplitude of the field A/R is constant over the region of interest. The field for the plane wave is found by evaluating Eq. (23) at $z = R$ and $\theta = 0$. The phase difference between the plane and the sphere is then

$$\Delta\phi(\rho) \approx \frac{\pi\rho^2}{\lambda R} \tag{29}$$

and the resulting intensity pattern is

$$I(\rho) = I_0\left[1 + \cos\left(\frac{\pi\rho^2}{\lambda R}\right)\right] \tag{30}$$

The fringe pattern is comprised of concentric circles, and the radial fringe spacing decreases as the radius ρ increases. The intensities of the two waves have been assumed to be equal at the observation plane. This result is valid only when ρ is much smaller than R.

The radius of the mth bright fringe can be found by setting $\Delta\phi = 2\pi m$:

$$\rho_m = \sqrt{2mR} \tag{31}$$

where m is an integer. The order of interference m increases with radius. Figure 5 shows a visualization of this situation using wavefronts. This fringe pattern is the Newton's ring pattern and is discussed in more detail later, under "Fizeau Interferometer." This picture also shows that the radii of the fringes increase as the square root of R.

The analysis of the spherical wave could also have been done by using the sag of a spherical wavefront to produce an OPD and then converting this value to a phase difference. The quadratic approximation for the sag of a spherical surface is $\rho^2/2R$. This

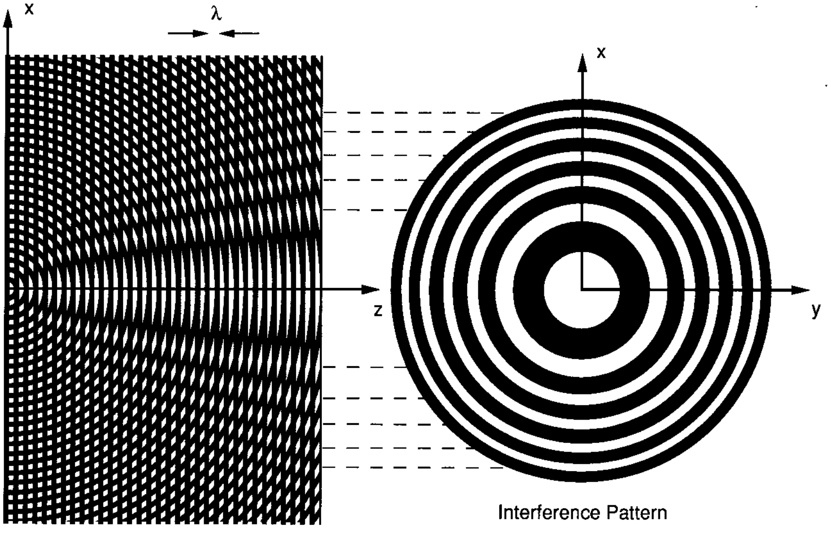

FIGURE 5 The interference of a plane wave and a spherical wave.

corresponds to the OPD between the spherical and planar wavefronts. The equivalent phase difference [Eq. (18)] is then $\pi\rho^2/\lambda R$, as before.

Two Spherical Waves

When considering two spherical waves, there are two particular geometries that we want to examine. The first places the observation plane perpendicular to a line connecting the two sources, and the second has the observation plane parallel to this line. Once again, the sources are at the same frequency.

When the observations are made on a plane perpendicular to a line connecting the two sources, we can use Eq. (28) to determine the complex amplitude of the two waves:

$$E_i(\rho, t) \approx (A/R)e^{i[\omega t - k(R_i + \rho^2/2R_i)]} \tag{32}$$

Let $d = R_1 - R_2$ be the separation of the two sources. For simplicity, we have also assumed that the amplitudes of the two waves are equal (R is an average distance). The phase difference between the two waves is

$$\Delta\phi = \left(\frac{\pi\rho^2}{\lambda}\right)\left(\frac{1}{R_1} - \frac{1}{R_2}\right) + \frac{2\pi d}{\lambda} \approx \frac{2\pi d}{\lambda} - \left(\frac{\pi\rho^2}{\lambda}\right)\left(\frac{d}{R^2}\right), \tag{33}$$

where the approximation $R_1R_2 \approx R^2$ has been made. There are two terms to this phase difference. The second is a quadratic phase term identical in form to the result obtained from spherical and plane waves. The pattern will be symmetric around the line connecting the two sources, and its appearance will be similar to Newton's rings. The equivalent radius of the spherical wave in Eq. (29) is R^2/d. The first term is a constant phase shift related to the separation of the two sources. If this term is not a multiple of 2π, the center of the fringe pattern will not be a bright fringe; if the term is π, the center of the pattern will be dark. Except for the additional phase shift, this intensity pattern is not distinguishable from the result in the previous section. It should be noted, however, that a relative phase shift can be introduced between a spherical wave and a plane wave to obtain this same result.

An important difference between this pattern and the Newton's ring pattern is that the order of interference ($|m|$ defined by $\Delta\phi = 2\pi m$) or phase difference is a maximum at the center of the pattern and decreases with radius. The phase difference is zero at some finite radius. The Newton's ring pattern formed between a plane and a spherical wave has a minimum order of interference at the center of the pattern. This distinction is important when using polychromatic sources.

There are several ways to analyze the pattern that is produced on a plane that is parallel to a line connecting the two sources. We could evaluate the complex amplitudes by using Eq. (28) and moving the center of the spherical waves to $\pm d/2$ for the two sources. An equivalent method is to compare the wavefronts at the observation plane. This is shown in Fig. 6. The OPD between the two wavefronts is

$$\text{OPD}(x, y) = \frac{[(x + d/2)^2 + y^2]}{2L} - \frac{[(x - d/2)^2 + y^2]}{2L} \tag{34}$$

where the quadratic approximation for the wavefront sag has been assumed, and L is the distance between the sources and the observation plane. After simplification, the OPD and phase differences are

$$\text{OPD}(x, y) = \frac{xd}{L} \tag{35}$$

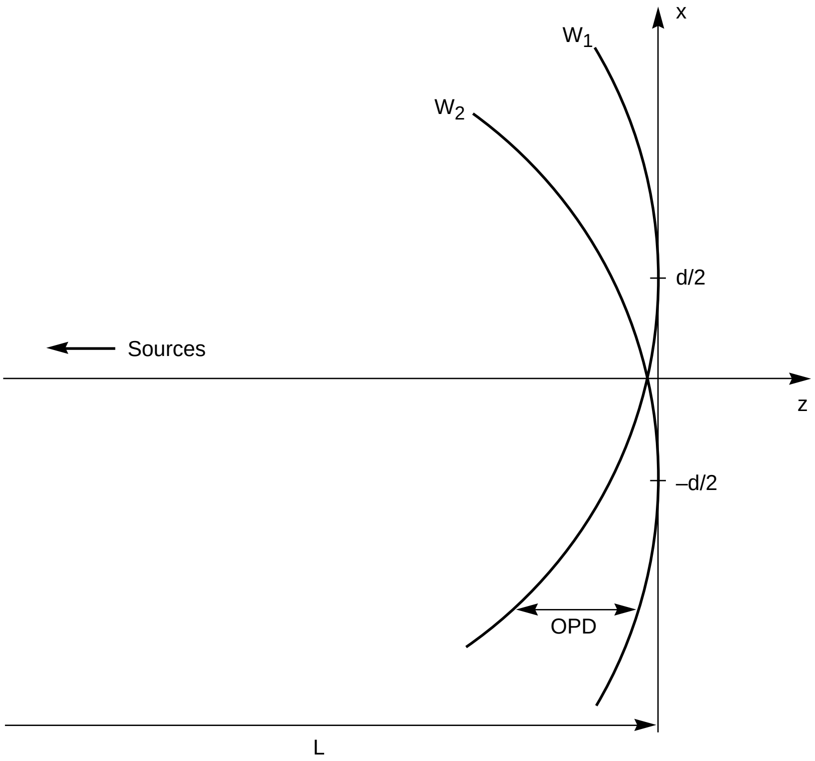

FIGURE 6 The interference of two spherical waves on a plane parallel to the sources.

and

$$\Delta\phi(x, y) = \frac{2\pi x d}{\lambda L} \tag{36}$$

Straight equispaced fringes parallel to the y axis are produced. The period of the fringes is $\lambda L/d$. This fringe pattern is the same as that produced by two plane waves. Note that these fringes increase in spacing as the distance from the sources increases. The approximations used require that L be much larger than ρ and d.

Figure 7 shows the creation of the fringe patterns for two point sources. The full three-dimensional pattern is a series of nested hyperboloids symmetric about the line connecting the sources. Above the two sources, circular fringes approximating Newton's rings are produced, and perpendicular to the sources, the fringes appear to be straight and equispaced.

Aberrated Wavefronts

When an aberrated or irregularly shaped wavefront is interfered with a reference wavefront, an irregularly shaped fringe pattern is produced. However, the rules for analyzing this pattern are the same as with any two wavefronts. A given fringe represents a contour of constant OPD or phase difference between the two wavefronts. Adjacent fringes differ in OPD by one wavelength or equivalently correspond to a phase difference

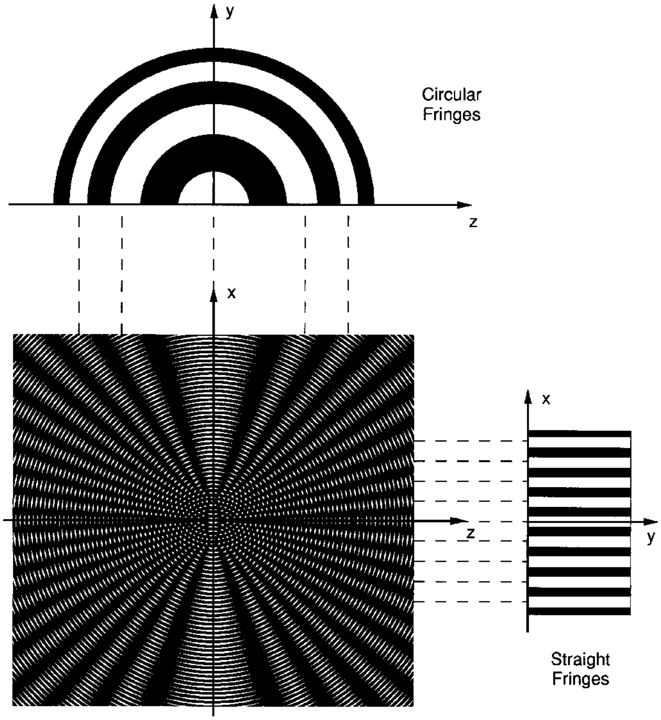

FIGURE 7 The interference of two spherical waves.

of 2π. If the reference is a plane wave, the absolute shape of the irregular wavefront is obtained. If the reference is a spherical wave, or another aberrated wave, the measured OPD or phase difference map represents the difference between the two wavefronts.

Temporal Beats

In Eq. (15) it was noted that if the waves are at different frequencies, the interference effects are modulated by a beat frequency. Rewriting this expression assuming equal-intensity parallel-polarized beams produces

$$I(x, y, t) = I_0\{1 + \cos [2\pi\, \Delta\nu t - \Delta\phi(x, y)]\} \tag{37}$$

where $\Delta\nu = \nu_1 - \nu_2$. The intensity at a given location will now vary sinusoidally with time at the beat frequency $\Delta\nu$. The phase difference $\Delta\phi$ appears as a spatially varying phase shift of the beat frequency. This is the basis of the heterodyne technique used in a number of interferometers. It is commonly used in distance-measuring interferometers.

In order for a heterodyne system to work, there must be a phase relationship between the two sources even though they are at different frequencies. One common method for obtaining this is accomplished by starting with a single source, splitting it into two beams, and frequency-shifting one beam with a known Doppler shift. The system will also work in reverse; measure the interferometric beat frequency to determine the velocity of the object producing the Doppler shift.

Coherence

Throughout this discussion of fringe patterns, we have assumed that the two sources producing the two waves have the same frequency. In practice, this requires that both sources be derived from a single source. Even when two different frequencies are used [Eq. (37)] there must be an absolute phase relation between the two sources. If the source has finite size, it is considered to be composed of a number of spatially separated, independently radiating point sources. If the source has a finite spectral bandwidth, it is considered to be composed of a number of spatially coincident point sources with different frequencies. These reductions in the spatial or temporal coherence of the source will decrease the visibility of the fringes at different locations in space. This is referred to as *fringe localization.* These effects will be discussed later in this chapter and also in Chap. 4, ''Coherence Theory.''

There are two general methods to produce mutually coherent waves for interference. The first is called *wavefront division,* where different points on a wavefront are sampled to produce two new wavefronts. The second is *amplitude division,* where some sort of beamsplitter is used to divide the wavefront at a given location into two separate wavefronts. These methods are discussed in the next sections.

2.5 INTERFERENCE BY WAVEFRONT DIVISION

Along a given wavefront produced by a monochromatic point source, the wavefront phase is constant. If two parts of this wavefront are selected and then redirected to a common volume in space, interference will result. This is the basis for *interference by wavefront division.*

Young's Double-Slit Experiment

In 1801, Thomas Young performed a fundamental experiment for demonstrating interference and the wave nature of light. Monochromatic light from a single pinhole illuminates an opaque screen with two additional pinholes or slits. The light diffracts from these pinholes and illuminates a viewing screen at a distance large compared to the pinhole separation. Since the light illuminating the two pinholes comes from a single source, the two diffracted wavefronts are coherent and interference fringes form where the beams overlap.

In the area where the two diffracted beams overlap, they can be modeled as two spherical waves from two point sources, and we already know the form of the solution for the interference from our earlier discussion. Equispaced straight fringes are produced, and the period of the fringes is $\lambda L/d$, where L is the distance to the screen and d is the separation of the pinholes. The fringes are oriented perpendicular to the line connecting the two pinholes.

Even though we already know the answer, there is a classic geometric construction we should consider that easily gives the OPD between the two wavefronts at the viewing

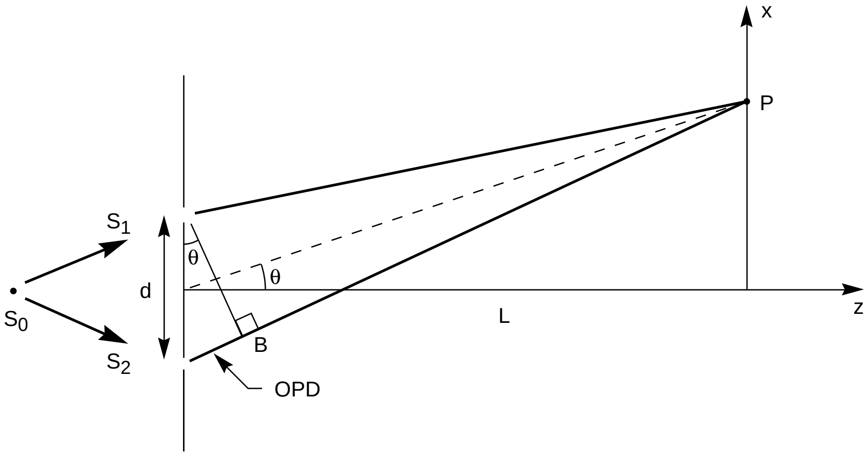

FIGURE 8 Young's double-slit experiment.

screen. This is shown in Fig. 8. S_0 illuminates both S_1 and S_2 and is equidistant from both slits. The OPD for an observation point P at an angle θ or position x is

$$\mathrm{OPD} = \overline{S_2P} - \overline{S_1P} \tag{38}$$

We now draw a line from S_1 to B that is perpendicular to the second ray. Since L is much larger than d, the distances from B to P and S_1 to P are approximately equal. The OPD is then

$$\mathrm{OPD} \approx \overline{S_2B} = d \sin \theta \approx d\theta \approx \frac{dx}{L} \tag{39}$$

and constructive interference or a bright fringe occurs when the OPD is a multiple of the wavelength: $\mathrm{OPD} = m\lambda$, where m is an integer. The condition for the mth order bright fringe is

$$\text{Bright fringe:} \quad \sin(\theta) \approx \theta = \frac{m\lambda}{d} \qquad \text{or} \qquad x = \frac{m\lambda L}{d} \tag{40}$$

This construction is useful not only for interference situations, but also for diffraction analysis.

Effect of Slit Width

The light used to produce the interference pattern is diffracted by the pinholes or slits. Interference is possible only if light is directed in that direction. The overall interference intensity pattern is therefore modulated by the single-slit diffraction pattern (assuming slit apertures):

$$I(x) = I_0 \operatorname{sinc}^2\left(\frac{Dx}{\lambda L}\right)\left[1 + \gamma(x)\cos\left(\frac{2\pi x d}{\lambda L}\right)\right] \tag{41}$$

where D is the slit width, and a one-dimensional expression is shown. The definition of a sinc function is

$$\operatorname{sinc}(\alpha) = \frac{\sin(\pi\alpha)}{\pi\alpha} \tag{42}$$

where the zeros of the function occur when the argument α is an integer. The intensity variation in the y direction is due to diffraction only and is not shown. Since the two slits are assumed to be illuminated by a single source, there are no coherence effects introduced by using a pinhole or slit of finite size.

The term $\gamma(x)$ is included in Eq. (41) to account for variations in the fringe visibility. These could be due to unequal illumination of the two slits, a phase difference of the light reaching the slits, or a lack of temporal or spatial coherence of the source S_0.

Other Arrangements

Several other arrangements for producing interference by division of wavefront are shown in Fig. 9. They all use a single source and additional optical elements to produce two separate and mutually coherent sources. Fresnel's biprism and mirror produce the two

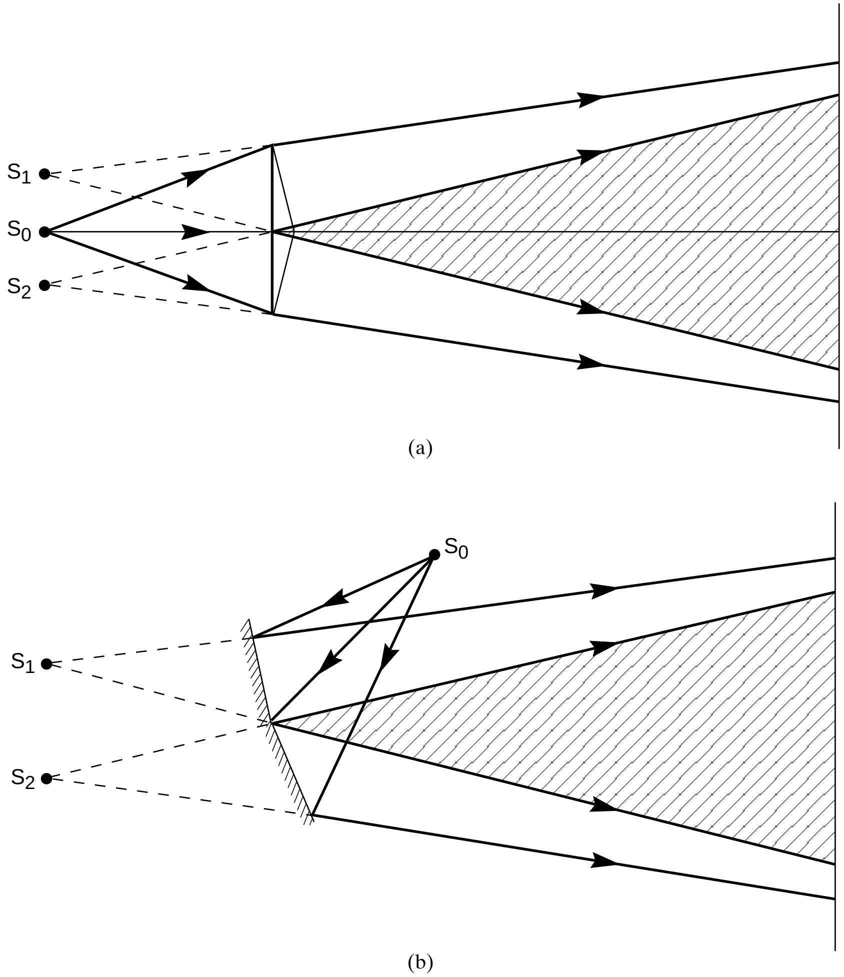

FIGURE 9 Arrangements for interference by division of wavefront: (*a*) Fresnel's biprism; (*b*) Fresnel's mirror; (*c*) Billet's split lens; and (*d*) Lloyd's mirror.

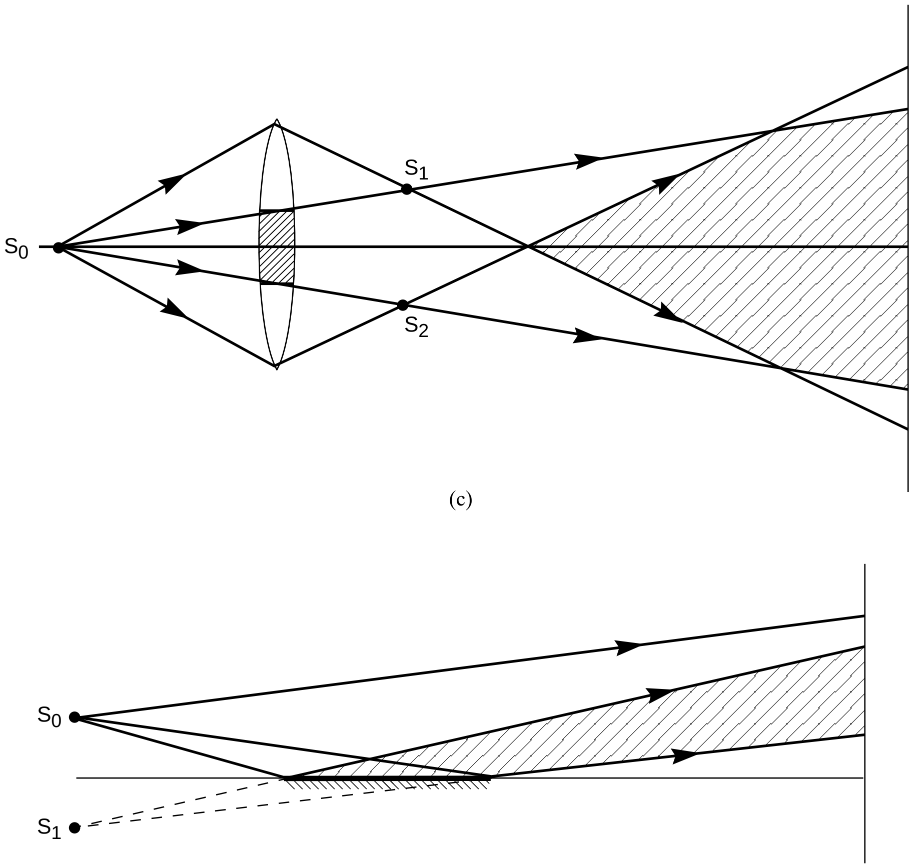

(c)

(d)

FIGURE 9 (*Continued*.)

virtual source images, Billet's split lens produces two real source images, and Lloyd's mirror produces a single virtual source image as a companion to the original source. Interference fringes form wherever the two resulting waves overlap (shaded regions). One significant difference between these arrangements and Young's two slits is that a large section of the initial wavefront is used instead of just two points. All of these systems are much more light efficient, and they do not rely on diffraction to produce the secondary wavefronts.

In the first three of these systems, a bright fringe is formed at the zero OPD point between the two sources as in the double-slit experiment. With Lloyd's mirror, however, the zero OPD point has a dark fringe. This is due to the π phase shift that is introduced into one of the beams on reflection from the mirror.

Source Spectrum

The simple fringe pattern produced by the two-slit experiment provides a good example to examine the effects of a source with a finite spectrum. In this model, the source can be considered to be a collection of sources, each radiating independently and at a different wavelength. All of these sources are colocated to produce a point source. (Note that this is an approximation, as a true point source must be monochromatic.) At each wavelength, an independent intensity pattern is produced:

$$I(x, \lambda) = I_0\left[1 + \cos\left(\frac{2\pi xd}{\lambda L}\right)\right] = I_0\left[1 + \cos\left(\frac{2\pi \text{ OPD}}{\lambda}\right)\right] \tag{43}$$

where the period of the fringes is $\lambda L/d$, and a fringe visibility of one is assumed. The total intensity pattern is the sum of the individual fringe patterns:

$$I(x) = \int_0^{\infty} S(\lambda)I(x, \lambda)\, d\lambda = \int_0^{\infty} S(\nu)I(x, \nu)\, d\nu \tag{44}$$

where $S(\lambda)$ or $S(\nu)$ is the source intensity spectrum which serves as a weighting function.

The effect of this integration can be seen by looking at a simple example where the source is composed of three different wavelengths of equal intensity. To further aid in visualization, let's use Blue (400 nm), Green (500 nm), and Red (600 nm). The result is shown in Fig. 10*a*. There are three cosine patterns, each with a period proportional to the wavelength. The total intensity is the sum of these curves. All three curves line up when the OPD is zero ($x = 0$), and the central bright fringe is now surrounded by two-colored dark fringes. These first dark fringes have a red to blue coloration with increasing OPD. As we get further away from the zero OPD condition, the three patterns get out of phase, the pattern washes out, and the color saturation decreases. This is especially true when the source is composed of more than three wavelengths.

It is common in white light interference situations for one of the two beams to undergo an additional π phase shift. This is the situation in Lloyd's mirror. In this case, there is a central dark fringe at zero OPD with colored bright fringes on both sides. This is shown in Fig. 10*b*, and the pattern is complementary to the previous pattern. In this case the first

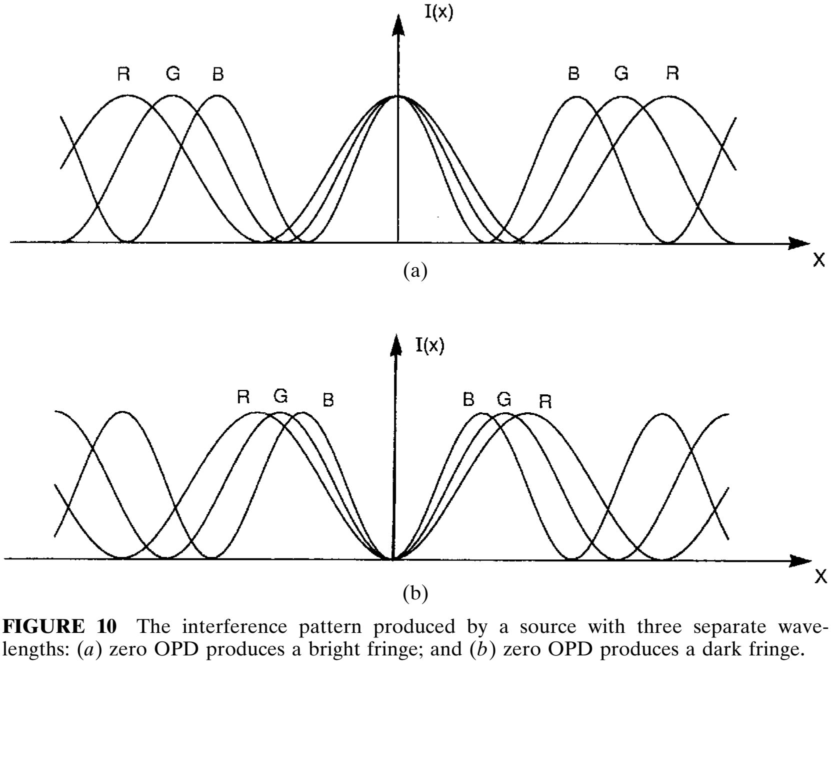

FIGURE 10 The interference pattern produced by a source with three separate wavelengths: (*a*) zero OPD produces a bright fringe; and (*b*) zero OPD produces a dark fringe.

bright fringe shows a blue to red color smear. The dark central fringe is useful in determining the location of zero OPD between the two beams.

The overall intensity pattern and resulting fringe visibility can be computed for a source with a uniform frequency distribution over a frequency range of $\Delta\nu$:

$$I(x) = \frac{1}{\Delta\nu}\int_{\nu_0-\Delta\nu/2}^{\nu_0+\Delta\nu/2} I(x, \nu)\,d\nu = \frac{1}{\Delta\nu}\int_{\nu_0-\Delta\nu/2}^{\nu_0+\Delta\nu/2} I_0\left[1 + \cos\left(\frac{2\pi\nu x d}{cL}\right)\right]d\nu \tag{45}$$

where ν_0 is the central frequency, and the $1/\Delta\nu$ term is a normalization factor to assure that the average intensity is I_0. After integration and simplification, the result is

$$I(x) = I_0\left[1 + \operatorname{sinc}\left(\frac{xd\,\Delta\nu}{cL}\right)\cos\left(\frac{2\pi\nu_0 x d}{cL}\right)\right] \tag{46}$$

where the sinc function is defined in Eq. (42). A fringe pattern due to the average optical frequency results, but it is modulated by a sinc function that depends on $\Delta\nu$ and x. The absolute value of the sinc function is the fringe visibility $\gamma(x)$, and it depends on both the spectral width and position of observation. The negative portions of the sinc function correspond to a π phase shift of the fringes.

It is informative to rewrite this expression in terms of the OPD:

$$I(x) = I_0\left[1 + \operatorname{sinc}\left(\frac{\text{OPD}\,\Delta\nu}{c}\right)\cos\left(\frac{2\pi\,\text{OPD}}{\lambda_0}\right)\right] \tag{47}$$

where λ_0 is the wavelength corresponding to ν_0. Good fringe visibility is obtained only when either the spectral width is small (the source is quasi-monochromatic) or the OPD is small. The fringes are *localized* in certain areas of space. This result is consistent with the earlier graphical representations. In the area where the OPD is small, the fringes are in phase for all wavelengths. As the OPD increases, the fringes go out of phase since they all have different periods, and the intensity pattern washes out.

This result turns out to be very general: for an incoherent source, the fringes will be localized in the vicinity of zero OPD. There are two other things we should notice about this result. The first is that the first zero of the visibility function occurs when the OPD equals $c/\Delta\nu$. This distance is known as the *coherence length* as it is the path difference over which we can obtain interference. The second item is that the visibility function is a scaled version of the Fourier transform of the source frequency spectrum. It is evaluated for the OPD at the measurement location. The Fourier transform of a uniform distribution is a sinc function. We will discuss this under "Coherence and Interference" later in the chapter.

2.6 INTERFERENCE BY AMPLITUDE DIVISION

The second general method for producing interference is to use the same section of a wavefront from a single source for both resulting wavefronts. The original wavefront amplitude is split into two or more parts, and each fraction is directed along a different optical path. These waves are then recombined to produce interference. This method is called *interference by amplitude division.* There are a great many interferometer designs based on this method. A few will be examined here, and many more will be discussed in Chap. 21 of Vol. 2, "Interferometers."

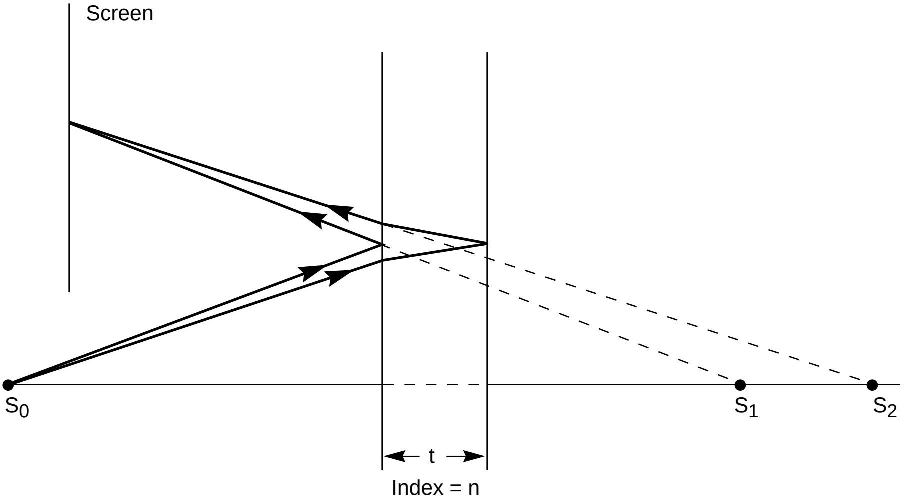

FIGURE 11 Interference from a plane-parallel plate and a point source.

Plane-Parallel Plate

A first example of interference by amplitude division is a plane-parallel plate illuminated by a monochromatic point source. Two virtual images of the point source are formed by the Fresnel reflections at the two surfaces, as shown in Fig. 11. Associated with each of the virtual images is a spherical wave, and interference fringes form wherever these two waves overlap. In this case, this is the volume of space on the source side of the plate. The pattern produced is the same as that found for the interference of two spherical waves (discussed earlier under "Two Spherical Waves"), and nonlocalized fringes are produced. The pattern is symmetric around the line perpendicular to the plate through the source. If a screen is placed along this axis, a pattern similar to circular Newton's ring fringes are produced as described by Eq. (33), where $d = 2t/n$ is now the separation of the virtual sources. The thickness of the plate is *t,* its index is *n,* and the distance *R* is approximately the screen-plate separation plus the source-plate separation. We have ignored multiple reflections in the plate. As with the interference of two spherical waves, the order of interference is a maximum at the center of the pattern.

The interference of two plane waves can be obtained by illuminating a wedged glass plate with a plane wavefront. If the angle of incidence on the first surface is θ and the wedge angle is α, two plane waves are produced at angles θ and $\theta + 2n\alpha$ due to reflections at the front and rear surfaces. Straight equispaced fringes will result in the volume of space where the two reflected waves overlap. The period of these fringes on a screen parallel to the plate is given by Eq. (26), where the two reflected angles are used.

Extended Source

An *extended source* is modeled as a collection of independent point sources. If the source is quasi-monochromatic, all of the point sources radiate at the same nominal frequency, but without a phase relationship. Each point source will produce its own interference pattern, and the net intensity pattern is the sum or integral of all the individual intensity patterns. This is the spatial analogy to the temporal average examined earlier under "Source Spectrum."

With an extended source, the fringes will be localized where the individual fringe position or spacing is not affected by the location of the point sources that comprise the extended source. We know from our previous examples that a bright fringe (or a dark fringe, depending on phase shifts) will occur when the OPD is zero. If there is a location where the OPD is zero independent of source location, all of the individual interference patterns will be in phase, and the net pattern will show good visibility. In fact, the three-dimensional fringe pattern due to a point source will tend to shift or pivot around this zero-OPD location as the point source location is changed. The individual patterns will therefore be out of phase in areas where the OPD is large, and the average intensity pattern will tend to wash out in these regions as the source size increases.

The general rule for fringe visibility with an extended quasi-monochromatic source is that the fringes will be localized in the region where the OPD between the two interfering wavefronts is small. For a wedged glass plate, the fringes are localized in or near the wedge, and the best visibility occurs as the wedge thickness approaches zero and is perhaps just a few wavelengths. The allowable OPD will depend on the source size and the method of viewing the fringes. This result explains why, under natural light, interference effects are seen in thin soap bubbles but not with other thicker glass objects. An important exception to this rule is the plane-parallel plate where the fringes are localized at infinity.

Fringes of Equal Inclination

There is no section of a plane-parallel plate that produces two reflected wavefronts with zero OPD. The OPD is constant, and we would expect, based on the previous section, that no high-visibility fringes would result with an extended source. If, however, a lens is used to collect the light reflected from the plate, fringes are formed in the back focal plane of the lens. This situation is shown in Fig. 12, and any ray leaving the surface at a particular angle θ is focused to the same point P. For each incident ray at this angle, there are two parallel reflected rays: one from the front surface and one from the back surface. The reflections from different locations on the plate at this angle are due to light from different points in the extended source. The OPD for any pair of these reflected rays is the same regardless of the source location. These rays will interfere at P and will all have the same phase difference. High-visibility fringes result. Different points in the image plane correspond to different angles. The formation of these fringes localized at infinity depends on the two surfaces of the plate being parallel.

The OPD between the reflected rays is a function of the angle of incidence θ, the plate index n, and thickness t:

$$\text{OPD} = 2nt \cos \theta' \tag{48}$$

where θ' is the internal angle. Taking into account the half-wave shift due to the phase change difference of π between an internal and an external reflection, a dark fringe will result for angles satisfying

$$2nt \cos \theta' = m\lambda \qquad \text{or} \qquad \cos \theta' = \frac{m\lambda}{2nt} \tag{49}$$

where m is an integer. Since only the angle of incidence determines the properties of the interference (everything else is constant), these fringes are called *fringes of equal inclination.* They appear in the back focal plane of the lens and are therefore localized at infinity since infinity is conjugate to the focal plane. As the observation plane is moved away from the focal plane, the visibility of the fringes will quickly decrease.

When the axis of the lens is normal to the surfaces of the plate, a beamsplitter arrangement is required to allow light from the extended source to be reflected into the lens as shown in Fig. 13. Along the axis, $\theta = \theta' = 90°$, and symmetry requires that the

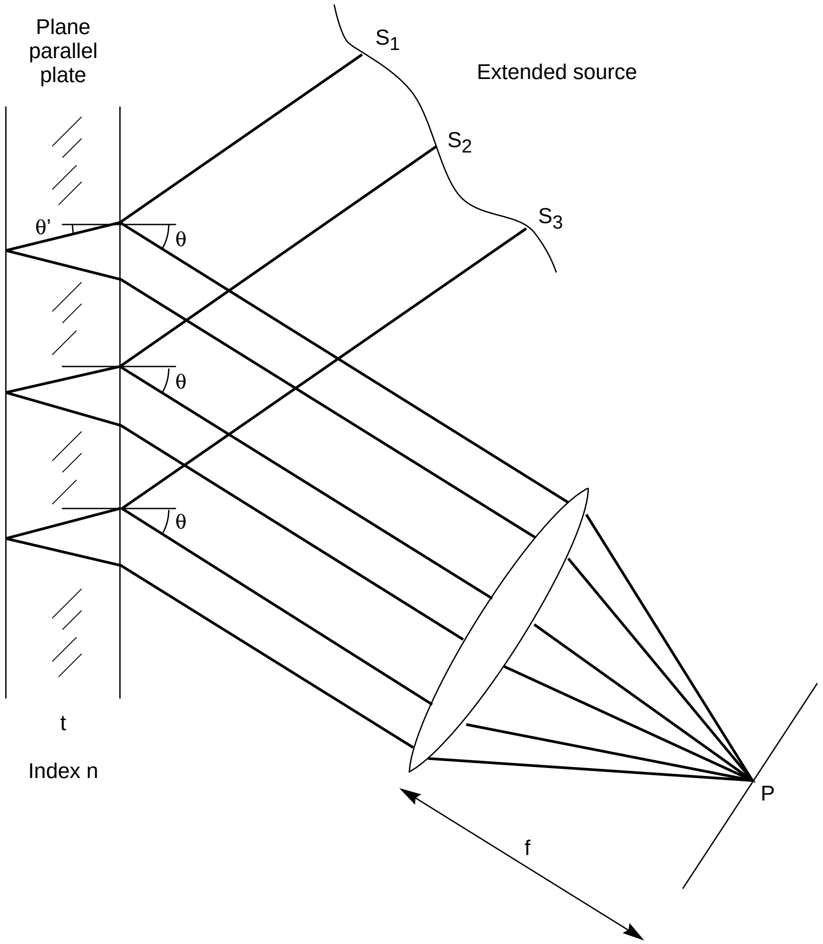

FIGURE 12 The formation of fringes of equal inclination.

fringes are concentric about the axis. In this special case, these fringes are called *Haidinger fringes,* and they are identical in appearance to Newton's rings [Eq. (30)]. If there is an intensity maximum at the center, the radii of the other bright fringes are proportional to the square roots of integers. As with other fringes formed by a plane-parallel plate (discussed earlier), the order of interference decreases with the observation radius on the screen. As θ' increases, the value of m decreases.

Fringes of Equal Thickness

The existence of fringes of equal inclination depends on the incident light being reflected by two parallel surfaces, and the angle of incidence is the mechanism which generates changes in the OPD. There are many arrangements with an extended source where the reflections are not parallel, and the resulting changes in OPD dominate the angle-of-incidence considerations. The fringes produced in this situation are called *fringes of equal*

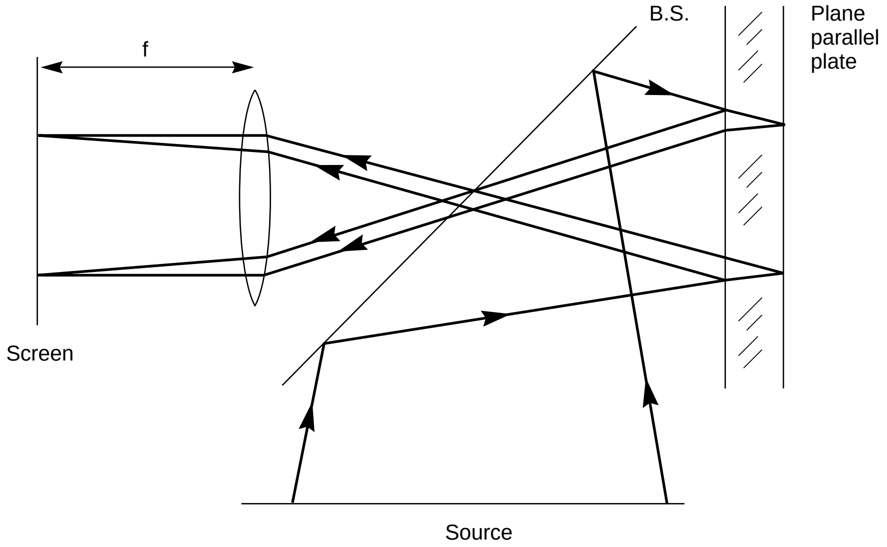

FIGURE 13 The formation of Haidinger fringes.

thickness, and we have stated earlier that they will be localized in regions where the OPD between the two reflections is small.

An example of fringes of equal thickness occurs with a wedged glass plate illuminated by a quasi-monochromatic extended source. We know that for each point in the source, a pattern comprised of equispaced parallel fringes results, and the net pattern is the sum of all of these individual patterns. However, it is easier to examine this summation by looking at the OPD between the two reflected rays reaching an observation point *P* from a source point *S*. This is shown in Fig. 14. The wedge angle is α, the thickness of the plate at this

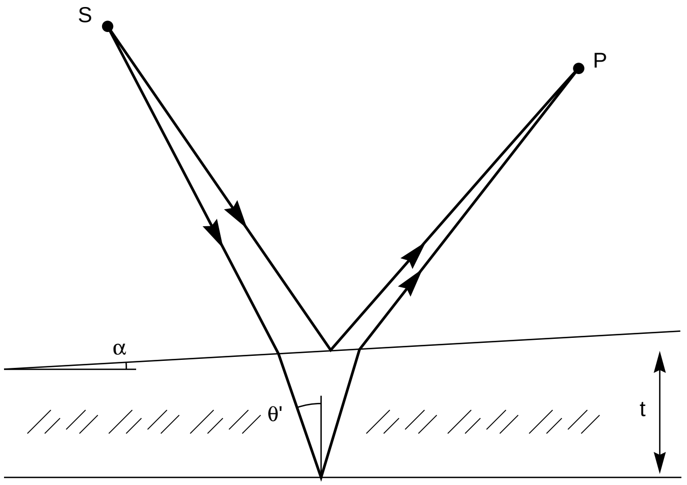

FIGURE 14 The ray path between a point source and an observation point for a wedged plate.

location is t, its index is n, and the internal ray angle is θ'. The exact OPD is difficult to calculate, but under the assumption that α is small and the wedge is sufficiently thin, the following result for the OPD is obtained:

$$\text{OPD} \approx 2nt \cos \theta' \tag{50}$$

As other points on the source are examined, the reflection needed to get light to the observation point will move to a different location on the plate, and different values of both t and θ' will result. Different source points may have greatly different OPDs, and in general the fringe pattern will wash out in the vicinity of P.

This reduction in visibility can be avoided if the observation point is placed in or near the wedge. In this case, all of the paths between S and P must reflect from approximately the same location on the wedge, and the variations in the thickness t are essentially eliminated. The point P where the two reflected rays cross may be virtual. The remaining variations in the OPD are from the different θ's associated with different source points. This variation may be limited by observing the fringe pattern with an optical system having a small entrance pupil. This essentially limits the amount of the source that is used to examine any area on the surface. A microscope or the eye focused on the wedge can be used to limit the angles. If the range of values of θ' is small, high-visibility fringes will appear to be localized at the wedge. The visibility of the fringes will decrease as the wedge thickness increases.

It is common to arrange the system so that the fringes are observed in a direction approximately normal to the surface. Taking into account the additional phase shift introduced at the reflection from one of the surfaces, the conditions for bright and dark fringes are then

$$\text{Bright:} \quad 2nt - \frac{\lambda}{2} = m\lambda \tag{51}$$

and

$$\text{Dark:} \quad 2nt = m\lambda \tag{52}$$

where m is an integer greater than or equal to zero. Since t increases linearly across the wedge, the observed pattern will be straight equispaced fringes.

These same conditions hold for any plate where the two surfaces are not parallel. The surfaces may have any shape, and as long as the surface angles are small and the plate is relatively thin, high-visibility fringes localized in the plate are observed. Along a given fringe the value of m is constant, so that a fringe represents a contour of constant optical path length nt. If the index is constant, we have fringes of equal thickness. The fringes provide a contour map of the plate thickness, and adjacent fringes correspond to a change of thickness of $\lambda/2n$. An irregularly shaped pattern will result from the examination of a plate of irregular thickness.

Thin Films

With the preceding background, we can easily explain the interference characteristics of *thin films*. There are two distinct types of films to consider. The first is a thin film of nonuniform thickness, and examples are soap bubbles and oil films on water. The second type is a uniform film, such as would be obtained by vacuum deposition and perhaps used as an antireflection coating. Both of these films share the characteristic of being extremely thin—usually not more than a few wavelengths thick and often just a fraction of a wavelength thick.

With a nonuniform film, fringes of equal thickness localized in the film are produced.

There will be a dark fringe in regions of the film where it is substantially thinner than a half wave. We are assuming that the film is surrounded by a lower-index medium such as air so that there is an extra π phase shift. If white light is used for illumination, colored bands will be produced similar to those diagramed in Fig. 10*b* (the curves would need to be modified to rescale the x axis to OPD or film thickness). Each color will produce its first maximum in intensity when the optical thickness of the film is a quarter of that wavelength. As the film thickness increases, the apparent fringe color will first be blue, then green, and finally red. These colored fringes are possible because the film is very thin, and the order of interference m is often zero or one [Eqs. (51) and (52)]. The interference patterns in the various colors are just starting to get out of phase, and interference colors are visible. As the film thickness increases, the various wavelength fringes become jumbled, and distinct fringe patterns are no longer visible.

When a uniform thin film is examined with an extended source, fringes of equal inclination localized at infinity are produced. These fringes will be very broad since the thickness of the film is very small, and large angles will be required to obtain the necessary OPD for a fringe [Eq. (49)]. A common use of this type of film is as an antireflection coating. In this application, a uniform coating that has an optical thickness of a quarter wavelength is applied to a substrate. The coating index is lower than the substrate index, so an extra phase shift is not introduced. A wave at normal incidence is reflected by both surfaces of the coating, and these reflected waves are interfered. If the incident wavelength matches the design of the film, the two reflected waves are out of phase and interfere destructively. The reflected intensity will depend on the Fresnel reflection coefficients at the two surfaces, but will be less than that of the uncoated surface. When a different wavelength is used or the angle of incidence is changed, the effectiveness of the antireflection coating is reduced. More complicated film structures comprised of many layers can be produced to modify the reflection or transmission characteristics of the film.

Fizeau Interferometer

The *Fizeau interferometer* compares one optical surface to another by placing them in close proximity. A typical arrangement is shown in Fig. 15, where the extended source is filtered to be quasi-monochromatic. A small air gap is formed between the two optical surfaces, and fringes of equal thickness are observed between the two surfaces. Equations (51) and (52) describe the location of the fringes, and the index of the thin wedge is now that of air. Along a fringe, the gap is of constant thickness, and adjacent fringes correspond to a change of thickness of a half wavelength. This interferometer is sometimes referred to as a *Newton interferometer.*

This type of interferometer is the standard test instrument in an optical fabrication shop. One of the two surfaces is a reference or known surface, and the interferometric comparison of this reference surface and the test surface shows imperfections in the test part. Differences in radii of the two surfaces are also apparent. The fringes are easy to interpret, and differences of as little as a twentieth of a wavelength can be visually measured. These patterns and this interferometer are further discussed in Chap. 30, Vol. 2, "Optical Testing." The interferometer is often used without the beamsplitter, and the fringes are observed in the direct reflection of the source from the parts.

The classic fringe pattern produced by a Fizeau interferometer is *Newton's rings.* These are obtained by comparing a convex sphere to a flat surface. The parabolic approximation for the sag of a sphere of radius R is

$$\text{sag}\,(\rho) = \frac{\rho^2}{2R} \tag{53}$$

and ρ is the radial distance from the vertex of the sphere. If we assume the two surfaces

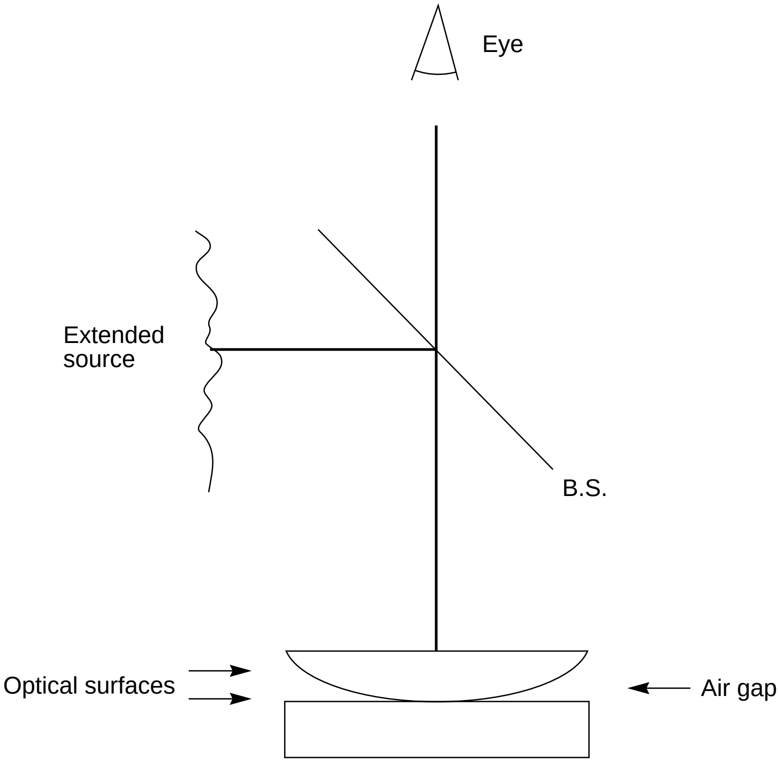

FIGURE 15 Fizeau interferometer.

are in contact at $\rho = 0$, the OPD between the reflected waves is twice the gap, and the condition for a dark fringe is

$$\rho = \sqrt{m\lambda R} \tag{54}$$

Circular fringes that increase in radius as the square root of ρ are observed. Note that a dark fringe occurs at the center of the pattern. In reflection, this point must be dark, as there is no interface at the contact point to produce a reflection.

Michelson Interferometer

There are many two-beam interferometers which allow the surfaces producing the two wavefronts to be physically separated by a large distance. These instruments allow the two wavefronts to travel along different optical paths. One of these is the *Michelson interferometer* diagramed in Fig. 16*a.* The two interfering wavefronts are produced by the reflections from the two mirrors. A plate beamsplitter with one face partially silvered is used, and an identical block of glass is placed in one of the arms of the interferometer to provide the same amount of glass path in each arm. This cancels the effects of the dispersion of the glass beamsplitter and allows the system to be used with white light since the optical path difference is the same for all wavelengths.

Figure 16*b* provides a folded view of this interferometer and shows the relative optical

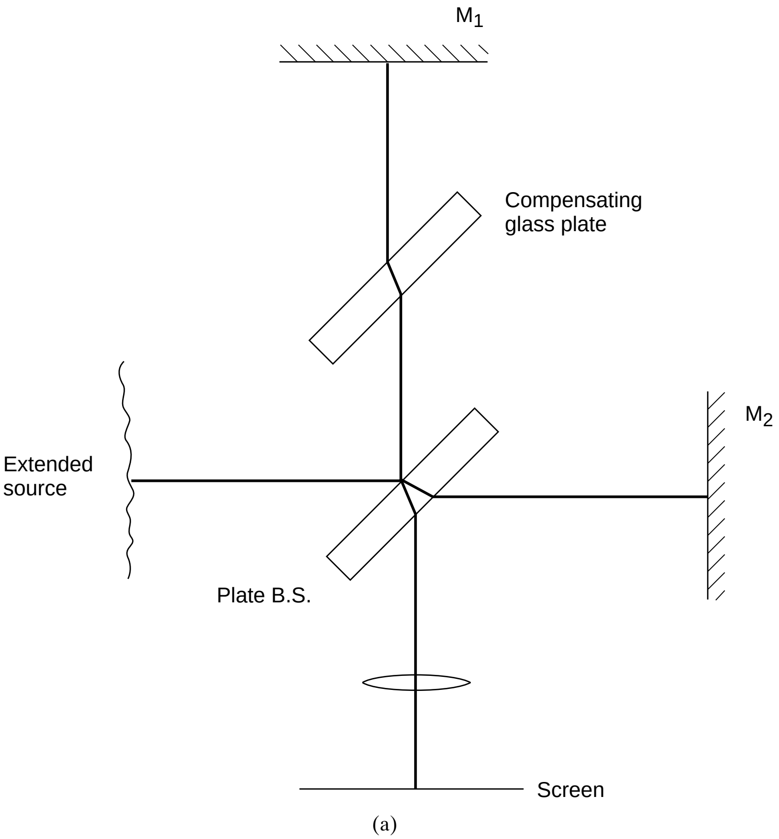

FIGURE 16 Michelson interferometer: (*a*) schematic view; and (*b*) folded view showing the relative optical position of the two mirrors.

position of the two mirrors as seen by the viewing screen. It should be obvious that the two mirrors can be thought of as the two surfaces of a ''glass'' plate that is illuminated by the source. In this case, the index of the fictitious plate is one, and the reflectivity at the two surfaces is that of the mirrors. Depending on the mirror orientations and shapes, the interferometer either mimics a plane-parallel plate of adjustable thickness, a wedge of arbitrary angle and thickness, or the comparison of a reference surface with an irregular or curved surface. The type of fringes that are produced will depend on this configuration, as well as on the source used for illumination.

When a monochromatic point source is used, nonlocalized fringes are produced, and the imaging lens is not needed. Two virtual-source images are produced, and the resulting fringes can be described by the interference of two spherical waves (discussed earlier). If the mirrors are parallel, circular fringes centered on the line normal to the mirrors result as with a plane-parallel plate. The source separation is given by twice the apparent mirror separation. If the mirrors have a relative tilt, the two source images appear to be laterally displaced, and hyperbolic fringes result. Along a plane bisecting the source images, straight equispaced fringes are observed.

When an extended monochromatic source is used, the interference fringes are localized. If the mirrors are parallel, fringes of equal inclination or Haidinger fringes (as described earlier) are produced. The fringes are localized at infinity and are observed in the rear

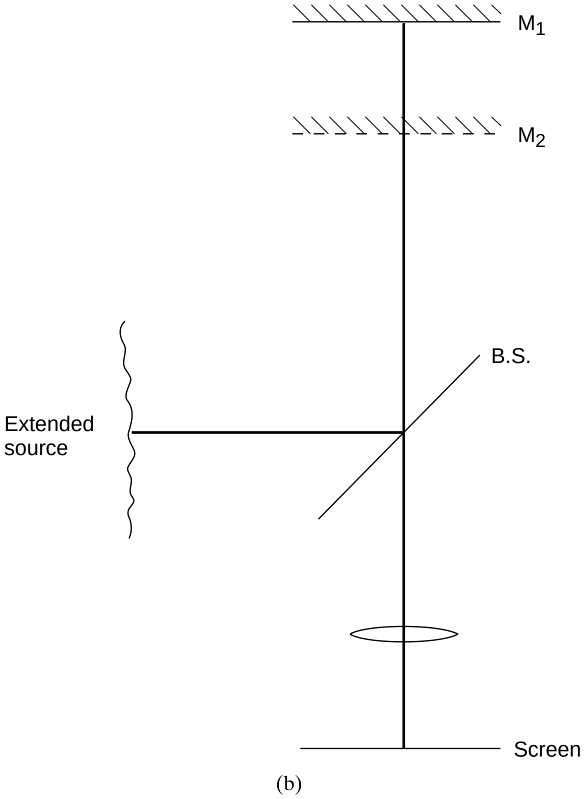

FIGURE 16 (*Continued.*)

focal plane of the imaging lens. Fringes of equal thickness localized at the mirrors are generated when the mirrors are tilted. The apparent mirror separation should be kept small, and the imaging lens should focus on the mirror surface.

If the extended source is polychromatic, colored fringes localized at the mirrors result. They are straight for tilted mirrors. The fringes will have high visibility only if the apparent mirror separation or OPD is smaller than the coherence length of the source. Another way of stating this is that the order of interference m must be small to view the colored fringes. As m increases, the fringes will wash out. The direct analogy here is a thin film. As the mirror separation is varied, the fringe visibility will vary. The fringe visibility as a function of mirror separation is related to the source frequency spectrum (see under ''Source Spectrum'' and ''Coherence and Interference''), and this interferometer forms the basis of a number of spectrometers. This topic is further discussed in Chap. 29, Vol. 2, ''Metrology.'' When the source spectrum is broad, chromatic fringes cannot be viewed with the mirrors parallel. This is because the order of interference for fringes of equal inclination is a maximum at the center of the pattern.

An important variation of the Michelson interferometer occurs when monochromatic collimated light is used. This is the *Twyman-Green interferometer,* and is a special case of point-source illumination with the source at infinity. Plane waves fall on both mirrors, and if the mirrors are flat, nonlocalized equispaced fringes are produced. Fringes of equal thickness can be viewed by imaging the mirrors onto the observation screen. If one of the mirrors is not flat, the fringes represent changes in the surface height. The two surfaces are compared as in the Fizeau interferometer. This interferometer is an invaluable tool for optical testing.

2.7 MULTIPLE BEAM INTERFERENCE

Throughout the preceding discussions, we have assumed that only two waves were being interfered. There are many situations where multiple beams are involved. Two examples are the diffraction grating and a plane-parallel plate. We have been ignoring multiple reflections, and in some instances these extra beams are very important. The net electric field is the sum of all of the component fields. The two examples noted above present different physical situations: all of the interfering beams have a constant intensity with a diffraction grating, and the intensity of the beams from a plane-parallel plate decreases with multiple reflections.

Diffraction Grating

A *diffraction grating* can be modeled as a series of equispaced slits, and the analysis bears a strong similarity to the Young's double slit (discussed earlier). It operates by division of wavefront, and the geometry is shown in Fig. 17. The slit separation is d, the OPD between successive beams for a given observation angle θ is $d \sin(\theta)$, and the corresponding phase difference $\Delta\phi = 2\pi d \sin(\theta)/\lambda$. The field due to the nth slit at a distant observation point is

$$E_j(\theta) = Ae^{i(j-1)\Delta\phi} \qquad j = 1, 2, \ldots, N \tag{55}$$

where all of the beams have been referenced to the first slit, and there are N total slits. The net field is

$$E(\theta) = \sum_{j=1}^{N} E_j(\theta) = A\sum_{j=1}^{N} (e^{i\Delta\phi})^{j-1} \tag{56}$$

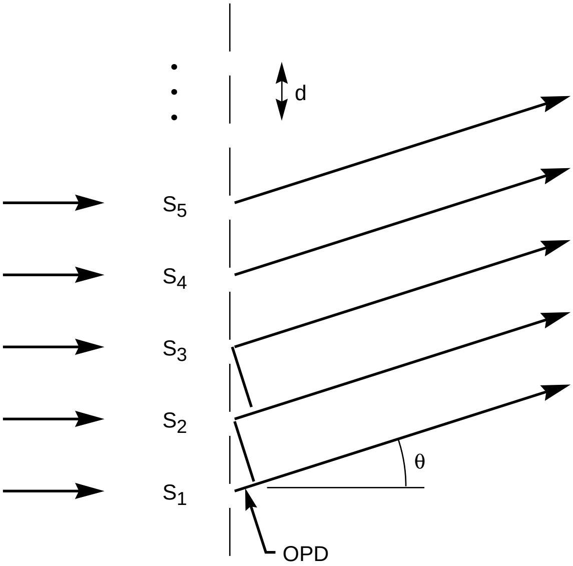

FIGURE 17 Diffraction grating: multiple-beam interference by division of wavefront.

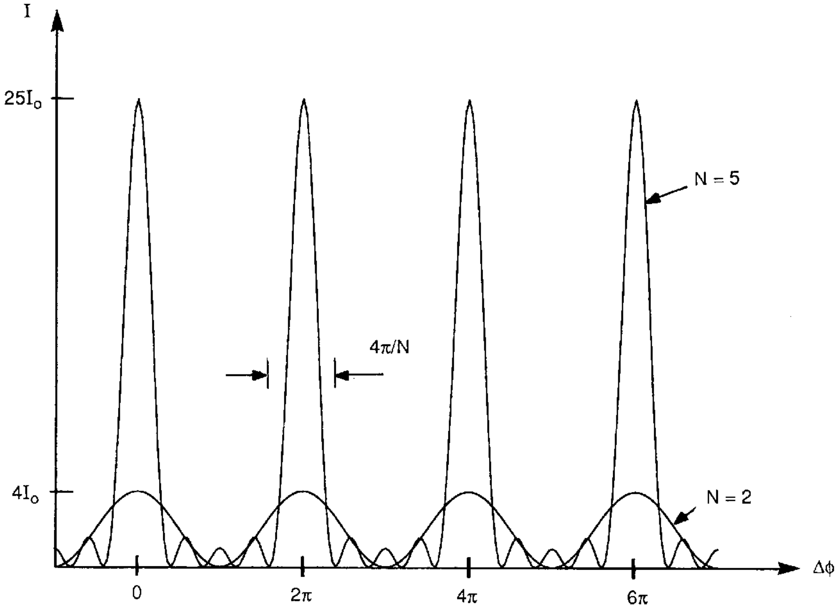

FIGURE 18 The interference patterns produced by gratings with 2 and 5 slits.

which simplifies to

$$E(\theta) = A\left(\frac{1 - e^{iN\Delta\phi}}{1 - e^{i\Delta\phi}}\right) \tag{57}$$

The resulting intensity is

$$I(\theta) = I_0\left[\frac{\sin^2\left(\frac{N\Delta\phi}{2}\right)}{\sin^2\left(\frac{\Delta\phi}{2}\right)}\right] = I_0\left[\frac{\sin^2\left(\frac{N\pi d \sin(\theta)}{\lambda}\right)}{\sin^2\left(\frac{\pi d \sin(\theta)}{\lambda}\right)}\right] \tag{58}$$

where I_0 is the intensity due to an individual slit.

This intensity pattern is plotted in Fig. 18 for $N = 5$. The result for $N = 2$, which is the double-slit experiment, is also shown. The first thing to notice is that the locations of the maxima are the same, independent of the number of slits. A maximum of intensity is obtained whenever the phase difference between adjacent slits is a multiple of 2π. These maxima occur at the diffraction angles given by

$$\sin(\theta) = \frac{m\lambda}{d} \tag{59}$$

where m is an integer. The primary difference between the two patterns is that with multiple slits, the intensity at the maximum increases to N^2 times that due to a single slit, and this energy is concentrated into a much narrower range of angles. The full width of a diffraction peak between intensity zero corresponds to a phase difference $\Delta\phi$ of $4\pi/N$.

The number of intensity zeros between peaks is $N-1$. As the number of slits increases, the angular resolution or resolving power of the grating greatly increases. The effects of a finite slit width can be added by replacing I_0 in Eq. (58) by the single-slit diffraction pattern. This intensity variation forms an envelope for the curve in Fig. 18.

Plane-Parallel Plate

The plane-parallel plate serves as a model to study the interference of multiple waves obtained by division of amplitude. As we shall see, the incremental phase difference between the interfering beams is constant but, in this case, the beams have different intensities. A plate of thickness t and index n with all of the reflected and transmitted beams is shown in Fig. 19. The amplitude reflection and transmission coefficients are ρ and ρ', and τ and τ', where the primes indicate reflection or transmission from within the plate. The first reflected beam is 180° out of phase with the other reflected beams since it is the only beam to undergo an external reflection, and $\rho = -\rho'$. Note that ρ' occurs only in odd powers for the reflected beams. Each successive reflected or transmitted beam is reduced in amplitude by ρ^2. The phase difference between successive reflected or transmitted beams is the same as we found when studying fringes of equal inclination from a plane-parallel plate:

$$\Delta\phi = \left[\frac{4\pi nt\cos(\theta')}{\lambda}\right] \tag{60}$$

where θ' is the angle inside the plate.

The transmitted intensity can be determined by first summing all of the transmitted amplitudes:

$$E(\Delta\phi) = \sum_{j=1}^{\infty} E_j = A\tau\tau' \sum_{j=1}^{\infty} (\rho^2 e^{i\Delta\phi})^{j-1} \tag{61}$$

where the phase is referenced to the first transmitted beam. The result of the summation is

$$E(\Delta\phi) = \left(\frac{A\tau\tau'}{1-\rho^2 e^{i\Delta\phi}}\right) \tag{62}$$

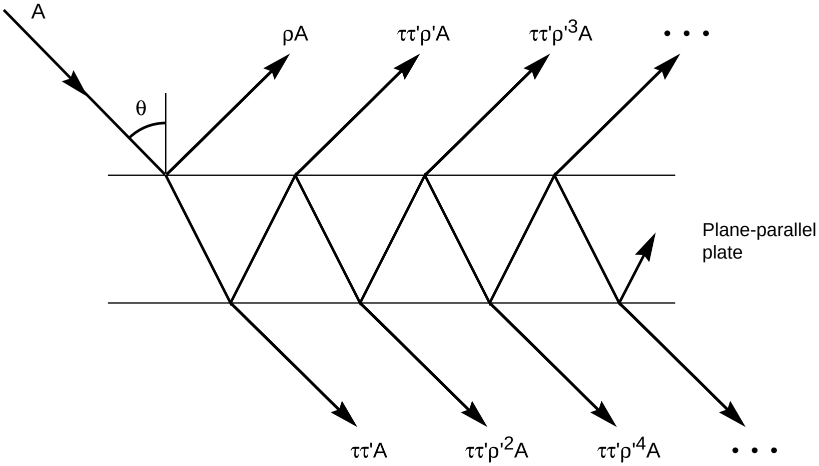

FIGURE 19 Plane-parallel plate: multiple-beam interference by division of amplitude.

The transmitted intensity I_t is the squared modulus of the amplitude which, after simplification, becomes

$$\frac{I_t}{I_0} = \frac{1}{1 + \left(\frac{2\rho}{1-\rho^2}\right)^2 \sin^2 (\Delta\phi/2)} \tag{63}$$

where I_0 is the incident intensity. We have also assumed that there is no absorption in the plate, and therefore $\tau\tau' + \rho^2 = 1$. Under this condition of no absorption, the sum of the reflected and transmitted light must equal the incident light: $I_t + I_r = I_0$. The expressions for the transmitted and reflected intensities are then

$$\frac{I_t}{I_0} = \frac{1}{1 + F \sin^2 (\Delta\phi/2)} \tag{64}$$

and

$$\frac{I_r}{I_0} = \frac{F \sin^2 (\Delta\phi/2)}{1 + F \sin^2 (\Delta\phi/2)} \tag{65}$$

and F is defined as

$$F \equiv \left(\frac{2\rho}{1-\rho^2}\right)^2 \tag{66}$$

F is the *coefficient of finesse* of the system and is a function of the surface reflectivity only. The value of F will have a large impact on the shape of the intensity pattern. Note that the reflected intensity could also have been computed by summing the reflected beams.

A maximum of transmitted intensity, or a minimum of reflected intensity, will occur when $\Delta\phi/2 = m\pi$, where m is an integer. Referring back to Eq. (60), we find that this corresponds to the angles

$$\cos \theta' = \frac{m\lambda}{2nt} \tag{67}$$

This is exactly the same condition that was found for a plane-parallel plate with two beams [Eq. (49)]. With an extended source, fringes of equal inclination are formed, and they are localized at infinity. They must be at infinity since all of the reflected or transmitted beams are parallel for a given input angle. The fringes are observed in the rear focal plane of a viewing lens. If the optical axis of this lens is normal to the surface, circular fringes about the axis are produced. The locations of the maxima and minima of the fringes are the same as were obtained with two-beam interference.

The shape of the intensity profile of these multiple beam fringes is not sinusoidal, as it was with two beams. A plot of the transmitted fringe intensity [Eq. (64)] as a function of $\Delta\phi$ is shown in Fig. 20 for several values of F. When the phase difference is a multiple of 2π, we obtain a bright fringe independent of F or ρ. When F is small, low-visibility fringes are produced. When F is large, however, the transmitted intensity is essentially zero unless the phase has the correct value. It drops off rapidly for even small changes in $\Delta\phi$. The transmitted fringes will be very narrow bright circles on an essentially black background. The reflected intensity pattern is one minus this result, and the fringe pattern will be very dark bands on a uniform bright background. The reflected intensity profile is plotted in Fig. 21 for several values of F.

The value of F is a strong function of the surface reflectivity $R = \rho^2$. We do not obtain appreciable values of F until the reflectivity is approximately one. For example, $R = 0.8$ produces $F = 80$, while $R = 0.04$ gives $F = 0.17$. This latter case is typical for uncoated glass, and dim broad fringes in reflection result, as in Fig. 21. The pattern is approximately sinusoidal, and it is clear that our earlier assumptions about ignoring multiple reflections when analyzing a plane-parallel plate are valid for many low-reflectivity situations.

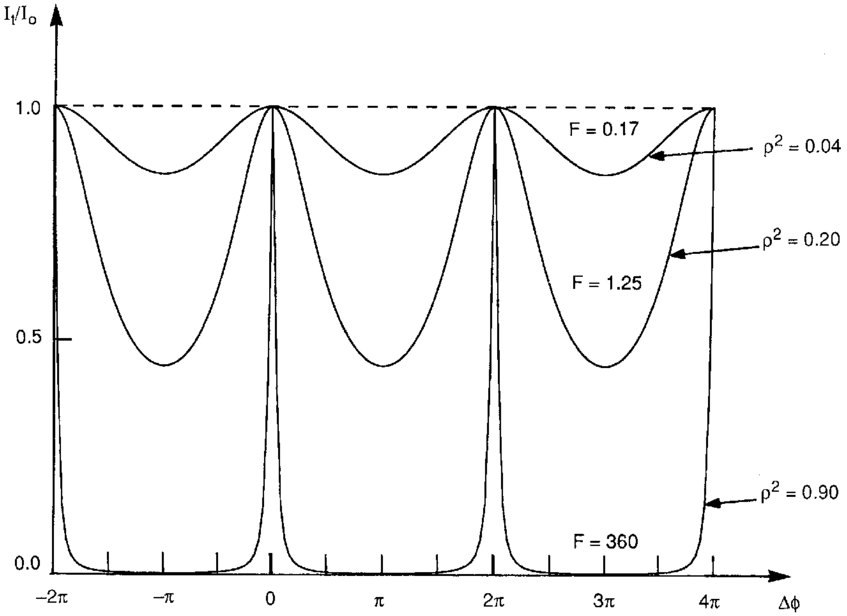

FIGURE 20 The transmitted intensity of a multiple-beam interference pattern produced by a plane-parallel plate.

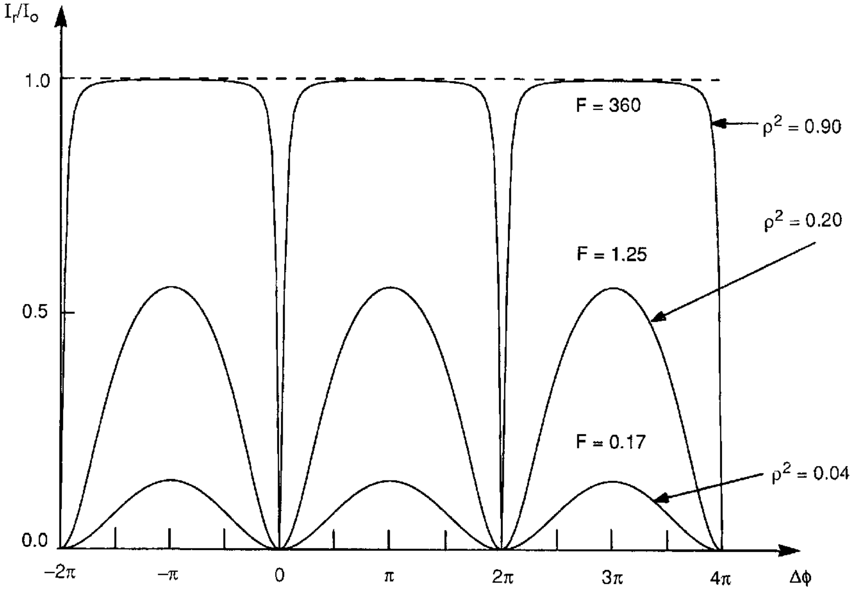

FIGURE 21 The reflected intensity of a multiple-beam interference pattern produced by a plane-parallel plate.

The multiple beam interference causes an energy redistribution much like that obtained from a diffraction grating. A strong response is obtained only when all of the reflected beams at a given angle add up in phase. The difference between this pattern and that of a diffraction pattern is that there are no oscillations or zeros between the transmitted intensity maxima. This is a result of the unequal amplitudes of the interfering beams. With a diffraction grating, all of the beams have equal amplitude, and the resultant intensity oscillates as more beams are added.

Multiple-beam fringes of equal thickness can be produced by two high-reflectivity surfaces in close proximity in a Fizeau interferometer configuration. The dark fringes will narrow to sharp lines, and each fringe will represent a contour of constant OPD between the surfaces. As before, a dark fringe corresponds to a gap of an integer number of half wavelengths. The area between the fringes will be bright. The best fringes will occur when the angle and the separation between the surfaces is kept small. This will prevent the multiple reflections from walking off or reflecting out of the gap.

Fabry-Perot Interferometer

The *Fabry-Perot interferometer* is an important example of a system which makes use of multiple-beam interference. This interferometer serves as a high-resolution spectrometer and also as an optical resonator. In this latter use, it is an essential component of a laser. The system is diagrammed in Fig. 22, and it consists of two highly reflective parallel surfaces separated by a distance *t.* These two separated reflective plates are referred to as a *Fabry-Perot etalon* or cavity, and an alternate arrangement has the reflected coatings applied to the two surfaces of a single glass plate. The two lenses serve to collimate the light from a point on the extended source in the region of the cavity and to then image this point onto the screen. The screen is located in the focal plane of the lens so that fringes of equal inclination localized at infinity are viewed. As we have seen, light of a fixed wavelength will traverse the etalon only at certain well-defined angles. Extremely sharp multiple-beam circular fringes in transmission are produced on the screen, and their profile is the same as that shown in Fig. 20.

If the source is not monochromatic, a separate independent circular pattern is formed for each wavelength. Equation (67) tells us that the location or scale of the fringes is dependent on the wavelength. If the source is composed of two closely spaced wavelengths, the ring structure is doubled, and the separation of the two sets of rings allows the hyperfine structure of the spectral lines to be evaluated directly. More

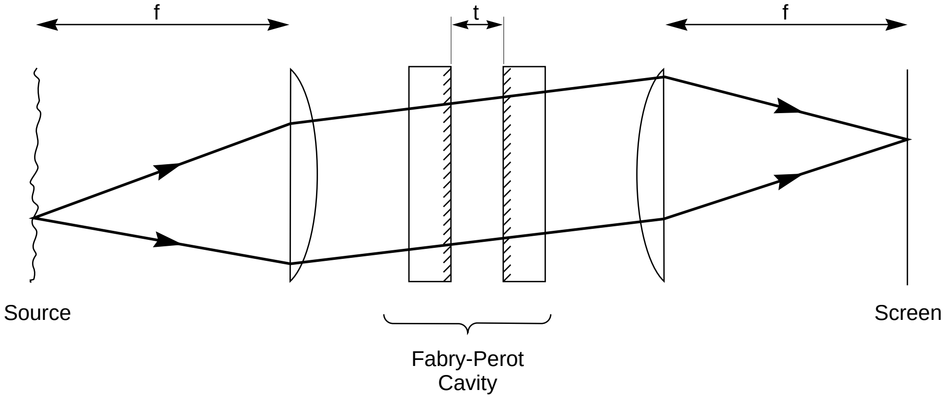

FIGURE 22 Fabry-Perot interferometer.

complicated spectra, usually composed of discrete spectral lines, can also be measured. This analysis is possible even though the order of interference is highest in the center of the pattern. If the phase change $\Delta\phi$ due to the discrete wavelengths is less than the phase change between adjacent fringes, nonoverlapping sharp fringes are seen.

A quantity that is often used to describe the performance of a Fabry-Perot cavity is the *finesse* $\mathcal{F}$. It is a measure of the number of resolvable spectral lines, and is defined as the ratio of the phase difference between adjacent fringes to the full width-half maximum FWHM of a single fringe. Since the fringe width is a function of the coefficient of finesse, the finesse itself is also a strong function of reflectivity. The phase difference between adjacent fringes is 2π, and the half width-half maximum can be found by setting Eq. (64) equal to $\frac{1}{2}$ and solving for $\Delta\phi$. The FWHM is twice this value, and under the assumption that F is large,

$$\text{FWHM} = \frac{4}{\sqrt{F}} \tag{68}$$

and the finesse is

$$\mathcal{F} \equiv \frac{2\pi}{\text{FWHM}} = \frac{\pi\sqrt{F}}{2} = \frac{\pi\rho}{1-\rho^2} = \frac{\pi\sqrt{R}}{1-R} \tag{69}$$

where ρ is the amplitude reflectivity, and R is the intensity reflectivity. Typical values for the finesse of a cavity with flat mirrors is about 30 and is limited by the flatness and parallelism of the mirrors. There are variations in $\Delta\phi$ across the cavity. Etalons consisting of two curved mirrors can be constructed with a much higher finesse, and values in excess of 10,000 are available.

Another way of using the Fabry-Perot interferometer as a spectrometer is suggested by rewriting the transmission [Eq. (64)] in terms of the frequency ν:

$$T = \frac{I_t}{I_0} = \frac{1}{1 + F\sin^2(2\pi t\nu/c)} \tag{70}$$

where Eq. (60) relates the phase difference to the wavelength, t is the mirror separation, and an index of one and normal incidence ($\theta' = 0$) have been assumed. This function is plotted in Fig. 23, and a series of transmission spikes separated in frequency by $c/2t$ are

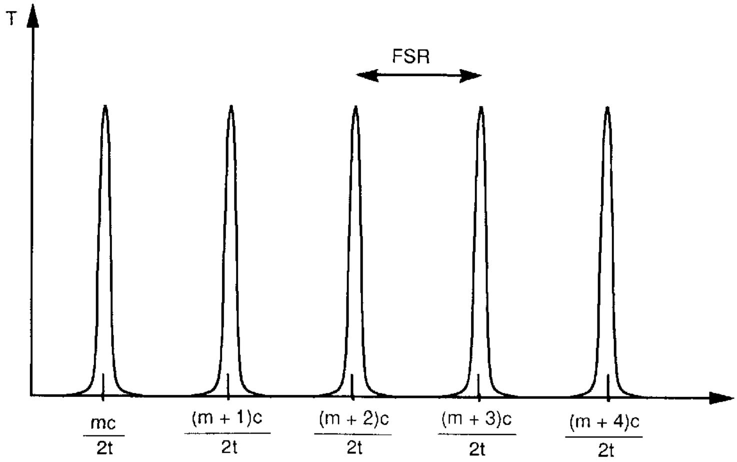

FIGURE 23 The transmission of a Fabry-Perot cavity as a function of frequency.

seen. A maximum occurs whenever the value of the sine is zero. The separation of these maxima is known as the *free spectral range,* FSR. If the separation of the mirrors is changed slightly, these transmission peaks will scan the frequency axis. Since the order of interference m is usually very large, it takes only a small change in the separation to move the peaks by one FSR. In fact, to scan one FSR, the required change in separation is approximately t/m. If the on-axis transmitted intensity is monitored while the mirror separation is varied, a high-resolution spectrum of the source is obtained. The source spectrum must be contained within one free spectral range so that the spectrum is probed by a single transmission peak at a time. If this were not the case, the temporal signal would contain simultaneous contributions from two or more frequencies resulting from different transmission peaks. Under this condition there are overlapping orders, and it is often prevented by using an auxiliary monochromator with the scanning Fabry-Perot cavity to preselect or limit the frequency range of the input spectrum. The resolution $\Delta\nu$ of the trace is limited by the finesse of the cavity.

For a specific cavity, the value of m at a particular transmission peak, and some physical insight into the operation of this spectrometer, is obtained by converting the frequency of a particular transmission mode $mc/2t$ into wavelength:

$$\lambda = \frac{2t}{m} \qquad \text{or} \qquad t = m\frac{\lambda}{2} \tag{71}$$

For the mth transmission maximum, exactly m half waves fit across the cavity. This also implies that the round-trip path within the cavity is an integer number of wavelengths. Under this condition, all of the multiply-reflected beams are in phase everywhere in the cavity, and therefore all constructively interfere. A maximum in the transmission occurs. Other maxima occur at different wavelengths, but these specific wavelengths must also satisfy the condition that the cavity spacing is an integer number of half wavelengths.

These results also allow us to determine the value of m. If a 1-cm cavity is used and the nominal wavelength is 500 nm, $m = 40{,}000$ and $\text{FSR} = 1.5 \times 10^{10}$ Hz. The wavelength interval corresponding to this FSR is 0.0125 nm. If a 1-mm cavity is used instead, the results are $m = 4000$ and $\text{FSR} = 1.5 \times 10^{11}\ \text{Hz} = 0.125$ nm. We see now that to avoid overlapping orders, the spectrum must be limited to a very narrow range, and this range is a function of the spacing. Cavities with spacings of a few tens of μm's are available to increase the FSR. Increasing the FSR does have a penalty. The finesse of a cavity depends only on the reflectivities, so as the FSR is increased by decreasing t, the FWHM of the transmission modes increases to maintain a constant ratio. The number of resolvable spectrum lines remains constant, and the absolute spectral resolution decreases.

A mirror translation of a half wavelength is sufficient to cover the FSR of the cavity. The usual scanning method is to separate the two mirrors with a piezoelectric spacer. As the applied voltage is changed, the cavity length will also change. An alternate method is to change the index of the air in the cavity by changing the pressure.

2.8 COHERENCE AND INTERFERENCE

The observed fringe visibility is a function of the spatial and temporal coherence of the source. The classical assumption for the analysis is that every point on an extended source radiates independently and therefore produces its own interference pattern. The net intensity is the sum of all of the individual intensity patterns. In a similar manner, each wavelength or frequency of a nonmonochromatic source radiates independently, and the temporal average is the sum of the individual temporal averages. *Coherence theory* allows the interference between the light from two point sources to be analyzed, and a good visual model is an extended source illuminating the two pinholes in Young's double slit. We need to determine the relationship between the light transmitted through the two pinholes. Coherence theory also accounts for the effects of the spectral bandwidth of the source.

With interference by division of amplitude using an extended source, the light from many point sources is combined at the observation point, and the geometry of the interferometer determines where the fringes are localized. Coherence theory will, however, predict the spectral bandwidth effects for division of amplitude interference. Each point on the source is interfered with an image of that same point. The temporal coherence function relates the interference of these two points independently of other points on the source. The visibility function for the individual interference pattern due to these two points is computed, and the net pattern is the sum of these patterns for the entire source. The temporal coherence effects in division of amplitude interference are handled on a point-by-point basis across the source.

In this section, the fundamentals of coherence theory as it relates to interference are introduced. Much more detail on this subject can be found in Chap. 4, "Coherence Theory."

Mutual Coherence Function

We will consider the interference of light from two point sources or pinholes. This light is derived from a common origin so that there may be some relationship between the complex fields at the two sources. We will represent these amplitudes at the pinholes as $E_1(t)$ and $E_2(t)$, as shown in Fig. 24. The propagation times between the two sources and the observation point are t_1 and t_2, where the times are related to the optical path lengths by $t_i = \mathrm{OPL}_i/c$. The two complex amplitudes at the observation point are then $E_1(t - t_1)$ and $E_2(t - t_2)$, where the amplitudes have been scaled to the observation plane. The time-average intensity at the observation point can be found by returning to Eq. (13), which is repeated here with the time dependence:

$$I = I_1 + I_2 + \langle E_1(t - t_1)E_2^*(t - t_2)\rangle + \langle E_1^*(t - t_1)E_2(t - t_2)\rangle \tag{72}$$

where I_1 and I_2 are the intensities due to the individual sources. If we now shift our time origin by t_2, we obtain

$$I = I_1 + I_2 + \langle E_1(t + \tau)E_2^*(t)\rangle + \langle E_1^*(t + \tau)E_2(t)\rangle \tag{73}$$

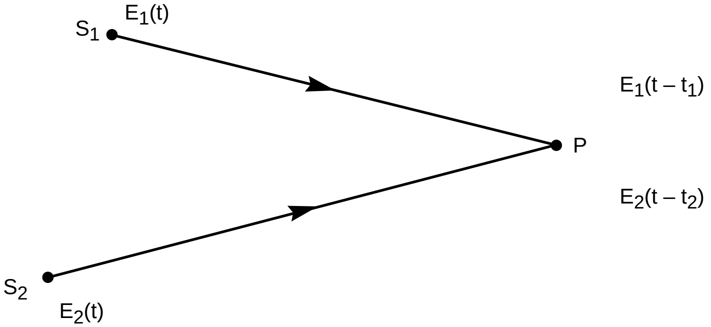

FIGURE 24 Geometry for examining the mutual coherence of two sources.

where

$$\tau = t_2 - t_1 = \frac{\text{OPL}_2 - \text{OPL}_1}{c} = \frac{\text{OPD}}{c} \tag{74}$$

The difference in transit times for the two paths is τ. The last two terms in the expression for the intensity are complex conjugates, and they contain the interference terms.

We will now define the *mutual coherence function* $\Gamma_{12}(\tau)$:

$$\Gamma_{12}(\tau) = \langle E_1(t+\tau)E_2^*(t)\rangle \tag{75}$$

which is the cross correlation of the two complex amplitudes. With this identification, the intensity of the interference pattern is

$$I = I_1 + I_2 + \Gamma_{12}(\tau) + \Gamma_{12}^*(\tau) \tag{76}$$

or, recognizing that a quantity plus its complex conjugate is twice the real part,

$$I = I_1 + I_2 + 2\,\text{Re}\,\{\Gamma_{12}(\tau)\} \tag{77}$$

It is convenient to normalize the mutual coherence function by dividing by the square root of the product of the two self-coherence functions. The result is the *complex degree of coherence*:

$$\gamma_{12}(\tau) = \frac{\Gamma_{12}(\tau)}{\sqrt{\Gamma_{11}(0)\Gamma_{22}(0)}} = \frac{\Gamma_{12}(\tau)}{\sqrt{\langle|E_1(t)|^2\rangle\langle|E_2(t)|^2\rangle}} = \frac{\Gamma_{12}(\tau)}{\sqrt{I_2 I_2}} \tag{78}$$

and the intensity can be rewritten:

$$I = I_1 + I_2 + 2\sqrt{I_1 I_2}\,\text{Re}\,\{\gamma_{12}(\tau)\} \tag{79}$$

We can further simplify the result by writing $\gamma_{12}(\tau)$ as a magnitude and a phase:

$$\gamma_{12}(\tau) = |\gamma_{12}(\tau)|\,e^{i\phi_{12}(\tau)} = |\gamma_{12}(\tau)|\,e^{i[\alpha_{12}(\tau) - \Delta\phi(\tau)]} \tag{80}$$

where $\alpha_{12}(\tau)$ is associated with the source, and $\Delta\phi(\tau)$ is the phase difference due to the OPD between the two sources and the observation point [Eq. (18)]. The quantity $|\gamma_{12}(\tau)|$ is known as the *degree of coherence.* The observed intensity is therefore

$$I = I_1 + I_2 + 2\sqrt{I_1 I_2}\,|\gamma_{12}(\tau)|\cos[\alpha_{12}(\tau) - \Delta\phi(\tau)] \tag{81}$$

The effect of $\alpha_{12}(\tau)$ is to add a phase shift to the intensity pattern. The fringes will be shifted. A simple example of this situation is Young's double-slit experiment illuminated by a tilted plane wave or a decentered source. With quasi-monochromatic light, the variations of both $|\gamma_{12}(\tau)|$ and $\alpha_{12}(\tau)$ with τ are slow with respect to changes of $\Delta\phi(\tau)$, so that the variations in the interference pattern in the observation plane are due primarily to changes in $\Delta\phi$ with position.

A final rewrite of Eq. (81) leads us to the intensity pattern at the observation point:

$$I = I_0\left\{1 + \frac{2\sqrt{I_1 I_2}}{I_1 + I_2}|\gamma_{12}(\tau)|\cos[\alpha_{12}(\tau) - \Delta\phi(\tau)]\right\} \tag{82}$$

where $I_0 = I_1 + I_2$. The fringe visibility is therefore

$$\gamma(\tau) = \frac{2\sqrt{I_1 I_2}}{I_1 + I_2}|\gamma_{12}(\tau)| \tag{83}$$

and is a function of the degree of coherence and τ. Remember that τ is just the temporal measure of the OPD between the two sources and the observation point. If the two intensities are equal, the fringe visibility is simply the degree of coherence: $\gamma(\tau) = |\gamma_{12}(\tau)|$. The degree of coherence will take on values betwen 0 and 1. The source is *coherent* when $|\gamma_{12}(\tau)| = 1$, and completely incoherent when $|\gamma_{12}(\tau)| = 0$. The source is said to be *partially coherent* for other values. No fringes are observed with an incoherent source, and the visibility is reduced with a partially coherent source.

Spatial Coherence

The spatial extent of the source and its distance from the pinholes will determine the visibility of the fringes produced by the two pinhole sources (see Fig. 25). Each point on the source will produce a set of Young's fringes, and the position of this pattern in the observation plane will shift with source position. The value of $\alpha_{12}(\tau)$ changes with source position. The existence of multiple shifted patterns will reduce the overall visibility. As an example, consider a quasi-monochromatic source that consists of a several point sources arranged in a line. Each produces a high modulation fringe pattern in the observation plane (Fig. 26*a*), but there is a lateral shift between each pattern. The net pattern shows a fringe with the same period as the individual patterns, but it has a reduced modulation due to the shifts (Fig. 26*b*). This reduction in visibility can be predicted by calculating the degree of coherence $|\gamma_{12}(\tau)|$ at the two pinholes.

Over the range of time delays between the interfering beams that are usually of interest, the degree of coherence is a slowly varying function and is approximately equal to the value at $\tau = 0$: $|\gamma_{12}(\tau)| = |\gamma_{12}(0)| = |\gamma_{12}|$. The *van Cittert–Zernike theorem* allows the degree of coherence in the geometry of Fig. 25 to be calculated. Let θ be the angular separation of the two pinholes as seen from the source. This theorem states that degree of coherence between two points is the modulus of the scaled and normalized Fourier transform of the source intensity distribution:

$$|\gamma_{12}| = \left| \frac{\iint_S I(\xi, \eta) e^{i(2\pi/\lambda)(\xi\theta_x + \eta\theta_y)} d\xi \, d\eta}{\iint_S I(\xi, \eta) \, d\xi \, d\eta} \right| \tag{84}$$

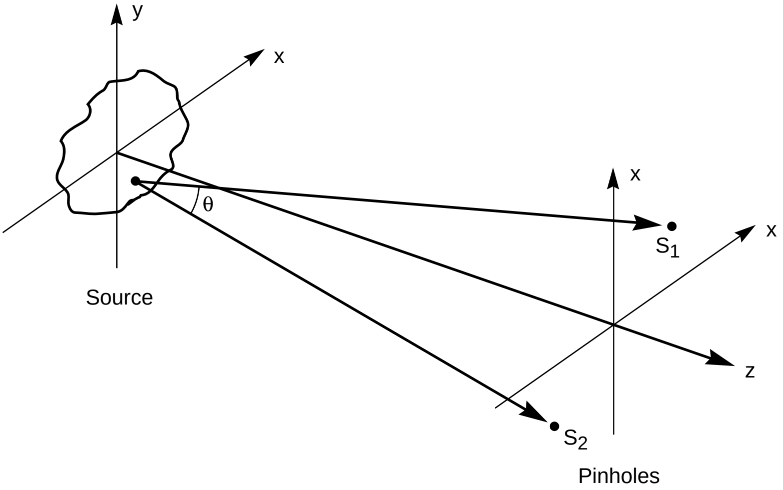

FIGURE 25 An extended source illuminating two pinholes.

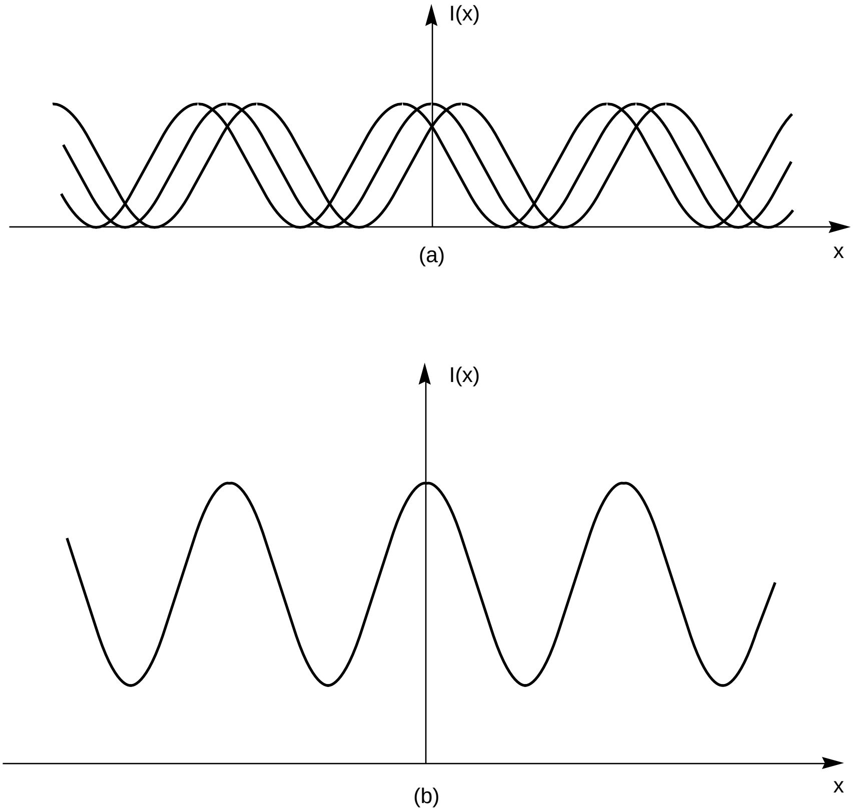

FIGURE 26 The interference pattern produced by a linear source: (*a*) the individual fringe patterns; and (*b*) the net fringe pattern with reduced visibility.

where θ_x and θ_y are the x and y components of the pinhole separation θ, and the integral is over the source.

Two cases that are of particular interest are a slit source and a circular source. The application of the van Cittert–Zernike theorem yields the two coherence functions:

$$\text{Slit source of width } w\text{:} \quad |\gamma_{12}| = \left|\text{sinc}\left(\frac{w\theta_x}{\lambda}\right)\right| = \left|\text{sinc}\left(\frac{wa}{\lambda z}\right)\right| \tag{85}$$

$$\text{Circular source of diameter } d\text{:} \quad |\gamma_{12}| = \left|\frac{2J_1\left(\frac{\pi\, d\theta_x}{\lambda}\right)}{\frac{\pi\, d\theta_x}{\lambda}}\right| = \left|\frac{2J_1\left(\frac{\pi\, da}{\lambda z}\right)}{\frac{\pi\, da}{\lambda z}}\right| \tag{86}$$

where a is the separation of the pinholes, z is the distance from the source to the pinholes, the sinc function is defined by Eq. (42), and J_1 is a first-order Bessel function. The pinholes are assumed to be located on the x-axis. These two functions share the common characteristic of a central core surrounded by low-amplitude side lobes. We can imagine these functions of pinhole spacing mapped onto the aperture plane. The coherence function is centered on one of the pinholes. If the other pinhole is then within the central core, high-visibility fringes are produced. If the pinhole spacing places the second pinhole outside the central core, low-visibility fringes result.

Michelson Stellar Interferometer

The *Michelson stellar interferometer* measures the diameter of stars by plotting out the degree of coherence due to the light from the star. The system is shown in Fig. 27. Two small mirrors separated by the distance a sample the light and serve as the pinholes. The spacing between these mirrors can be varied. This light is then directed along equal path lengths into a telescope, and the two beams interfere in the image plane. To minimize chromatic effects, the input light should be filtered to a small range of wavelengths. The modulation of the fringes is measured as a function of the mirror spacing to measure the degree of coherence in the plane of the mirrors. This result will follow Eq. (86) for a circular star, and the fringe visibility will go to zero when $a = 1.22\lambda\alpha$, where $\alpha = d/z$ is the angular diameter of the star. We measure the mirror separation that produces zero visibility to determine α. In a similar manner, this interferometer can be used to measure the spacing of two closely spaced stars.

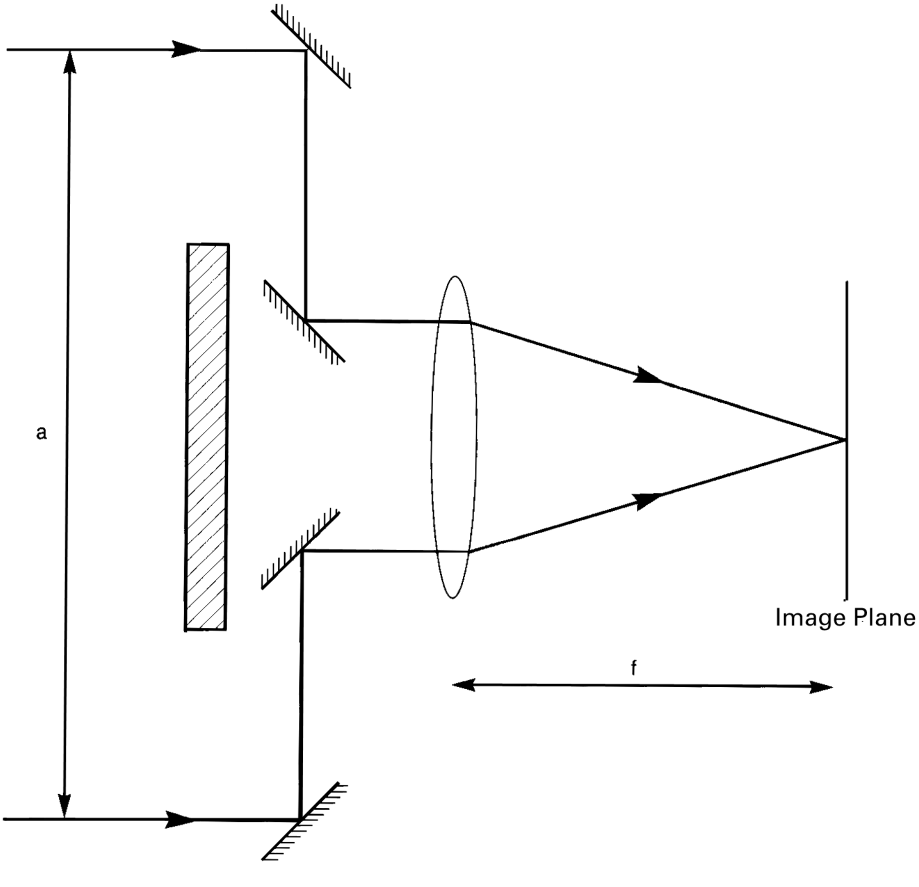

FIGURE 27 Michelson stellar interferometer.

Temporal Coherence

When examining temporal coherence effects, we use a source of small dimensions (a point source) that radiates over a range of wavelengths. The light from this source is split into two beams and allowed to interfere. One method to do this is to use an amplitude-splitting interferometer. Since the two sources are identical, the mutual coherence function becomes the *self-coherence function* $\Gamma_{11}(\tau)$. Equal-intensity beams are assumed. The complex degree of temporal coherence becomes

$$\gamma_{11}(\tau) = \frac{\Gamma_{11}(\tau)}{\Gamma_{11}(0)} = \frac{\langle E_1(t+\tau)E_1^*(t)\rangle}{\langle |E_1(t)|^2\rangle} \tag{87}$$

After manipulation, it follows from this result that $\gamma_{11}(\tau)$ is the normalized Fourier transform of the source intensity spectrum $S(\nu)$:

$$\gamma_{11}(\tau) = \frac{FT\{S(\nu)\}}{\int_0^\infty S(\nu)\,d\nu} = \frac{\int_0^\infty S(\nu)e^{i2\pi\nu\tau}\,d\nu}{\int_0^\infty S(\nu)\,d\nu} \tag{88}$$

The fringe visibility is the modulus of this result. Since $\gamma_{11}(\tau)$ has a maximum at $\tau = 0$, the maximum fringe visibility will occur when the time delay between the two beams is zero. This is consistent with our earlier observation under "Source Spectrum" that the fringes will be localized in the vicinity of zero OPD.

As an example, we will repeat the earlier problem of a uniform source spectrum:

$$S(\nu) = \text{rect}\left(\frac{\nu - \nu_0}{\Delta\nu}\right) \tag{89}$$

where ν_0 is the average frequency and $\Delta\nu$ is the bandwidth. The resulting intensity pattern is

$$I = I_0\{1 + \text{Re}\,\{\gamma_{12}(\tau)\}\} = I_0[1 + \text{sinc}\,(\tau\Delta\nu)\cos(2\pi\tau\nu_0)] \tag{90}$$

where the sinc function is the Fourier transform of the rect function. Using $\tau = \text{OPD}/c$ from Eq. (74), we can rewrite this equation in terms of the OPD to obtain the same result expressed in Eq. (47).

Laser Sources

The laser is an important source for interferometry, as it is a bright source of coherent radiation. Lasers are not necessarily monochromatic, as they may have more than one longitudinal mode, and it is important to understand the unique temporal coherence properties of a laser in order to get good fringes. The laser is a Fabry-Perot cavity that contains a gain medium. Its output spectrum is therefore a series of discrete frequencies separated by $c/2nL$, where L is the cavity length. For gas lasers, the index is approximately equal to one, and we will use this value for the analysis. If $G(\nu)$ is the gain bandwidth, the frequency spectrum is

$$S(\nu) = G(\nu)\,\text{comb}\left(\frac{2L\nu}{c}\right) \tag{91}$$

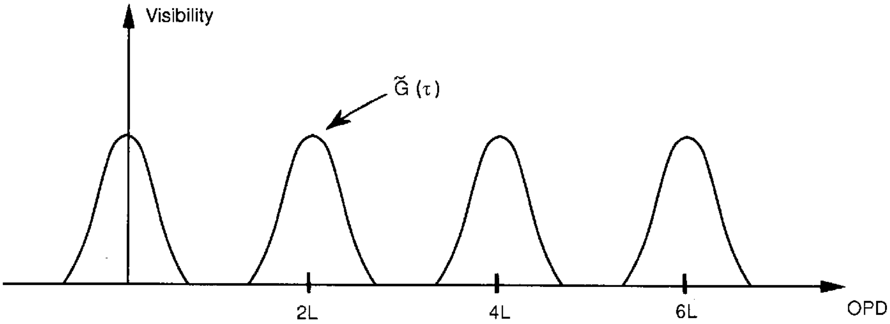

FIGURE 28 The fringe visibility versus OPD for a laser source.

where a comb function is a series of equally spaced delta functions. The number of modes contained under the gain bandwidth can vary from 1 or 2 up to several dozen. The resulting visibility function can be found by using Eq. (88):

$$\gamma(\tau) = |\gamma_{11}(\tau)| = \left|\tilde{G}(\tau) * \mathrm{comb}\left(\frac{c\tau}{2L}\right)\right| = \left|\tilde{G}(\tau) * \mathrm{comb}\left(\frac{\mathrm{OPD}}{2L}\right)\right| \tag{92}$$

where $\tilde{G}(\tau)$ is the normalized Fourier transform of the gain bandwidth, and $*$ indicates convolution. This result is plotted in Fig. 28, where $\tilde{G}(\tau)$ is replicated at multples of $2L$. The width of these replicas is inversely proportional to the gain bandwidth. We see that as long as the OPD between the two optical paths is a multiple of twice the cavity length, high-visibility fringes will result. This condition is independent of the number of longitudinal modes of the laser. If the laser emits a single frequency, it is a coherent source and good visibility results for any OPD.

3.1 GLOSSARY

A	amplitude
$\mathbf{E}$	electric field
f	focal length
G	Green function
I	irradiance
p, q	direction cosines
$\mathbf{r}$	spatial vector
$\mathbf{S}$	Poynting vector
t	time
ϵ	dielectric constant
μ	permeability
ν	frequency
ψ	wave function
$\hat{}$	Fourier transform

3.2 INTRODUCTION

Starting with waves as solutions to the wave equation obtained from Maxwell's equations, basics of diffraction of light are covered in this article. The discussion includes those applications where the geometry permits analytical solutions. At appropriate locations references are given to the literature and/or textbooks for further reading. The discussion is limited to an explanation of diffraction, and how it may be found in some simple cases with plots of fringe structure.

Selection of topics is not easy, some topics that are normally included in textbooks may not be found in this chapter. One thing that is not covered is Cornu's spiral and all associated phasor diagrams. These form convenient tools but are not absolutely necessary to understand the results. Material on these topics is in all of the textbooks listed in the article. Derivations are here excluded. Use of the two-pinhole experiments to describe the influence of partial coherence of light on the visibility of fringes is not mentioned [Thompson, B. J., and E. Wolf, "Two-Beam Interference with Partially Coherent Light," *J. Opt. Soc. Am.* **47**(10):895–902 (1957)]. So also the diffractive effect of the finite size of the apertures on this experiment is not described [Marathay, A. S., and D. B. Pollock, "Young's Interference Fringes with Finite-Sized Sampling Apertures," *J. Opt. Soc. Am.* A, **1:**1057–1059 (1984)]. Walls of mathematics and computer programs and/or plots have been avoided. These are found in the current literature, vector-diffraction calculation being a case in point.

Closely related chapters in the handbook are Chap. 1 by Douglas Goodman, Chap. 2 by J. Greivenkamp, Chap. 4, by William H. Carter, Chap. 5 by Bennett, Chap. 6 by Bohren, and Vol. II, Chap. 5 by Zissis. Appropriate chapters will be cross-referenced as needed.

3.3 LIGHT WAVES

Light waves propagate through free space or a vacuum. They exhibit the phenomenon of diffraction with every obstacle they encounter. Maxwell's equations form a theoretical basis for describing light in propagation, diffraction, scattering and, in general, its interaction with material media. Experience has shown that the electric field **E** plays a central role in detection of light and interaction of light with matter. We begin with some mathematical preliminaries.

The electric field **E** obeys the wave equation in free space or a vacuum

$$\nabla^2\mathbf{E} - \frac{1}{c^2}\frac{\partial^2\mathbf{E}}{\partial t^2} = 0 \tag{1}$$

where c is the velocity of light in a vacuum. Each cartesian component $\mathbf{E}_j$, $(j = x,\ y,\ z)$ obeys the equation and, as such, we use a scalar function $\psi(\mathbf{r}, t)$ to denote its solutions, where the radius vector $\mathbf{r}$ has components, $\mathbf{r} = \hat{i}x + \hat{j}y + \hat{k}z$.

The wave equation is a linear second-order partial differential equation. Linear superposition of its two linearly independent solutions offers the most general solution. It has plane waves, spherical waves and cylindrical waves as solutions. These solutions represent optical wave forms. A frequently used special case of these solutions is the time harmonic version of these waves. We start with the Fourier transform on time,

$$\psi(\mathbf{r}, t) = \int \hat{\psi}(\mathbf{r}, \nu) \exp(-i2\pi\nu t)\, d\nu \tag{2}$$

where ν is a temporal (linear) frequency in Hz. The spectrum $\hat{\psi}(\mathbf{r}, \nu)$ obeys the Helmholtz equation,

$$\nabla^2\hat{\psi} + k^2\hat{\psi} = 0 \tag{3}$$

with the propagation constant $k = 2\pi/\lambda = 2\pi\nu/c \equiv \omega/c$, where λ is the wavelength and ω is the circular frequency. A Fourier component traveling in a medium of refractive index

$n = \sqrt{\epsilon}$, where ϵ is the dielectric constant, is described by the Helmholtz equation with k^2 replaced by n^2k^2. The effect of each component with proper account of dispersion, n as a function of frequency, is superimposed as dictated by the Fourier integral to yield the field $\psi(\mathbf{r}, t)$.

As a further special case, a wave may be harmonic in time as well as in space (see Chap. 2).

$$\psi(\mathbf{r}, t) = A \cos (\mathbf{k} \cdot \mathbf{r} - \omega t) \tag{4}$$

where $\mathbf{k} \equiv k\hat{s}$, $\hat{s}$ is a unit vector in the direction of propagation and A is a constant. An expanding spherical wave may be written in the form,

$$\psi(r, t) = \frac{A}{r} \cos (kr - \omega t) \tag{5}$$

For convenience of operations, a complex form frequently is used. For example, we write

$$\psi(\mathbf{r}, t) = A \exp [i(\mathbf{k} \cdot \mathbf{r} - \omega t)] \tag{6}$$

in place of Eq. (4) bearing in mind that only its real part corresponds to the optical wave form. The function $\psi(\mathbf{r}, t)$ is called the optical "disturbance" while the coefficient A is the amplitude.

In the general discussion of diffraction phenomena throughout this chapter several classic source books have been used.[1–9] This discussion is a blend of ideas contained in these sources.

The mathematical solutions described heretofore, although ideal, are nevertheless often approximated. A suitable experimental arrangement with a self-luminous source and a condensing lens to feed light to a small enough pinhole fitted with a narrowband spectral filter serves as a quasi-monochromatic, or almost monochromatic, point source. In Fig. 1, light behind the pinhole S is in the form of ever-expanding spherical waves. These waves are of limited spatial extent; all are approximately contained in a cone with its apex at the pinhole. When intercepted by a converging lens, L_1, with the pinhole on its axis and at the front focal point, these spherical waves are converted to plane waves behind L_1. These plane waves also are limited spatially to the extent dictated by the aperture of the converging lens. A second converging lens, L_2, is behind the first converging lens and is oriented so that both lenses have a common optical axis and can form an image of the pinhole. The image S' is on the axis at the focal point behind the second lens and is formed by converging spherical waves. These waves, which converge toward the image, are

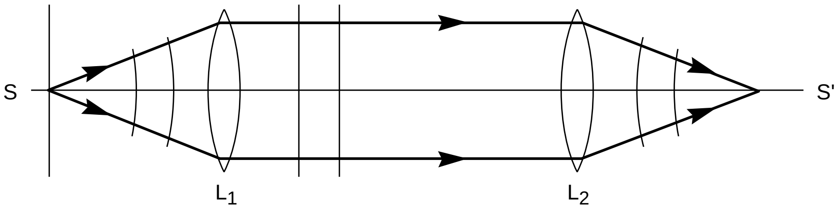

FIGURE 1 Experimental layout to describe the notation used for spherical and plane waves. S: pinhole source. L_1, L_2: lenses. S': image.

limited spatially to the extent dictated by the aperture of the second lens and are approximately contained in a cone with its apex at the image of the pinhole.

It is necessary to clarify that "a small enough pinhole" means that the optics behind the pinhole is not able to resolve its structure.[1] A "narrowband filter" means that its pass band, $\Delta\nu$, is much smaller than the mean frequency $\bar{\nu}$, that is, $\Delta\nu \ll \bar{\nu}$. In this situation, the experimental arrangement may be described by a quasi-monochromatic theory, provided that the path differences, Δl, of concern in the optics that follows the pinhole are small enough, as given by, $\Delta l \le c/\Delta\nu$. If the path differences Δl involved are unable to obey this condition, then a full polychromatic treatment of the separate Fourier components contained within $\Delta\nu$ is necessary, even if $\Delta\nu \ll \bar{\nu}$. See, for example, Beran and Parrent[10] and Marathay.[11]

Limiting the extent of plane waves and spherical waves, as discussed before, causes diffraction, a topic of primary concern in this chapter. The simplifying conditions stated above are assumed to hold throughout the chapter, unless stated otherwise.

As remarked earlier, the electric field **E** $[V/m]$ plays a central role in optical detection (see Chap. 16). There are detectors that attain a steady state for constant incident beam power $[W]$, and there are those like the *photographic plate* that integrate the incident power over a certain time (see Chap. 20). For a constant beam power, the darkening of the photographic plate depends on the product of the power and exposure time. Since detectors inherently take the time average, the quantity of importance is the average radiant power $\Phi[W]$. Furthermore, light beams have a finite cross-sectional area, so it is meaningful to talk about the average power in the beam per unit area of its cross section measured in square meters or square centimeters. In the radiometric nomenclature this sort of measurement is called *irradiance* $[Wm^{-2}]$. For a plane wave propagating in free space, the irradiance, I, may be expressed in terms of the Poynting vector, **S** by

$$I = |\langle \mathbf{S} \rangle| = \left(\frac{1}{2}\right)\left(\frac{\epsilon_0}{\mu_0}\right)^{1/2} \langle \mathbf{E} \cdot \mathbf{E} \rangle \tag{7}$$

The constants given in Eq. (7) may not be displayed with every theoretical result. (We have used the symbol I; however, the radiometrically accepted symbol E is easily confused with the electric field E.) The Poynting vector and irradiance are discussed further in Ref. 11 (pp. 280–285).[11]

Light is properly described by a transverse vector field (see Chap. 6). Nevertheless, a scalar field is a convenient artifice to use in understanding the wave nature of light without the added complication of the vector components. The transverse nature of the field will be accounted for when the situation calls for it.

3.4 HUYGENS-FRESNEL CONSTRUCTION

Without the benefit of a fundamental theory based on Maxwell's equations and the subsequent mathematical development, Huygens sought to describe wave propagation in the days before Maxwell. Waves are characterized by constant-phase surfaces, called *wavefronts.* If the initial shape at time t of such a wavefront is known in a vacuum or in any medium, Huygens proposed a geometrical construction to obtain its shape at a later time, $t + \Delta t$. He regarded each point of the initial wavefront as the origin of a new disturbance that propagates in the form of secondary wavelets in all directions with the same speed as the speed v of propagation of the initial wave in the medium. These secondary wavelets of radii $v\,\Delta t$ are constructed at each point of the initial wavefront. A surface tangential to all these secondary wavelets, called the *envelope* of all these wavelets, is then the shape and position of the wavefront at time $t + \Delta t$. With this construct Huygens explained the phenomena of reflection and refraction of the wavefront. To explain the phenomenon of diffraction, Fresnel modified Huygens' construction by attributing the property of mutual interference to the secondary wavelets (see Chap. 2). The modified Huygens construction is called the Huygens-Fresnel construction. With further minor modifications it helps explain the phenomenon of diffraction and its various aspects, including those that are not so intuitively obvious.

We will begin with the Huygens-Fresnel construction and will show how it explains some simple optical experiments on diffraction. This will be followed by the Fresnel-Kirchhoff formula and related topics.

Fresnel Zones

Let P_0 be a point source of light that produces monochromatic spherical waves. A typical spherical wave, $A/r_0 \exp[-i(\omega t - kr_0)]$, of radius r_0 at time t is shown in Fig. 2. The coefficient A stands for the amplitude of the wave at unit distance from the source P_0. At a later time this wave will have progressed to assume a position passing through a point of observation P with radius, $r_0 + b$. Fresnel zone construction on the initial wave offers a way to obtain the wave in the future by applying the Huygens-Fresnel construction. The zone construction forms a simple basis for studying and understanding diffraction of light.

From the point of observation P, we draw spheres of radii b, $b + \lambda/2$, $b + 2\lambda/2$, $b + 3\lambda/2, \ldots, b + j\lambda/2, \ldots,$ to mark zones on the wave in its initial position, as shown in Fig. 2. The zones are labeled $z_1, z_2, \ldots z_j \ldots$ The zone boundaries are successively half a wavelength away from the point of observation P. By the Huygens-Fresnel construction, each point of the wave forms a source of a secondary disturbance. Each secondary source produces wavelets that are propagated to the point P. A linear superposition of the contribution of all such wavelets yields the resulting amplitude at the point P. It is reasonable to expect that the contribution of the secondary wavelets is not uniform in all directions. For example, a wavelet at C is in line with the source P_0 and the point of

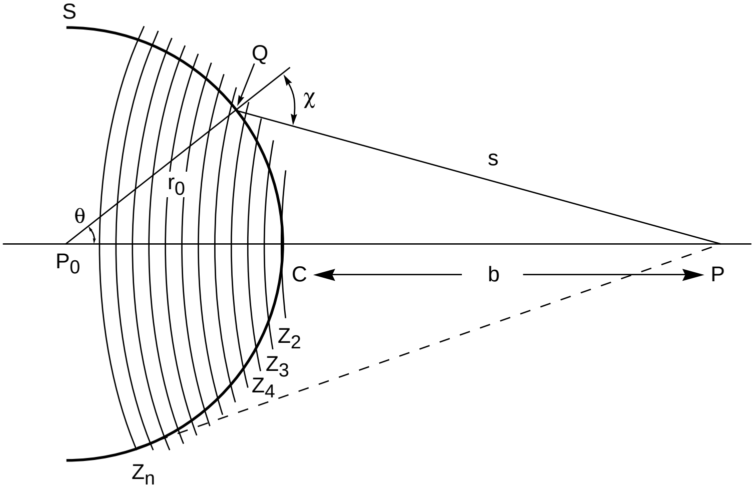

FIGURE 2 Fresnel zone construction. P_0: point source. S: wavefront. r_0: radius of the wavefront b: distance CP. s: distance QP. (*After Born and Wolf*[1].)

observation P, while a wavelet at Q sees the point P at an angle χ with respect to the radius vector from the source P_0. To account for this variation, an obliquity or inclination factor $K(\chi)$ is introduced. In the phenomenological approach developed by Fresnel, no special form of $K(\chi)$ is used. It is assumed to have the value unity at C where $\chi = 0$, and it is assumed to decrease at first slowly and then rapidly as χ increases. The obliquity factors for any two adjacent zones are nearly equal and it is assumed that it becomes negligible for zones with high enough index j.

The total contribution to the disturbance at P is expressed as an area integral over the primary wavefront,

$$\psi(P) = A\,\frac{\exp\left[-i(\omega t - kr_0)\right]}{r_0}\iint_S \frac{\exp(iks)}{s}\,K(\chi)\,dS \tag{8}$$

where dS is the area element at Q. The subscript S on the integrals denotes the region of integration on the wave surface. The integrand describes the contribution of the secondary wavelets. Fresnel-zone construction provides a convenient means of expressing the area integral as a sum over the contribution of the zones.

For optical problems, the distances involved, such as r_0 and b, are much larger than the wavelength, λ. This fact is used very effectively in approximating the integral. The phases of the wavelets within a zone will not differ by more than π. The zone boundaries are successively $\lambda/2$ further away from the point of observation P. The average distance of successive zones from P differs by $\lambda/2$; the zones, therefore, are called half-period zones. Thus, the contributions of the zones to the disturbance at P alternate in sign,

$$\psi(P) = \psi_1 - \psi_2 + \psi_3 - \psi_4 + \psi_5 - \psi_6 + \ldots \tag{9}$$

where ψ_j stands for the contribution of the jth zone, $j = 1, 2, 3, \ldots$ The contribution of each annular zone is directly proportional to the zone area and is inversely proportional to the average distance of the zone to the point of observation P. The ratio of the zone area to its average distance from P is independent of the zone index j. Thus, in summing the contributions of the zones we are left with only the variation of the obliquity factor, $K(\chi)$. To a good approximation, the obliquity factors for any two adjacent zones are nearly equal and for a large enough zone index j the obliquity factor becomes negligible. The total disturbance at the point of observation P may be approximated by

$$\psi(P) = 1/2(\psi_1 \pm \psi_n) \tag{10}$$

where the index n stands for the last zone contributing to P. The ± sign is taken according to whether n is odd or even. For an unobstructed wave, the integration is carried out over the whole spherical wave. In this case, the last term ψ_n is taken to be zero. Thus, the resulting disturbance at the point of observation P equals one-half of the contribution of the first Fresnel zone,

$$\psi(P) = 1/2\psi_1 \tag{11}$$

The contribution ψ_1 is found by performing the area integral of Eq. (8) over the area of the first zone. The procedure results in

$$\psi(P) = \frac{A}{r_0 + b}\,\lambda \exp\{-i[\omega t - k(r_0 + b) - \pi/2]\} \tag{12}$$

whereas a freely propagating spherical wave from the source P_0 that arrives at point P is known to have the form

$$\psi(P) = \frac{A}{r_0 + b} \exp\{-i[\omega t - k(r_0 + b)]\} \tag{12'}$$

The synthesized wave of Eq. (12) can be made to agree with this fact, if one assumes that the complex amplitude of the secondary waves, $\exp(iks)/s$ of Eq. (8) is $[1/\lambda \exp(-i\pi/2)]$ times the primary wave of unit amplitude and zero phase. With the time dependence $\exp(-i\omega t)$, the secondary wavelets are required to oscillate a quarter of a period ahead of the primary.

The synthesis of propagation of light presented above has far-reaching consequences. The phenomenon of light diffraction may be viewed as follows. Opaque objects that interrupt the free propagation of the wave block some or parts of zones. The zones, or their portions that are unobstructed, contribute to the diffraction amplitude (disturbance) at the point of observation P. The obstructed zones do not contribute.

Diffraction of Light from Circular Apertures and Disks

Some examples of unobstructed zones are shown in Fig. 3. Suppose a planar opaque screen with a circular aperture blocks the free propagation of the wave. The center C of the aperture is on the axis joining the source point S and the observation point P, as shown in

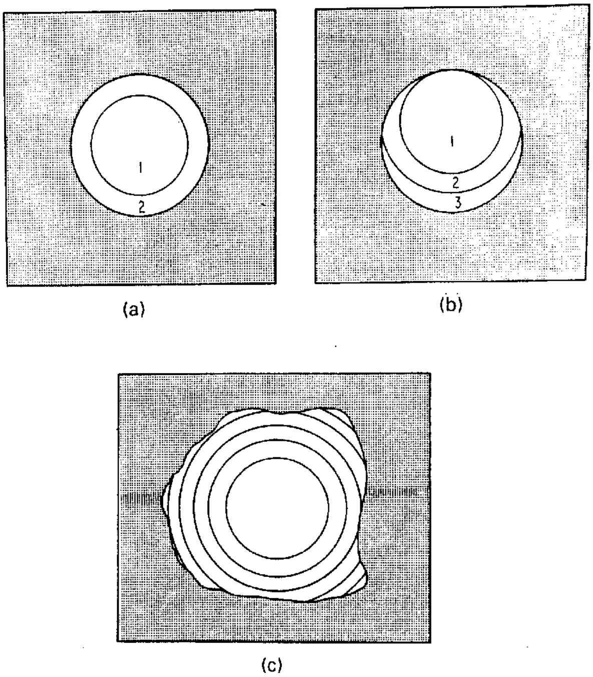

FIGURE 3 Some examples of unobstructed Fresnel zones that contribute to the amplitude at the observation point P. (*After Andrews.*[8])

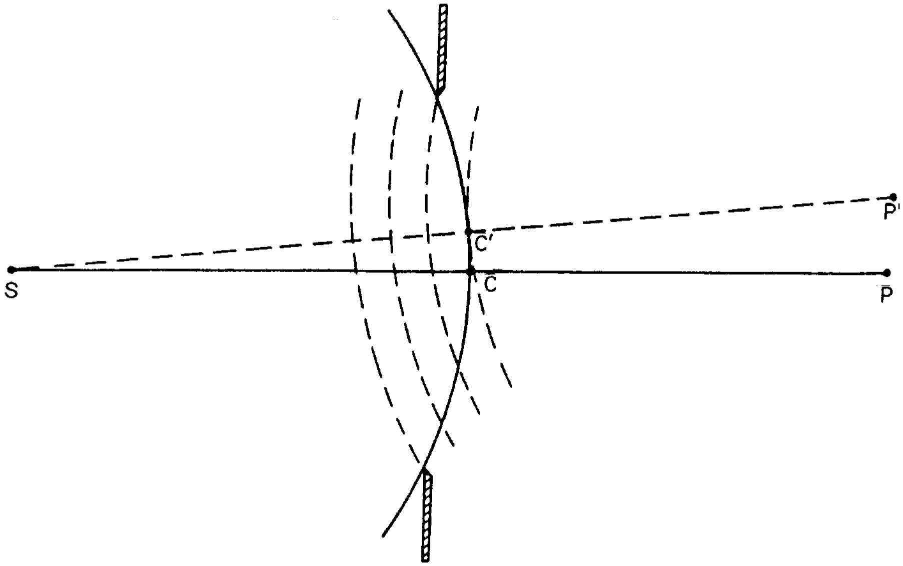

FIGURE 4 The redrawn zone structure for use with an off-axis point P'. (*After Andrews.*[8])

Fig. 4. The distance and the size of the aperture are such that, with respect to point P, only the first two zones are uncovered as in Fig. 3*a*. To obtain the diffraction amplitude for an off-axis point such as P', one has to redraw the zone structure as in Fig. 4. Figure 3*b* shows the zones and parts of zones uncovered by the circular aperture in this case. Figure 3*c* shows the uncovered zones for an irregularly shaped aperture.

In Fig. 3*a* the first two zones are uncovered. Following Eq. (9), the resulting diffraction amplitude at P for this case is

$$\psi(P) = \psi_1 - \psi_2 \tag{13}$$

but, since these two contributions are nearly equal, the resulting amplitude is $\psi(P) = 0$!

Relocating point P necessitates redrawing the zone structure. The first zone may just fill the aperture if point P is placed farther away from it. In this case the resulting amplitude is

$$\psi(P) = \psi_1 \tag{14}$$

which is twice what it was for the unobstructed wave! Therefore the irradiance is four times as large!

On the other hand, if the entire aperture screen is replaced by a small opaque disk, the irradiance at the center of the geometrical shadow is the same as that of the unobstructed wave! To verify this, suppose that the disk diameter and the distance allows only one Fresnel zone to be covered by the disk. The rest of the zones are free to contribute and *do* contribute. Per Eq. (9) we have

$$\psi(P) = -\psi_2 + \psi_3 - \psi_4 + \psi_5 - \psi_6 + \cdots$$

The discussion after Eq. (9) also applies here and the resulting amplitude on the axis behind the center of the disk is

$$\psi(P) = -\tfrac{1}{2}\psi_2 \tag{15}$$

which is the same as the amplitude of the unobstructed wave. Thus, the irradiance is the same at point P as though the wave were unobstructed. As the point P moves farther

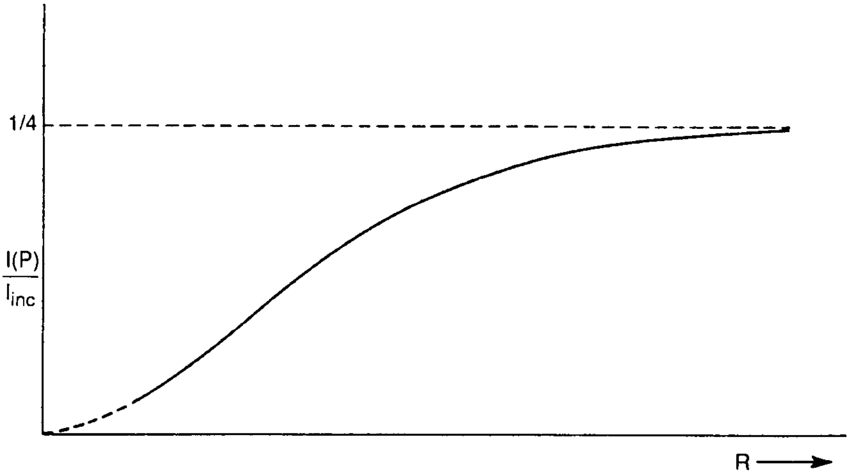

FIGURE 5 Variation of on-axis irradiance behind an opaque disk. R: distance along the axis behind the disk. (*From Marion and Heald.*[5])

away from the disk, the radius of the first zone increases and becomes larger than the disk. Alternatively one may redraw the zone structure starting from the edge of the disk. The analysis shows that the point P continues to be a bright spot of light. As the point P moves closer to the disk, more and more Fresnel zones get covered by the disk, but the analysis continues to predict a bright spot at P. There comes a point where the unblocked zone at the edge of the disk is significantly weak; the point P continues to be bright but has reduced irradiance. Still closer to the disk, the analysis ceases to apply because P enters the near-field region, where the distances are comparable to the size of the wavelength. In Fig. 5, the variation of irradiance on the axial region behind the disk is shown. It is remarkable that the axial region is nowhere dark! For an interesting historical note, see Refs. 1 and 5.

For comparison we show the variation of on-axis irradiance behind a circular opening in Fig. 6. It shows several on-axis locations where the irradiance goes to zero. These correspond to the situation where an even number of zones are exposed through the circular aperture. Only the first few zeros are shown, since the number of zeros per unit length (linear density) increases as the point P is moved closer to the aperture. The linear density increases as the square of the index j when P moves closer to the aperture. While far enough away, there comes a point where the first zone fills the aperture and, thereafter, there are no more zeros as the distance increases.

Figure 7 shows a series of diffraction patterns from a circular aperture. The pictures are taken at different distances from the aperture to expose one, two, three, etc., zones. Each time an odd number of zones is uncovered the center spot becomes bright. As we approach the pictures at the bottom right, more zones are exposed.

Babinet Principle

Irradiances for the on-axis points are quite different for the circular disk than for the screen with a circular opening. The disk and the screen with a hole form of a pair of complementary screens, that is, the open areas of one are the opaque areas of the other and vice versa. Examples of pairs of such complementary screens are shown in Fig. 8. Observe that the open areas of screen S_a taken with the open areas of the complementary screen S_b add up to no screen at all.

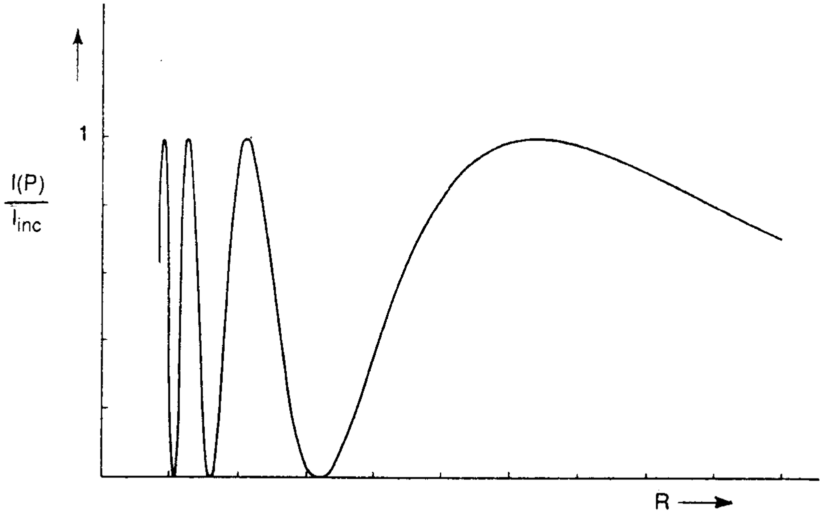

FIGURE 6 Variation of on-axis irradiance behind a circular opening. R: distance along the axis behind the opening. (*From Marion and Heald*[5])

The Babinet principle states that the wave disturbance $\psi_S(P)$ at any point of observation P due to a diffracting screen S_a added to the disturbance $\psi_{CS}(P)$ due to the complementary screen S_b at the same point P equals the disturbance at P due to the unobstructed wave. That is,

$$\psi_S(P) + \psi_{CS}(P) = \psi_{UN}(P) \tag{16}$$

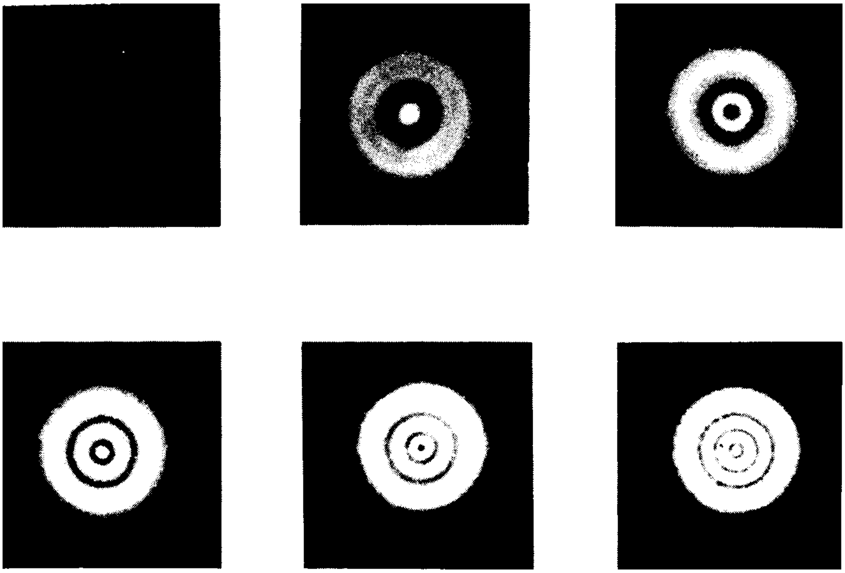

FIGURE 7 A series of pictures of diffraction patterns from circular apertures. (*After Andrews.*[8])

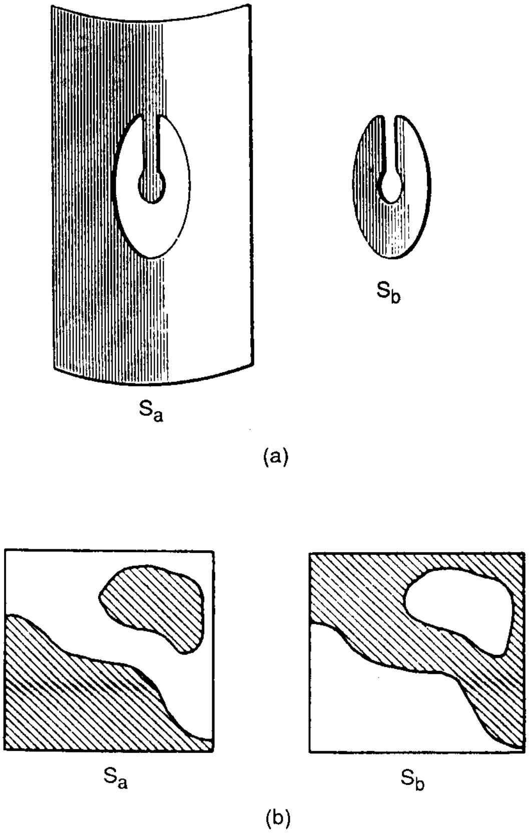

FIGURE 8 Examples of complementary screens, labeled S_a and S_b. (*After Jackson*[12] *and Andrews.*[8])

Recall that the wave disturbance at any point of observation P behind the screen is a linear superposition of the contributions of the unobstructed zones or portions thereof. This fact, with the observation that the open areas of screen S_a taken with the open areas of the complementary screen S_b add up to no screen at all, implies the equality indicated by the Babinet principle.

The behavior of the on-axis irradiance for the case of the opaque disk is quite different from that of the complementary circular aperture. There is no simple relationship between the irradiances of the two cases because they involve a squaring operation that brings in cross terms.

Zone Plate

If alternate zones are blocked the contribution of the unblocked zones will add in phase to yield a large irradiance at the point of observation. An optical device that blocks alternate zones is called a *zone plate.* Figure 9*a* and *b* shows two zone plates made up of concentric circles with opaque alternate zones. They block odd-indexed or even-indexed zones, respectively. The radii of the zone boundaries are proportional to the square root of

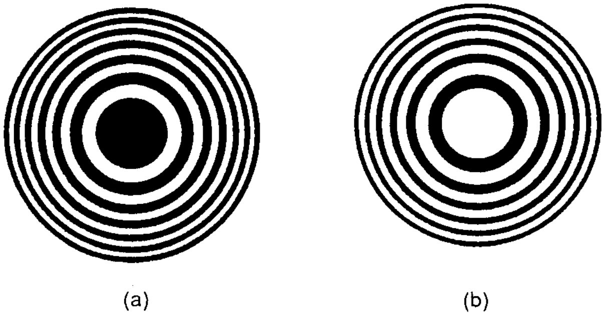

FIGURE 9 Two zone plates made up of concentric circles with alternate zones made opaque. They block odd-indexed or even-indexed zones respectively. The radii of the zone boundaries are proportional to the square root of natural numbers. (*From Hecht and Zajac.*[9])

natural numbers. As in Fig. 2, we place a point source at a distance r_0 in front of the zone plate. If R_m is the radius of the mth zone, a bright image of this source is observed at a distance b behind the plate, so that

$$\frac{1}{r_0}+\frac{1}{b}=\frac{m\lambda}{R_m^2} \tag{17}$$

where λ is the wavelength of light from the source. This equation for the condition on the distance b is like the paraxial lens formula from which the focal length of the zone plate may be identified or may be obtained by setting the source distance $r_0 \rightarrow \infty$ (see Chap. 1). The focal length f_1 so obtained is

$$f_1=\frac{R_m^2}{m\lambda} \tag{18}$$

and is called the *primary focal length*. For unlike, the case of the lens, the zone plate has several secondary focal lengths. These are given by

$$f_{2n-1}=\frac{R_m^2}{(2n-1)m\lambda} \tag{19}$$

where $n = 1, 2, 3 \ldots$ In the case of the primary focal length, each opaque zone of the zone plate covers exactly one Fresnel zone. The secondary focal length f_3 is obtained when each opaque zone covers three Fresnel zones. It is a matter of regrouping the right-hand side of Eq. (9) in the form

$$\begin{aligned}\psi(P) &= (\psi_1-\psi_2+\psi_3)-\langle\psi_4-\psi_5+\psi_6\rangle+(\psi_7-\psi_8+\psi_9)\\ &\quad -\langle\psi_{10}-\psi_{11}+\psi_{12}\rangle+(\psi_{13}-\psi_{14}+\psi_{15})-\cdots\end{aligned} \tag{20}$$

The zone plate in Fig. 9*b*, for example, blocks all even-indexed zones. It corresponds to omitting the terms enclosed in the angular brackets, $\langle\cdots\rangle$, in Eq. (20). The remaining terms grouped in parentheses add in phase to form a secondary image of weaker irradiance. The higher-order images are formed successively closer to the zone plate and are successively weaker in irradiance.

Further discussion is given in several books of the bibliography, for example, Ref. 9 (p. 375). The radii of the concentric circles in a zone plate are proportional to the square root of natural numbers. For equidistant source and image locations, say 10.0 cm at a wavelength of 500 nm, $R_m = \sqrt{m}$ (0.16 mm). Due to the smallness of the radii, a photographic reduction of a large-scale drawing is used.

Incidentally, the pair of zone plates of Fig. 9*a* and *b* form a pair of complementary screens. Per the Babinet principle, the groupings are

$$\begin{aligned}\psi_{UN}(P) &= \psi_S(P) + \psi_{CS}(P)\\ &= (\psi_1 + \psi_3 + \psi_5 + \psi_7 + \psi_9 + \psi_{11}\cdots)\\ &\quad - (\psi_2 + \psi_4 + \psi_6 + \psi_8 + \psi_{10} + \psi_{12} + \cdots)\end{aligned} \tag{21}$$

The first group of terms correspond to the zone plate of Fig. 9*b* and the second group of items correspond to Fig. 9*a*.

3.5 CYLINDRICAL WAVEFRONT

A line source generates cylindrical wavefronts. It is frequently approximated in practice by a slit source, which, in turn, can illuminate straightedges, rectangular or slit apertures (see Fig. 10*a*). In this case, as we shall see, the phenomena of diffraction can be essentially reduced to a one-dimensional analysis for this source and aperture geometry.

Fresnel zones for cylindrical wavefronts take the form of rectangular strips, as shown in Fig. 10(*a*). The edges of these strip zones are $\lambda/2$ farther away from the point of observation *P*. The treatment for the cylindrical wave parallels the treatment used for the spherical wave in Section 3.4. The line M_0 on the wavefront intersects at right angles to the line joining the source *S* and the point of observation *P*. Refer to M_0 as the axis line of the wavefront with respect to the point *P*. Let *a* be the radius of the wavefront with respect to the source slit and let *b* the distance of *P* from M_0. Fresnel zones are now in the form of strips above and below M_0 and are parallel to it. The line pairs M_1M_1', M_2M_2', etc., are marked $\lambda/2$ farther away from the point of observation *P*. Fresnel zones are now half-period strips. Thus $\overline{PM_m} = b + m\lambda/2$ and, to a good approximation, the arc length $(M_mM_{m+1}) = aK(\sqrt{m+1} - \sqrt{m})$, where the constant, $K = \sqrt{mb\lambda/a(a+b)}$. For small values of *m* such as 1, 2, etc., the arc widths decrease rapidly while, for large values of *m,* the neighboring strips have nearly equal widths. The lower-order strips have much larger areas compared to the ones further up from M_0. This effect is much more dominant than the variation of the obliquity factor $K(\chi)$ that is neglected in this analysis.

Consider one single strip as marked in Fig. 10*b*. Imagine that this strip is divided into half-period sections as shown. The wavefront is almost planar over the width of this strip. All the sections on either side of the arc M_1M_2 contribute to the disturbance at *P*. The boundaries of these are marked N_1, N_2, etc. The area of these sections are proportional to $K'(\sqrt{n+1} - \sqrt{n})$, where the constant $K' = \sqrt{c\lambda}$. The areas of those half-period sections decrease rapidly at first and then slowly. The contribution to the disturbance at *P* from the higher-order sections is alternately positive and negative with respect to the first section near M_1M_2. Consequently, their contribution to the total disturbance at *P* is nearly zero.

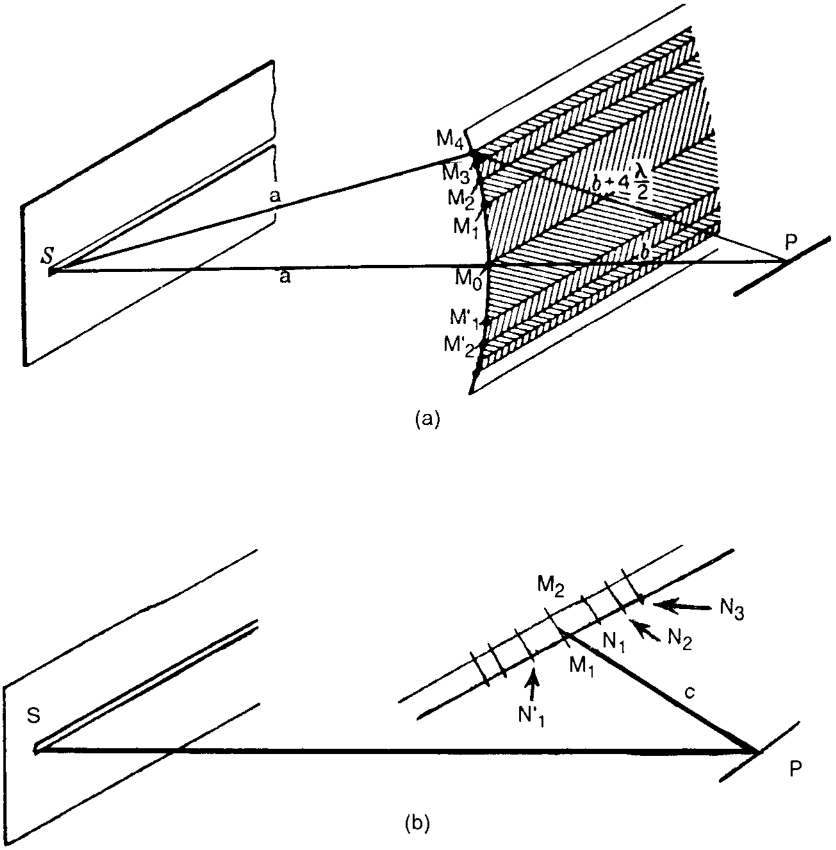

FIGURE 10 Fresnel zones for cylindrical wavefront. *S*: slit source; *a*: radius of the cylindrical wavefront; *b*: distance M_0P. M_1, M_1', etc.: zone boundaries. (*Adapted from Jenkins and White.*[2])

The disturbance at *P* due to a single strip consists of the dominant contribution of the two sections from N_1 to N_1'. This conclusion holds for all the strips of the cylindrical wave.

Following the procedure of Eq. (9) employed for the spherical wave,

$$\psi(P) = \psi_1 - \psi_2 + \psi_3 - \psi_4 + \psi_5 - \psi_6 + \cdots \tag{9'}$$

where $\psi(P)$ is the disturbance at *P* and ψ_m denotes the secondary wavelet contributions from strip zones of either side of the axis line M_0 of Fig. 10*a*. As in Eq. (11) the series can be summed, but here we need to account for the strip zone contribution from both sides of the axis line M_0: therefore, we have

$$\psi(P) = \psi_1 \tag{11'}$$

The first zone contributions can be computed and compared with the freely propagating cylindrical wave. Without going into the details as carried out with Eqs. (12) and (12′) for the spherical wave, we shall discuss qualitative features of some typical diffraction patterns resulting from cylindrical waves.

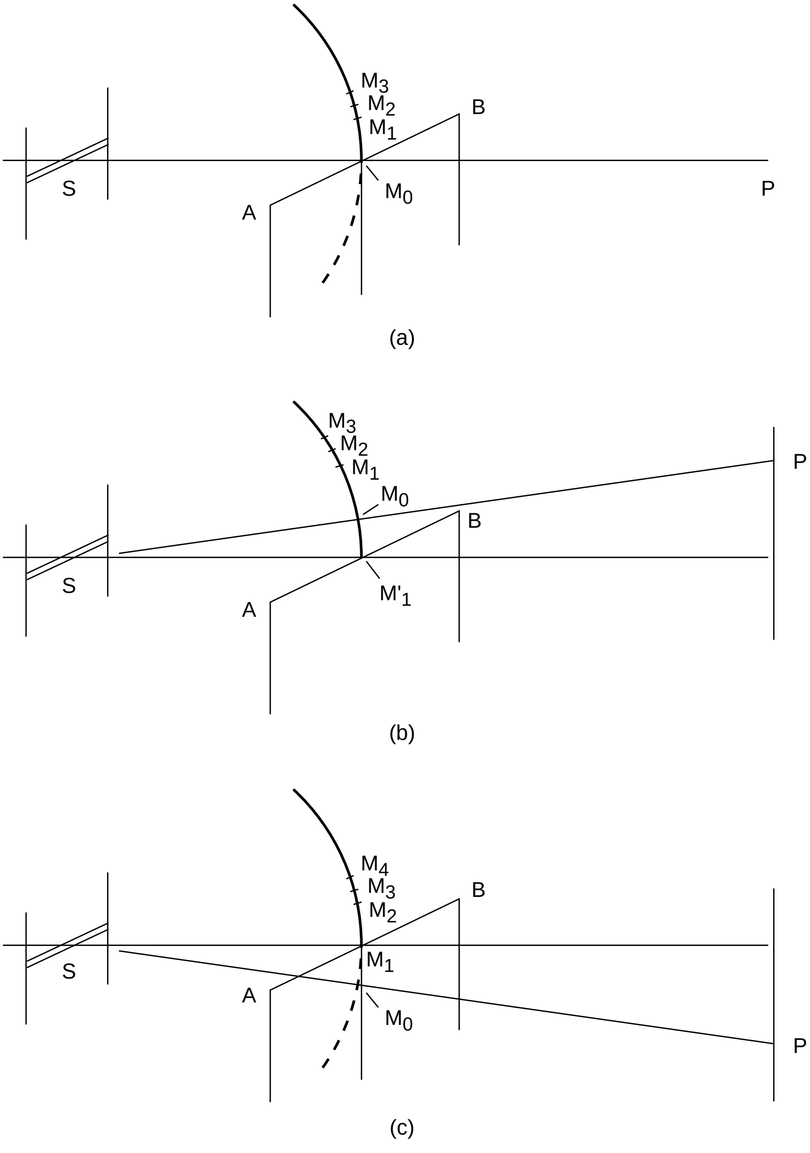

FIGURE 11 Fresnel zones for a cylindrical wavefront. The edges of these strip zones are $\lambda/2$ farther away from the point of observation *P*. *S*: slit source. *P*: point of observation. M_0: axis line of the cylindrical wave. *AB*: straight-edge opaque obstruction. (*After Jenkins and White.*[2])

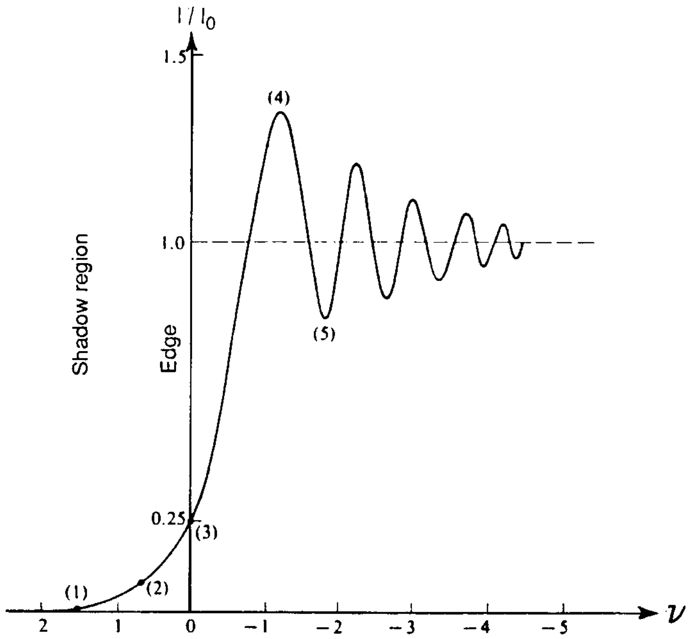

FIGURE 12 The plot of irradiance in the diffraction pattern of a straight edge *AB*. The plot is normalized to unity for the irradiance of the unobstructed wave. Labels 1 and 2 show points *P* in the geometrical shadow. Label 3 is at the edge of the geometrical shadow, while Labels 4 and 5 are in the illuminated region. *v* is a unitless variable to label distances along the plane of observation. (*From Hecht and Zajac.*[9])

Straightedge

A cylindrical wave from a slit source *S* illuminates an opaque screen with a straightedge *AB* oriented parallel to the slit, as shown in Fig. 11. It shows three special positions of the point of observation *P*. In Fig. 11*a, P* is such that all the strip zones above the axis line M_0 are exposed, while those below are blocked. The point *P* in Fig. 11*b* is such that the strip zones above M_0 and one zone below, marked by the edge M_1', are exposed. In Fig. 11*c, P* has moved into the geometrical shadow region. The strip M_1M_0 and all those below M_0 are blocked.

A plot of the irradiance in the diffraction pattern of a straightedge is shown in Fig. 12. Following the discussion in Section 3.4, we discuss the disturbance at *P* for the three cases of Fig. 11. At the edge of the geometrical shadow

$$\psi_a(P) = 1/2\psi_1 \tag{22}$$

For Fig. 11*b* we have

$$\psi_b(P) = 1/2\psi_1 + \psi_1 = 3/2\psi_1 \tag{23}$$

As *P* is moved further up, there comes a point for which two strip zones below M_0 are exposed, resulting in $\psi(P) = 3/2\psi_1 - \psi_2$. As *P* explores the upper half of the observation plane, the amplitude and, hence, the irradiance go through maxima and minima according to whether an odd or even number of (lower) strip zones is exposed. Furthermore, the maxima decrease gradually while the minima increase gradually until the fringes merge into a uniform illumination that corresponds to the unobstructed wave.

In the geometrical shadow (see Fig. 11*c*),

$$\psi_c(P) = -1/2\psi_2 \tag{24}$$

As P goes further down, we get $\psi(P) = 1/2\psi_3$; in general, the number of exposed zones decreases and the irradiance falls off monotonically.

A plot of the irradiance in the diffraction pattern of a straightedge is shown in Fig. 12. It is interesting to observe that the edge is neither at the maximum of the first fringe nor at the half-way point. It appears at one-fourth of the irradiance of the unobstructed wave.

Rectangular Aperture

Figure 13 is a series of diagrams of irradiance distributions for light diffracted by single-slit apertures. A pair of marks on the horizontal axis indicate the edges of the geometrical shadow of the slit relative to the diffraction pattern. In all cases, relatively little light falls in the geometrical shadow region. The last diagram corresponds to a rather wide slit. It appears as two opposing straightedge diffraction patterns corresponding to the two edges of the slit.

These patterns may be interpreted as obtained with the plane of observation fixed for different-size slits. Alternately, the slit size may be held fixed but move the plane of observation. For the first diagram the plane is far away. For the successive diagrams the plane is moved closer to the slit. The plane of observation is the closest for the last

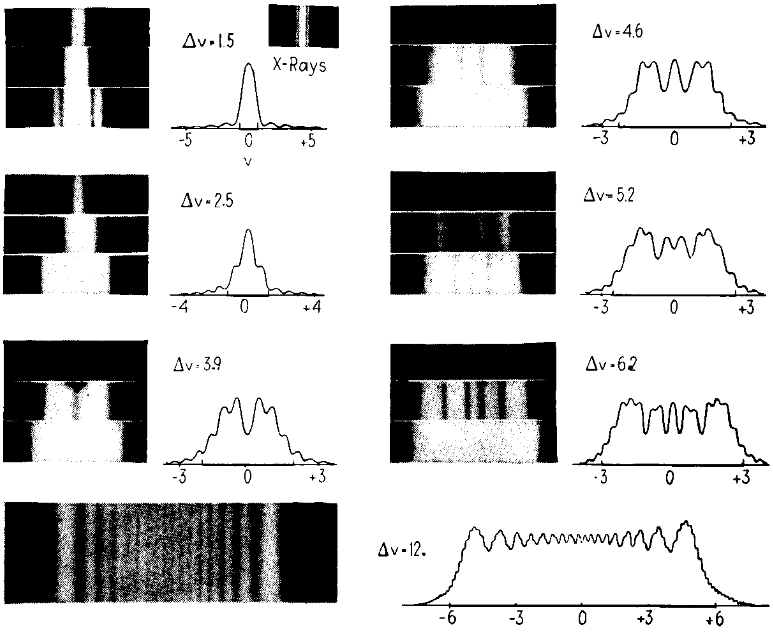

FIGURE 13 A series of diagrams of irradiance distributions for light diffracted by single-slit apertures of different widths. (*From Jenkins and White.*[2])

diagram of Fig. 13. The important parameter is the angular subtense of the slit to the observation plane. A similar comment applies to the case of the circular aperture shown in Fig. 7. See Jenkins and White[2] for further discussion.

Opaque Strip Obstruction

A slit aperture and an opaque strip or a straight wire form a pair of complementary screens. In Fig. 14 photographs of Fresnel diffraction patterns produced by narrow wires are shown with the corresponding theoretical curves. These theoretical curves show some more detail. Generally, the figures show the characteristic unequally spaced diffraction fringes of a straight edge on either side of the geometrical shadow. These fringes get closer and closer together, independently of the width of the opaque obstruction, and finally merge into a uniform illumination. Figure 14 also shows the maximum in the center and equally spaced narrow fringes within the shadow. The width of these fringes is inversely proportional to the width of the obstruction. We shall now discuss this detail.

Figure 15 shows the arrangement of the source *S*, opaque strip *AB*, and the plane of observation. A point *x* in the geometrical shadow receives light from Fresnel zones of both sides of the opaque strip. At each edge of the opaque strip the exposed zones add up effectively to one-half of the contribution of a single zone adjacent to that edge. Owing to the symmetry, the resulting disturbance from each edge starts out in phase. Light from the two edges adds constructively or destructively according to whether the path difference to

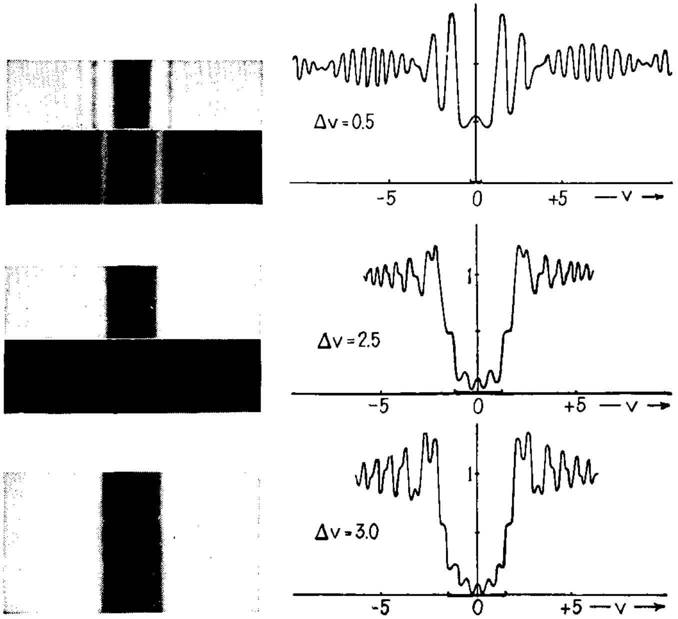

FIGURE 14 Fresnel diffraction patterns produced by narrow wires are shown with the corresponding theoretical curves. (*From Jenkins and White.*[2])

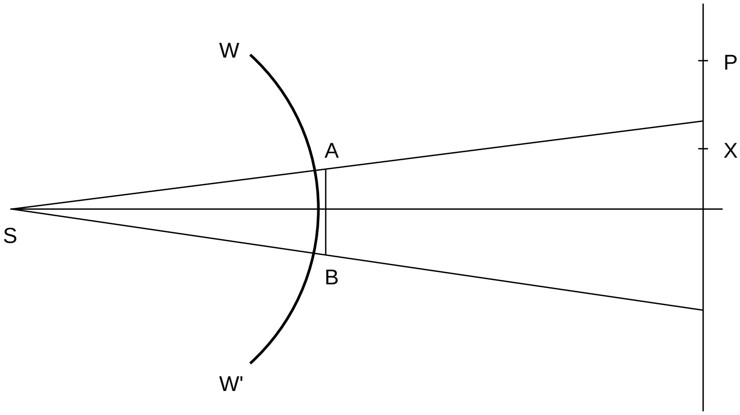

FIGURE 15 Arrangement of the source *S*, opaque strip *AB*, and the plane of observation. Point *x* is in the geometrical shadow region.

the point x in the shadow region is an even or an odd multiple of $\lambda/2$ (see Chap. 2). The situation is similar to two coherent sources separated by the width of the opaque strip. Young examined these fringes inside the geometrical shadow. In particular, he showed that if an opaque screen is introduced on one side of the opaque strip to block that part of the wave, then the straightedge diffraction fringes due to that edge, as well as the interference fringes in the shadow region, vanished.

3.6 MATHEMATICAL THEORY OF DIFFRACTION

Kirchhoff showed that the Huygens-Fresnel construction follows from an integral theorem starting from the wave equation. The resulting mathematical expression is called the Fresnel-Kirchhoff diffraction formula.[1] This theory was further modified by Rayleigh and Sommerfeld.[6,11] At each stage the modifications previously referred to were for removing certain mathematical inconsistencies. In view of the approximations applicable to practical optical situations, the mathematical details will not be discussed here. There are several other theoretical aspects and different approaches[1] to the mathematics of diffraction theory.

It is well known in wave theory that the field values inside a volume enclosed by a bounding surface are determined by the values of the field and/or its normal derivative on this bounding surface. The solution is expressed in terms of the Green's function of the problem, as in

$$\psi(P) = \left(\frac{1}{4\pi}\right)\iint_S \left\{\psi\left(\frac{\partial G}{\partial n}\right) - G\left(\frac{\partial \psi}{\partial n}\right)\right\} dS \tag{25}$$

where G is the Green's function of the problem. The integral is over the arbitrary closed surface S. The symbol $(\partial/\partial n)$ stands for the normal derivative with the normal pointing into the volume enclosed by the surface.[1] A convenient Green's function is the expanding spherical wave, $\exp(iks)/s$ from the point of observation P. The closed surface for the diffraction problem is made up of the aperture plane and a large partial sphere centered at

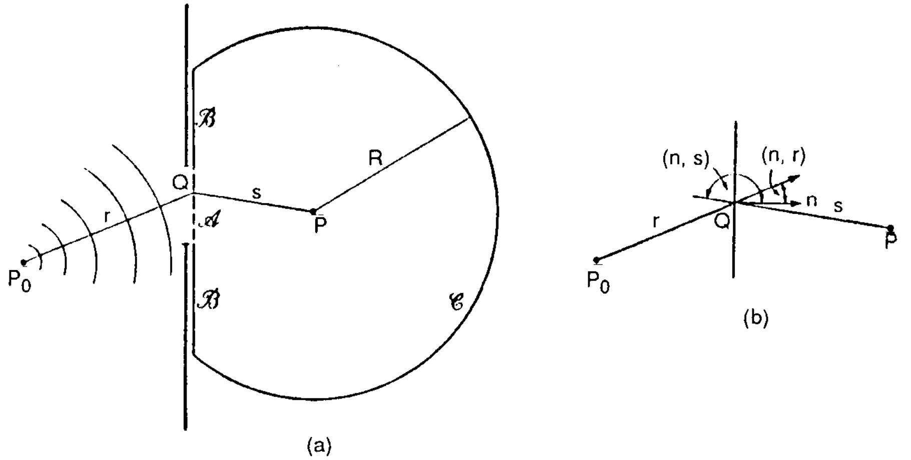

FIGURE 16 The closed surface for the diffraction problem. It is made up of the aperture plane and a large partial sphere centered at the point of observation P. (*From Born and Wolf.*[1])

the point of observation P, as shown in Fig. 16. This is the starting point of Kirchhoff theory. It requires specifying the field values and its normal derivative on the bounding surface to obtain the field $\psi(P)$ at P in the volume enclosed by the surface. It is possible to show that the contribution of the surface integral from the partial sphere is zero. Kirchhoff assumed that the field and its normal derivative are zero on the opaque portion of the aperture plane. On the open areas of the aperture plane he assumed the values to be the same as (unperturbed) incident values. If the incident field is an expanding spherical wave $(a/r)\exp(ikr)$, then the field $\psi(P)$ is given by

$$\psi(P) = -\left\{\frac{ia}{2\lambda}\right\}\iint_A \left[\frac{\exp(ikr)}{r}\right]\left[\frac{\exp(iks)}{s}\right][\cos(n, r) - \cos(n, s)]\,dS \tag{26}$$

The area integral is over the open areas A of the aperture. As shown in Fig. 16, (n, s) and (n, r) are the angles made by s and r, respectively, with the normal to the aperture plane. The above equation is referred to as the Fresnel-Kirchhoff diffraction formula.

From a strictly mathematical point of view the specification of field and its normal derivative is overspecifying the boundary conditions. It is possible to modify the Green function so that either the field ψ or its normal derivative $\partial\psi/\partial n$ needs to be specified. With this modification one obtains

$$\psi(P) = -\left(\frac{ia}{\lambda}\right)\iint_A \left[\frac{\exp(ikr)}{r}\right]\left[\frac{\exp(iks)}{s}\right]\cos(n, s)\,dS \tag{27}$$

This is referred to as the Rayleigh-Sommerfeld diffraction formula. Other than mathematical consistency, both formulas yield essentially similar results when applied to practical optical situations. They both use the approximate boundary conditions, namely, that the field is undisturbed in the open areas of the aperture and zero on the opaque regions of the aperture plane. The cosine factors in the above formulas play the role of the obliquity factor of the Huygens wave used in Section 3.4 Eq. (8).

More generally the field (for a single temporal frequency) at the point of observation P, x, y, z may be expressed by[11]

$$\psi(x, y, z) = \iint_A \psi(x_s, y_s, 0)\left[\frac{i}{2\pi}\frac{z}{\rho}(1 - ik\rho)\frac{\exp(ik\rho)}{\rho^2}\right] dx_s\, dy_s \tag{28}$$

where $\psi(x_s, y_s, 0)$ are the field values in the aperture A, at $z = 0$. The expression in the square brackets is the normal derivative of the modified Green function. In this expression $\rho = [(x - x_s)^2 + (y - y_s)^2 + z^2]^{1/2}$, the distance between a point in the aperture and the point of observation P, and the ratio z/ρ is the direction cosine of the difference vector. In the far zone where $k\rho \gg 1$, Eq. (28) reduces to Eq. (27) for the case of a spherical wave illumination. Since the expression in the square brackets depends on the coordinate difference, $(x - x_s)$ and $(y - y_s)$, Eq. (28) has the form of a convolution integral. It is well known that the convolution integral has a corresponding product relationship in the Fourier-spatial-frequency domain. The two-dimensional Fourier decomposition of the field ψ is

$$\psi(x, y, z) = \iint \hat{\psi}(p/\lambda, q/\lambda, z) \exp[+i2\pi(px + qy)/\lambda]\, d(p/\lambda)\, d(q/\lambda) \tag{29}$$

where p and q are the two-direction cosines. The third-direction cosine m is defined by

$$m = +(1 - p^2 - q^2)^{1/2}, \text{ for } p^2 + q^2 \leq 1$$

$$\text{and} \qquad m = +i(p^2 + q^2 - 1)^{1/2}, \text{ for } p^2 + q^2 > 1 \tag{30}$$

A similar decomposition as in Eq. (29) is used for the field in the aperture at $z = 0$, wherein the finite area of the aperture is included in the description of the incident field. With the help of Weyl's plane-wave decomposition of a spherical wave,

$$\frac{\exp(ikr)}{r} = \frac{i}{\lambda}\iint \frac{1}{m}\exp(ikmz)\exp\left[\frac{i2\pi}{\lambda}(px + qy)\right] dp\, dq \tag{31}$$

the Fourier transform of the expression in square brackets in Eq. (28) can be found.[11] The product relationship in the Fourier domain has the form

$$\hat{\psi}(p/\lambda, q/\lambda, z) = \hat{\psi}(p/\lambda, q/\lambda, 0)\exp(ikmz) \tag{32}$$

The inverse Fourier transform yields the disturbance in x, y, z space at point P. At $z = 0$ it reproduces the assumed boundary conditions, a property not shared by the Fresnel-Kirchhoff formula.

A plane-wave decomposition describes a function in (x, y, z) space in terms of the weighted sum of plane waves, each propagating in a direction given by the direction cosines (p, q, m). Equation (32) may be referred to as the angular spectrum formulation of diffraction. For application of this formulation see Chap. 4, Coherence Theory by W. H. Carter.

Fresnel and Fraunhofer Approximations

In practical optical situations diffraction is mainly studied in the forward direction, that is, for small angles from the direction of propagation of the incident field. Furthermore, the distances involved are much larger than the wavelength λ, $r \gg \lambda$. In this situation the distance ρ of Eq. (28) may be approximated by the low-order terms in the binomial expansion of the square root,

$$\begin{aligned}\rho &= [(x - x_s)^2 + (y - y_s)^2 + z^2]^{1/2} \\ &\simeq \left(r - \frac{xx_s + yy_s}{r} + \frac{x_s^2 + y_s^2}{2r}\right)\end{aligned} \tag{33}$$

where r is the radial distance of the observation point P, $r = \sqrt{x^2 + y^2 + z^2}$. When the terms quadratic in the aperture variables are retained, namely, $(x_s^2 + y_s^2)$, we have a description of Fresnel diffraction. Let d be the maximum dimension of the aperture. If the plane of observation is moved to distance $z \gg d^2/\lambda$ the quadratic terms are negligible and Eq. (28) is approximated by

$$\psi(x, y, z) = \left(-\frac{i}{\lambda r}\right) \exp(ikr) \iint_A \psi(x_s, y_s, 0) \exp\left[-\frac{ik(xx_s + yy_s)}{r}\right] dx_s\, dy_s \tag{34}$$

This is the formula for Fraunhofer diffraction.

Fraunhofer Diffraction

Far enough away from the aperture, $z \gg d^2/\lambda$, Fraunhofer-type diffraction is found. Eq. (34) shows that it has the form of a Fourier transform of the light distribution in the aperture. For more general conditions on the distance and angles to obtain Fraunhofer diffraction, see Born and Wolf,[1] sec. 8.3.3. Thus, instead of moving the observation plane to the far field, parallel light incident on the aperture can be brought to a focus by a converging lens as in Fig. 17, thus producing a Fraunhofer pattern of the aperture in the focal plane.

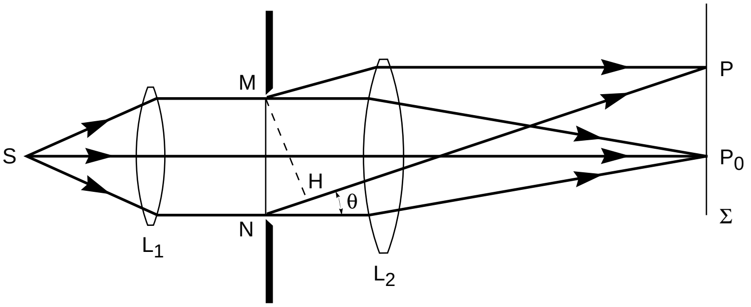

FIGURE 17 Arrangement to observe a Fraunhofer diffraction by a slit aperture. (*After Rossi.*[7])

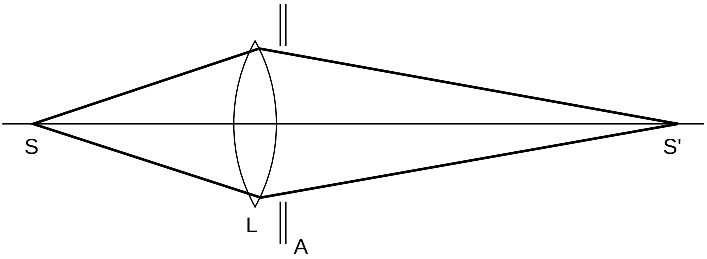

FIGURE 18 Fraunhofer diffraction of an aperture *A*, with a converging spherical wave. *S*: point source. *L*: converging lens. *S'*: image.

In an imaging situation (see Fig. 18), a diverging spherical wave is brought to a focus in the image plane. This is also an example of Fraunhofer diffraction pattern of the light distribution in the aperture *A* by a converging spherical wave. To realize Fraunhofer diffraction, a similar situation is obtained when a narrow diffracting aperture is held next to the eye when it is focused on a distant point source. The diffraction pattern is observed in the plane of the source.

An optical processing setup is shown in Fig. 19 where collimated or parallel light is incident normally on plane 1. In this arrangement an inverted image of plane 1 is formed in plane 3 (see Chap. 1). The imaging process may be thought of as a Fourier transform (Fraunhofer diffraction) of the light distribution in plane 1 onto plane 2, followed by another Fourier transform of the light distribution in plane 2 onto plane 3.

Recall our earlier discussion in relation to Eqs. (33) and (34). When the quadratic phase factor, $\exp[+i\pi(x_s^2 + y_s^2)/\lambda r]$, may be approximated by unity, we are in the domain of Fraunhofer diffraction. From the point of view of Fresnel zone construction, the far-field condition, $z \gg d^2/\lambda$, means that for these distances z the first Fresnel zone overfills the aperture. The entire aperture contributes to the disturbance at any point in the Fraunhofer pattern. In Fresnel diffraction only relatively small portions of the aperture contribute to any one point in the pattern.

In this context the term Fresnel number is frequently used. It is defined in terms of the product of two ratios. The radius r of the aperture to the wavelength λ times the radius of the aperture to the distance b measured from the aperture to the plane of observation:

$$\text{Fresnel number} \equiv N = \frac{r}{\lambda} \cdot \frac{r}{b} = \frac{1}{4b}\frac{d^2}{\lambda} \tag{35}$$

Thus, Fresnel number can also be expressed as the ratio of the far-field distance, d^2/λ, to

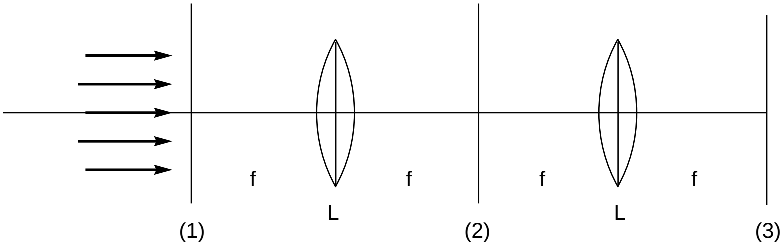

FIGURE 19 Optical processing arrangement. Collimated or parallel light is incident normally on plane 1. The system images plane 1 onto plane 3 with a Fourier transform in plane 2.

the distance, b, from the aperture. With the definition of the Fresnel zones Section 3.4, these ratios indicate that the Fresnel number equals the number of Fresnel zones that may be drawn within the aperture from a point P at a distance b from the aperture.

Thus, well within the Fresnel region, $b \ll d^2/\lambda$, where the Fresnel number is (high) large. There are many zones in the aperture. As seen in Figs. 7 and 13, very little light falls within the geometrical shadow region; most of the light is in the confines of the aperture boundary dictated by geometrical optics. In the study of cavity resonators[12,13] and modes it is found that diffraction losses are small for large Fresnel numbers, $N \gg 1$. In the Fraunhofer region $b > d^2/\lambda$, $N < 1$ where the first Fresnel zone overfills the aperture as pointed out before—well into the Fraunhofer region $N \ll 1$.

In Figs. 20 and 21 the theoretical plots of Fraunhofer patterns of a rectangular aperture and a circular aperture, respectively, are shown. In the rectangular case the central maximum has equally spaced zeros on either side, while in the circular case the central maximum is surrounded by unequally spaced concentric dark rings. In both cases the central maximum occurs at the geometrical image of the point source that produced parallel light illumination on the aperture. The unitless variable x shown in the plots is defined as follows. (1) In the case of rectangular aperture, $x = 2\pi ap/\lambda$, where $2a$ is the width of the aperture in the x_s direction. In the other dimension $y = 2\pi bq/\lambda$, and $2b$ is the dimension in the y_s direction. As before, p, q are the direction cosines of the vector joining the center of the aperture to the point of observation. (2) In the case of circular aperture, the unitless radial variable $x = 2\pi aw/\lambda$, where $2a$ is the diameter of the aperture in the x_s, y_s plane and $w = \sqrt{p^2 + q^2}$.

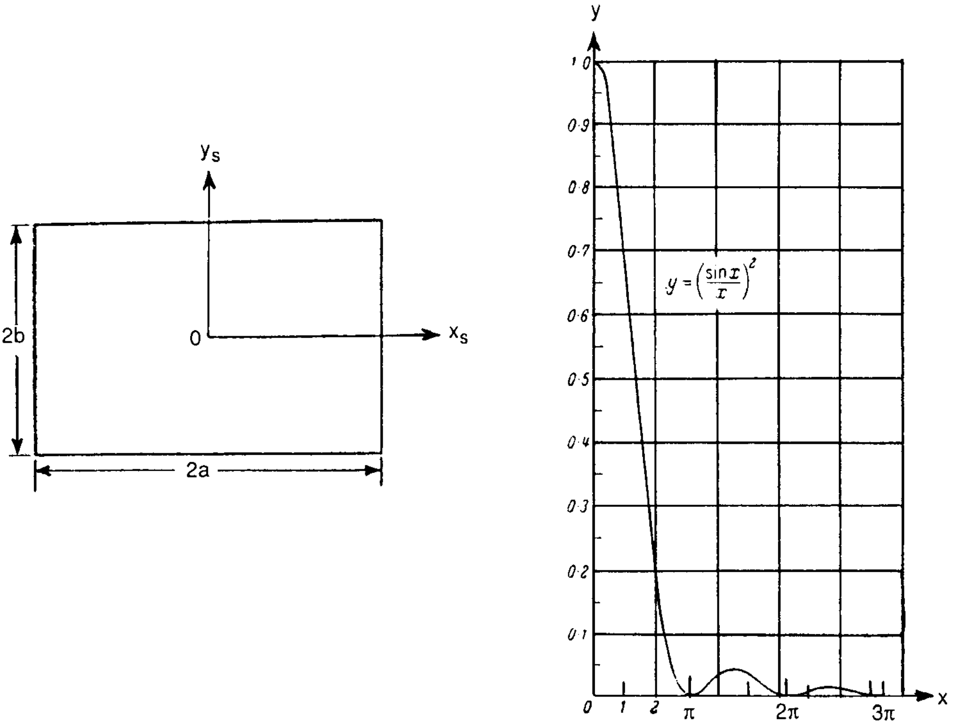

FIGURE 20 Rectangular aperture (in coordinates x_s and y_s) and one section of the diffraction pattern. Normalized irradiance y plotted against a unitless variable x as discussed in the text. (*From Born and Wolf.*[1])

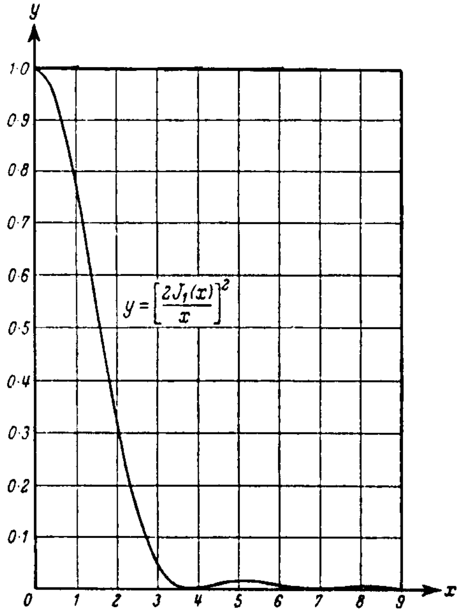

FIGURE 21 A section of the diffraction pattern of a circular aperture. The normalized irradiance y is plotted against a unitless variable x in the plane of observation as discussed in the text. (*From Born and Wolf.*[1])

In the far field the size of the diffraction pattern is very large compared to the aperture that produced it. In the focal plane of the lens, $z = f$ and the size of the diffraction pattern is much smaller than the aperture. In both cases the patterns are in a reciprocal width relationship, i.e., if the aperture is narrow in the x_s direction compared to y_s, the pattern is broader in the x direction compared to the y. A converging spherical lens illuminated by a plane wave produces in the focal plane a Fraunhofer diffraction pattern of the amplitude and phase of the aperture of a circular lens. When the lens has negligible phase errors, the diffraction pattern has a bright disk in the center surrounded by concentric dark rings. This is called an *Airy disk* and it plays an important role in the Rayleigh criterion of resolving power. This topic is discussed in Chap. 1, "Geometric Optics," by D. Goodman.

Fraunhofer Diffraction Pattern of a Double Slit

The diffraction pattern of two slits may be observed by using the optical arrangement of Fig. 22. The center-to-center separation of the two slits is h. The off-axis point P is in the direction θ from the axis as shown in the figure. The maxima and minima are determined according to whether the path difference O_1H is an even or odd multiple of a half-wave. Let I_0 be the irradiance at the center of the single-slit diffraction pattern. The irradiance distribution in the plane of observation Σ, is given by

$$I = 4I_0\left(\frac{\sin\alpha}{\alpha}\right)^2 (\cos\delta)^2 \tag{36}$$

where $\delta = \pi h \sin\theta/\lambda$. The irradiance at the center of the double-slit pattern is $4I_0$. The second term, $(\sin\alpha/\alpha)^2$, describes the diffraction pattern of a single slit of width $2a$. Here

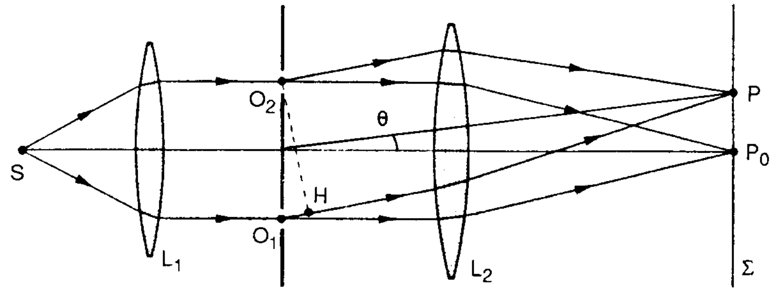

FIGURE 22 Arrangement to observe the Fraunhofer diffraction of an aperture consisting of two slits. *S*: point source. *P*: point of observation. O_1, O_2: two slit apertures with center-to-center separation *h*. (*From Rossi.*[7])

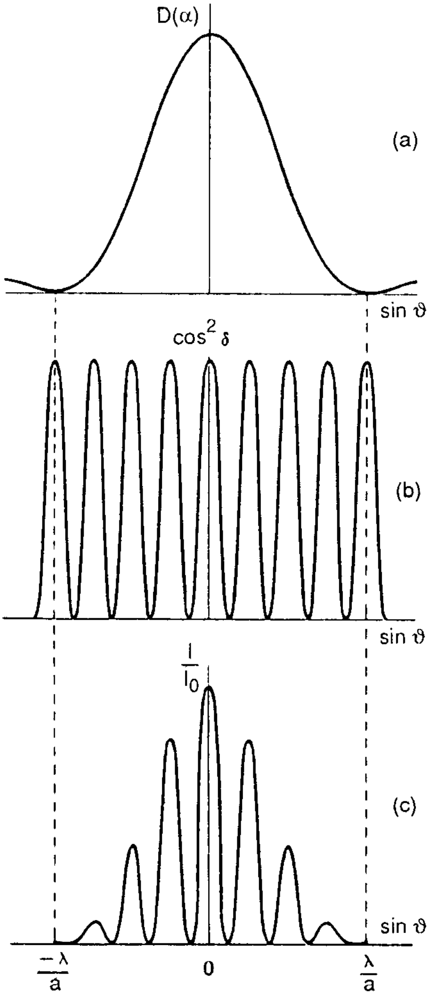

FIGURE 23 (*a*) Plot of a single-slit diffraction pattern $D(\alpha)$; (*b*) Plot of a two-slit interference pattern; and (*c*) their product I/I_0. (*From Rossi.*[7])

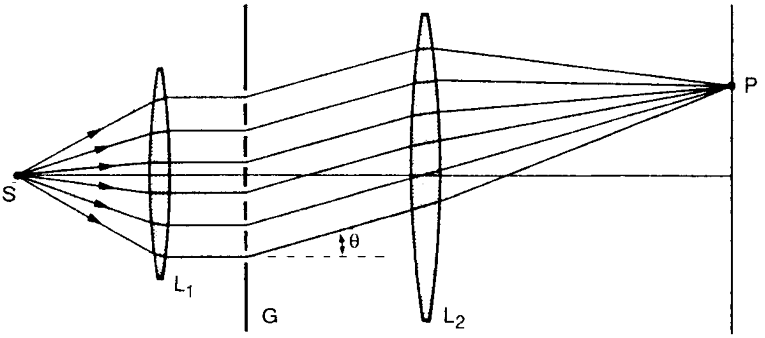

FIGURE 24 Arrangement to observe the Fraunhofer diffraction of an aperture consisting of N slits. S: slit source, P: point of observation. G: grating. (*From Rossi.*[7])

$\alpha = 2\pi ap/\lambda,$ where $p = \sin\theta$. The term $(\cos\delta)^2$ is the interference pattern of two slits. These two patterns as well as their product are sketched in Fig. 23.

Diffraction Grating

In Fig. 24 an arrangement similar to Fig. 22 permits observation of the Fraunhofer diffraction pattern of a grating, of N parallel and equidistant slits. The center-to-center separation between neighboring slits is h. As in the two-slit case, the Fraunhofer pattern consists of the diffraction due to one slit times the interference pattern of N slits. The irradiance distribution in the plane of observation is given by

$$I = N^2 I_0 \left(\frac{\sin\alpha}{\alpha}\right)^2 \left(\frac{\sin N\gamma}{N\sin\gamma}\right)^2 \tag{37}$$

where $\gamma = \pi h \sin\theta/\lambda$ and $N^2 I_0$ is proportional to the irradiance at the center of the N-slit pattern. The term $(\sin\alpha/\alpha)^2$ is the single-slit pattern as used with Eq. 36. In the case of multiple slits each slit is very narrow; hence, this pattern is very broad, a characteristic of Fraunhofer diffraction. The interference term $(\sin N\gamma/N\sin\gamma)^2$ shows prominent maxima when both the numerator and denominator are simultaneously zero; this happens when $\gamma = \pi h \sin\theta/\lambda = m\pi$, where m is an integer. It leads to the grating equation, namely,

$$h\sin\theta = m\lambda \tag{38}$$

There are several, $(N-1)$, subsidiary minima in between the principal maxima. This happens when the numerator is zero but the denominator is not: $\gamma = m\pi/N$. For the case of $N = 10$, these effects are sketched in Fig. 25, which shows the effect of the product of the diffraction and interference terms.

In general, as N increases the subsidiary maxima become more nearly negligible, while the principal maxima become narrower, being proportional to $(1/N)$. The location of the principal maxima other than the zeroth order $(m = 0)$ are proportional to the wavelength λ. The diffraction grating thus forms an important spectroscopic tool. Further discussion of gratings is given in Chap. 5, by Zissis, in Vol. II of this Handbook.

3.7 VECTOR DIFFRACTION

The popularity of the Fresnel-Kirchhoff diffraction formula in the scalar case stems from the fact that it is widely applicable and relatively easy to use. In the study of

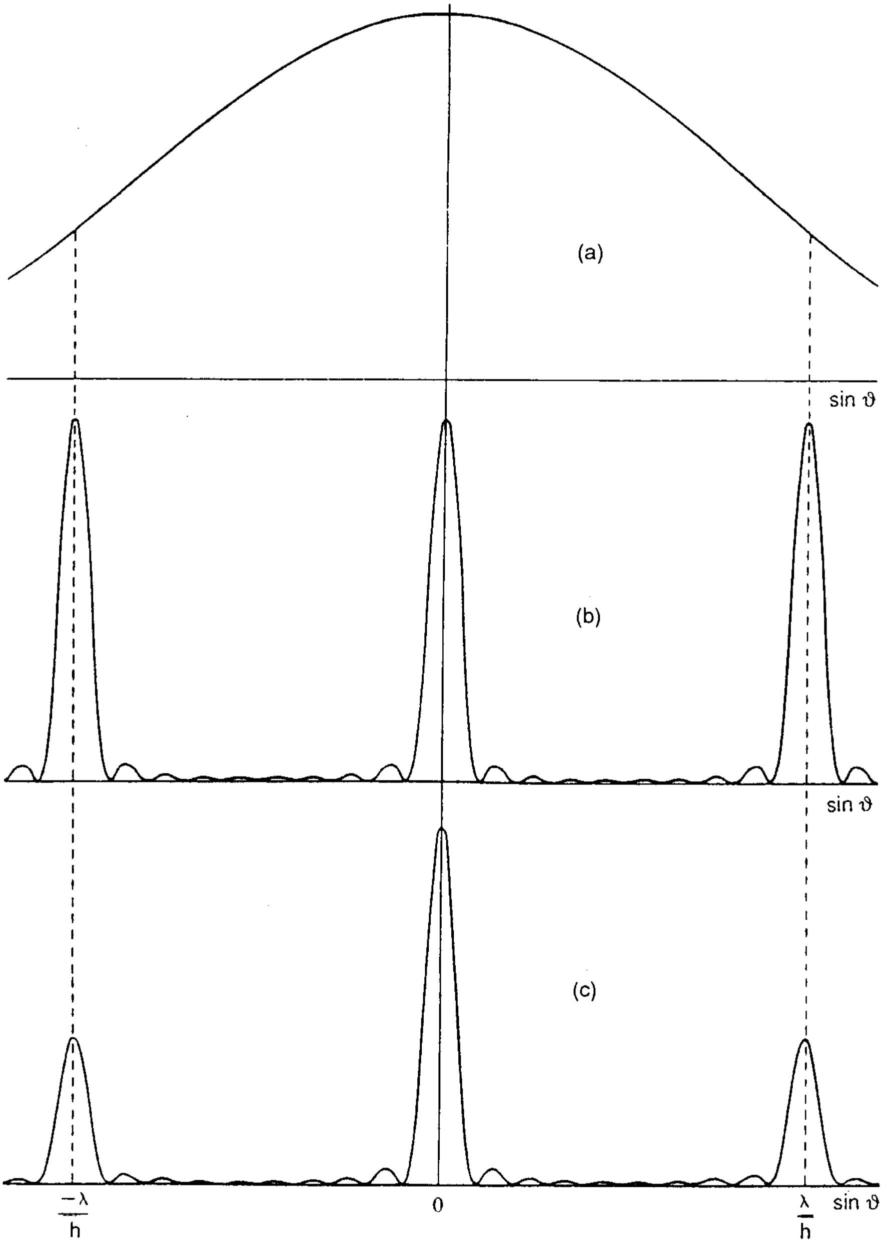

FIGURE 25 (*a*) Plot of a single-slit diffraction pattern; (*b*) partial plot of an $N = 10$ slit interference pattern; and (*c*) their product (*From Rossi.*[7])

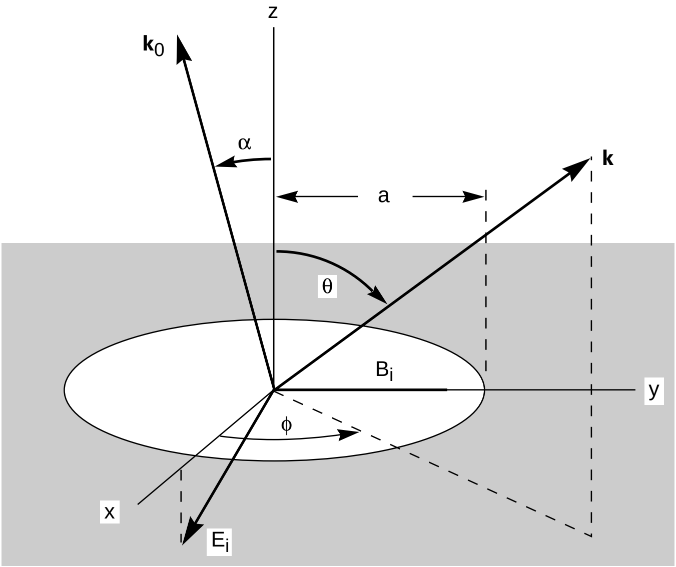

FIGURE 26 Coordinate system and aperture geometry for vector diffraction. α: angle of incidence. The E field is in the xz plane. $\mathbf{k}_0$: the wave vector of the incident wave. and $\mathbf{k}$: the diffracted field. (*From Jackson.*[12])

electromagnetic diffraction[14,15] a similar formula can be obtained [see Eq. (9.156) in sec. 9.12 of Ref. 14] but has limited applicability because of the boundary conditions that must be satisfied. These conditions are the ones related to perfectly conducting screens. They are not adequately approximated at optical frequencies. The study with finite conductivity makes for complicated mathematical procedures. From the point of view of instrumental optics the applicability of the theory then is severely limited.

In the optical literature, periodic structures such as gratings (both shallow and deep compared to the wavelength) have been studied.[16,17] Boundary conditions are applied to perfectly conducting grating profiles. The equation of the grating dictating the angular positions of the diffraction orders such as Eq. (38) continues to apply; the amount of power found in the different orders is significantly different in the vector theory compared to the scalar theory.

Without going into the mathematical procedures and/or displaying involved formulas we discuss a special case of interest discussed in detail by Jackson.[14] We consider a plane wave incident at an angle α on a thin, perfectly conducting screen with a circular hole of radius a in the x-y plane. The polarization vector (**E** field) of the incident wave lies in the x-z plane, which is taken to be the plane of incidence. The arrangement is shown in Fig. 26 where $\mathbf{k}_0$ stands for the wave vector of the incident wave and $\mathbf{k}$ is used for the diffracted field.

The vector and scalar approximations are compared in Fig. 27. The angle of incidence is equal to 45° and the aperture is one wavelength in diameter, $ka = \pi$. The angular distribution is shown in Fig. 27 for two cases. Figure 27*a* shows the distribution of the power per unit solid angle in the plane of incidence which contains the **E** field and Fig. 27*b* the distribution for the plane perpendicular to it. Both vector and scalar theories contain the Airy-disk-type distribution; the differences show in the angular distribution. For

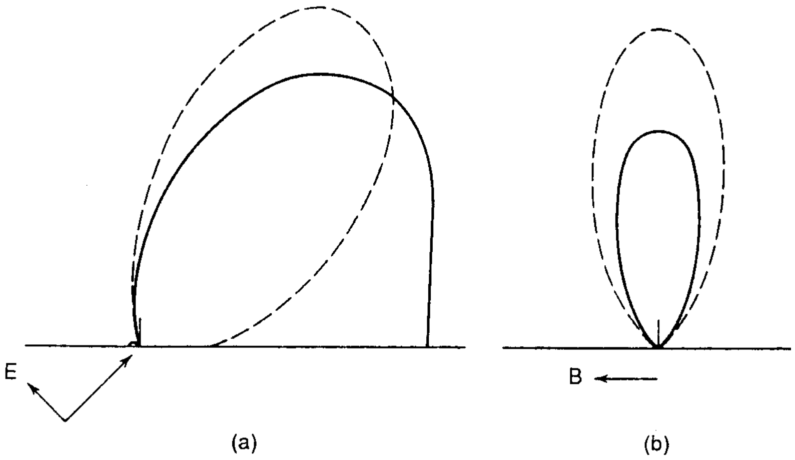

FIGURE 27 Fraunhofer diffraction pattern for a circular opening one wavelength in diameter in a thin-plane conducting screen. The angle of incidence is 45°. (*a*) power-per-unit solid angle (radiant intensity) in the plane of incidence; and (*b*) perpendicular to it. The solid (dotted) curve gives the vector (scalar) approximation in each case. (*From Jackson.*[12])

normal incidence $\alpha = 0$ and $ka \gg 1$ the polarization dependence is unimportant and the diffraction is confined to very small angles in the forward direction (Airy-disk-type distribution) as we found before in Fig. 21 under Fraunhofer diffraction.

CHAPTER 4
COHERENCE THEORY

William H. Carter*
Naval Research Laboratory
Washington, D.C.

4.1 GLOSSARY

I	intensity [use irradiance or field intensity]
k	radian wave number
$\mathbf{p}$	unit propagation vector
t	time
U	field amplitude
u	Fourier transform of U
W_ω	cross-spectral density function
$\mathbf{x}$	spatial vector
$\Gamma_{12}(\tau)$	mutual coherence function
$\Delta\ell$	coherence length
$\Delta\tau$	coherence time
μ_ω	complex degree of spatial coherence
ϕ	phase
ω	radian frequency
Real ( )	real part of ( )

4.2 INTRODUCTION

Classical Coherence Theory

All light sources produce fields that vary in time with highly complicated and irregular waveforms. Because of diffraction, these waveforms are greatly modified as the fields propagate. All light detectors measure the intensity time averaged over the waveform. This measurement depends on the integration time of the detector and the waveform of the light at the detector. Generally this waveform is not precisely known. Classical coherence theory[1–8] is a mathematical model which is very successful in describing the effects of this unknown waveform on the observed measurement of time-averaged intensity. It is based on the electromagnetic wave theory of light as formulated from Maxwell's equations, and uses statistical techniques to analyze the effects due to fluctuations in the waveform of the field in both time and space.

* The author was a visiting scientist at the Johns Hopkins University Applied Physics Laboratory while this chapter was written. He is now Acting Program Director for Quantum Electronic Waves and Beams at the National Science Foundation, 4201 Wilson Blvd., Arlington, VA 22230.

Quantum Coherence Theory

Classical coherence theory can deal very well with almost all presently known optical coherence phenomena; however, a few laboratory experiments require a much more complicated mathematical model, quantum coherence theory[9–11] to explain them. This theory is not based on classical statistical theory, but is based on quantum electrodynamics.[12–14] While the mathematical model underlying classical coherence theory uses simple calculus, quantum coherence theory uses the Hilbert space formulation of abstract linear algebra, which is very awkward to apply to most engineering problems. Fortunately, quantum coherence theory appears to be essential as a model only for certain unusual (even though scientifically very interesting) phenomena such as squeezed light states and photon antibunching. All observed naturally occuring phenomena outside of the laboratory appear to be modeled properly by classical coherence theory or by an approximate semiclassical quantum theory. This article will deal only with the simple classical model.

4.3 SOME ELEMENTARY CLASSICAL CONCEPTS

Analytical Signal Representation

Solutions of the time-dependent, macroscopic Maxwell's equations yield six scalar components of the electric and the magnetic fields which are functions of both time and position in space. As in conventional diffraction theory, it is much more convenient to treat monochromatic fields than it is to deal with fields that have complicated time dependencies. Therefore, each of these scalar components is usually represented at some typical point in space (given with respect to some arbitrary origin by the radius vector $\mathbf{x} = (x, y, z)$ by a superposition of monochromatic real scalar components. Thus the field amplitude for a typical monochromatic component of the field with radial frequency ω is given by

$$U_r(\mathbf{x}, \omega) = U_0(\mathbf{x}) \cos[\phi(\mathbf{x}) - \omega t] \tag{1}$$

where $U_0(\mathbf{x})$ is the field magnitude and $\phi(\mathbf{x})$ is the phase. Trigonometric functions like that in Eq. (1) are awkward to manipulate. This is very well known in electrical circuit theory. Thus, just as in circuit theory, it is conventional to represent this field amplitude by a "phasor" defined by

$$U(\mathbf{x}, \omega) = U_0(\mathbf{x}) e^{i\phi(\mathbf{x})} \tag{2}$$

The purpose for using this complex field amplitude, just as in circuit theory, is to eliminate the need for trigonometric identities when adding or multiplying field amplitudes. A time-dependent complex analytic signal (viz., Ref. 15, sec. 10.2) is usually defined as the Fourier transform of this phasor, i.e.,

$$u(\mathbf{x}, t) = \int_0^\infty U(\mathbf{x}, \omega) \mathrm{e}^{-i\omega t}\, d\omega \tag{3}$$

The integration in Eq. (3) is only required from zero to infinity because the phasor is defined with hermitian symmetry about the origin, i.e., $U(-\mathbf{x}, \omega) = U^*(\mathbf{x}, \omega)$. Therefore, all of the information is contained within the domain from zero to infinity. To obtain the actual field component from the analytical signal just take the real part of it. The Fourier transform in Eq. (3) is well defined if the analytical signal represents a deterministic field. However, if the light is partially coherent, then the analytic signal is usually taken to be a stationary random process. In this case the Fourier inverse of Eq. (3) does not exist. It is then possible to understand the spectral decomposition given by Eq. (3) only within the theory of generalized functions (viz., see Ref. 16, the appendix on generalized functions, and Ref. 17, pp. 25–30).

Scalar Field Amplitude

Each monochromatic component of an arbitrary deterministic light field propagating through a homogeneous, isotropic medium can always be represented using an angular spectrum of plane waves for each of the six scalar components of the vector field. The six angular spectra are coupled together by Maxwell's equations so that only two are independent.[18–20] Any two of the six angular spectra can be used to define two scalar fields from which the complete vector field can be determined. A polarized light field can be represented in this way by only one scalar field.[20,21] Thus it is often possible to represent one polarized component of a vector electromagnetic field by a single scalar field. It has also been found useful to represent completely unpolarized light by a single scalar field. In more complicated cases, where the polarization properties of the light are important, a vector theory is sometimes needed as discussed later under Explicit Vector Representations.

Temporal Coherence and Coherence Time

Within a short enough period of time, the time dependence of any light field at a point in space can be very closely approximated by a sine wave (Ref. 15, sec. 7.5.8). The length of time for which this is a good approximation is usually called the *coherence time* $\Delta\tau$. The coherence time is simply related to the spectral bandwidth for any light wave by the uncertainty principle, i.e.,

$$\Delta\tau\,\Delta\omega \geq 1 \tag{4}$$

For a light wave which is also highly directional within some region of space (like a beam) so that it propagates generally in some fixed direction (given by the unit vector **p**), the field amplitude is given by

$$u(\mathbf{x}, t) = f(\mathbf{p} \cdot \mathbf{x} - ct). \tag{5}$$

Such a traveling wave will be approximately sinusoidal (and hence coherent) over some coherence length $\Delta\ell$ in the direction of **p** where from Eq. (4) we see that

$$\Delta\ell = c\,\Delta\tau \approx c/\Delta\omega \tag{6}$$

so that the coherence length varies inversely with bandwidth.

Spatial Coherence and Coherence Area

The time-dependent waveform for any light field is approximately the same at any point within a sufficiently small volume of space called the *coherence volume*. The projection of this volume onto a surface is termed a *coherence area*. If we have a field that, within some region, is roughly directional so that its field amplitude is given by Eq. (5), then the coherence length gives the dimension of the coherence volume in the direction of propagation **p**, and the coherence area gives the dimensions of the coherence volume normal to this direction.

Measurements of Coherence

Coherence is usually measured by some form of interferometer that takes light from two test points in a light field, $\mathbf{x}_1$ and $\mathbf{x}_2$, and then allows them to interfere after introducing a time advance τ in the light from $\mathbf{x}_1$ relative to that from $\mathbf{x}_2$. If the field intensity of the interference pattern is measured as a function of τ, then in general it has the form (see Ref. 15, sec. 10.3.1)

$$I(\tau) = I(\mathbf{x}_1) + I(\mathbf{x}_2) + 2\ \text{Real}\ (\Gamma_{12}(\tau)) \tag{7}$$

where $I(\mathbf{x}_1)$ is the intensity at the ith test point, and $\Gamma_{12}(\tau)$ is the mutual coherence function which measures the τ advanced correlation between the waveforms at the two test points (as subsequently defined under "Mutual Coherence Function"). There are many interferometers which have been developed to measure $\Gamma_{12}(\tau)$ in this way. One of the earliest techniques was developed by Thompson and Wolf.[22] They used a diffractometer to measure the coherence over a surface normal to the direction of propagation for a collimated beam from a partially coherent source. More recently, Carter[23] used an interferometer made from a grating and a microscope to similarly measure the coherence of a beam transverse to the direction of propagation.

4.4 DEFINITIONS OF COHERENCE FUNCTIONS

Mutual Coherence Function

In an older form of coherence theory[1] the principal coherence function was the mutual coherence function defined by[24]

$$\Gamma_{12}(\tau) \underset{T\to\infty}{\approx} \frac{1}{2T}\int_{-T}^{T} u(\mathbf{x}_1, t+\tau)u^*(\mathbf{x}_2, t)\, dt \tag{8}$$

where $u(\mathbf{x}, t)$ represents the complex analytic time-dependent signal at some point $\mathbf{x}$ and some time t as defined in Eq. (3). This definition was originally motivated by the fact that the intensity, as actually measured, is precisely this time averaged function with $\mathbf{x}_1 = \mathbf{x}_2$ and $\tau = 0$, and that this function is the most readily measured since it appears directly in Eq. (7). Thus it was clearly possible to measure $\Gamma_{12}(\tau)$ over some input plane, propagate it to an output plane,[25] and then find the intensity over the output plane from $\Gamma_{12}(\tau)$. It was assumed in this definition in Eq. (8) that $u(\mathbf{x}, t)$ is stationary in time so that $\Gamma_{12}(\tau)$ is only a function of τ and not of t. In most of the older literature, sharp brackets were usually used to represent this time average rather than an ensemble average (see Ref. 15, sec. 10.3.1). In the early 1960s it was found to be much more convenient to treat $u(\mathbf{x}, t)$ as an ergodic, stationary random process so that Eq. (8) could be replaced by

$$\Gamma_{12}(\tau) = \langle u(\mathbf{x}_1, t+\tau)u^*(\mathbf{x}_2, t)\rangle \tag{9}$$

where (everywhere in this article) the sharp brackets denote an ensemble average. After the change to ensemble averages the cross-spectral density function (to be defined shortly) became the most used correlation function in the coherence literature, because of the simpler and more general rules for its propagation (as discussed later under "Two Representations").

Complex Degree of Coherence

To obtain a function that depends only on the coherence properties of a light field it is often useful to normalize the mutual coherence function in the manner of

$$\gamma_{12}(\tau) = \frac{\langle u(\mathbf{x}_1, t+\tau)u^*(\mathbf{x}_2, t)\rangle}{\sqrt{\langle u(\mathbf{x}_1, t)u^*(\mathbf{x}_1, t)\rangle\langle u(\mathbf{x}_2, t)u^*(\mathbf{x}_2, t)\rangle}} \tag{10}$$

This is called the *complex degree of coherence.* It is a properly normalized correlation coefficient, so that $\gamma_{11}(0) = \gamma_{22}(0) = 1$. This indicates that the field at a point in space must always be perfectly coherent with itself. All other values of $\gamma_{12}(\tau)$ are generally complex with an amplitude less than one. This indicates that the fields at two different points, or at the same point after a time delay τ, are generally less than perfectly coherent with each other. The magnitude of the complete degree of spatial coherence (from zero to one) is a measure of the mutual coherence between the fields at the two test points and after a time delay τ.

Cross-Spectral Density Function

Just as in classical diffraction theory, it is much easier to propagate monochromatic light than light with a complicated time waveform. Thus the most frequently used coherence function is the cross-spectral density function, $W_\omega(\mathbf{x}_1, \mathbf{x}_2)$, which is the ensemble-averaged correlation function between a typical monochromatic component of the field at some point $\mathbf{x}_1$ with the complex conjugate of the same component of the field at some other point $\mathbf{x}_2$. It may be defined by

$$\delta(\omega - \omega')W_\omega(\mathbf{x}_1, \mathbf{x}_2) = \langle U(\mathbf{x}_1, \omega)U^*(\mathbf{x}_2, \omega')\rangle \tag{11}$$

The amplitude $U(\mathbf{x}, \omega)$ for a field of arbitrary coherence is taken to be random variable. Thus $U(\mathbf{x}, \omega)$ represents an ensemble of all of the possible fields, each of which is represented by a complex phasor amplitude like that defined in Eq. (2). The sharp brackets denote an ensemble average over all of these possible fields weighted by the probability for each of them to occur. The correlation functions defined by Eqs. (11) and (9) are related by the Fourier transform pairs

$$\Gamma_{12}(\tau) = \int_0^\infty W_\omega(\mathbf{x}_1, \mathbf{x}_2)\mathrm{e}^{-i\omega\tau}\,d\omega \tag{12}$$

and

$$W_\omega(\mathbf{x}_1, \mathbf{x}_2) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \Gamma_{12}(\tau)e^{i\omega\tau}\,d\tau \tag{13}$$

which is easily shown, formally, by substitution from Eq. (3) into (9) and then using (11). These relations represent a form of the generalized Wiener-Khintchine theorem (see Ref. 26, pp. 107–108).

Complex Degree of Spectral Coherence

Because the cross-spectral density function contains information about both the intensity (see ''Intensity,'' which follows shortly) and the coherence of the field, it is useful to define another coherence function which describes the coherence properties only. This is the complex degree of spectral coherence (not to be confused with the complex degree of *spatial* coherence, which is a totally different function), which is usually defined by[27]

$$\mu_\omega(\mathbf{x}_1, \mathbf{x}_2) = \frac{W_\omega(\mathbf{x}_1, \mathbf{x}_2)}{\sqrt{W_\omega(\mathbf{x}_1, \mathbf{x}_1)W_\omega(\mathbf{x}_2, \mathbf{x}_2)}} \tag{14}$$

It is easy to show that this function is a properly normalized correlation coefficient which is always equal to unity if the field points are brought together, and is always less than or equal to unity as they are separated. If the magnitude of $\mu_\omega(\mathbf{x}_1, \mathbf{x}_2)$ is unity, it indicates that the monochromatic field component with radial frequency ω is perfectly coherent between the two points $\mathbf{x}_1$ and $\mathbf{x}_2$. If the magnitude of this function is less than unity it indicates less-than-perfect coherence. If the magnitude is zero it indicates complete incoherence between the field amplitudes at the two test points. For most partially coherent fields the cross-spectral density function has significantly large values only for point separations which keep the two field points within the same coherence volume. This function depends only on the positions of the points and the single radial frequency that the field components at the two points share. Field components of different frequency are always uncorrelated (and therefore incoherent), even at the same point.

Spectrum and Normalized Spectrum

Recently, the changes in the spectrum of light due to propagation have been studied using coherence theory. It is therefore useful to define the spectrum of light as just the monochromatic intensity (which is just the trace of the cross-spectral density function) as a function of omega, and the spectrum of a primary source as a very similar function, i.e.,

$$\begin{aligned} S_U(\mathbf{x}, \omega) &= \langle U_\omega(\mathbf{x}) U^*_\omega(\mathbf{x}) \rangle = W_U(\mathbf{x}, \mathbf{x}) \\ S_Q(\mathbf{x}, \omega) &= \langle \rho_\omega(\mathbf{x}) \rho^*_\omega(\mathbf{x}) \rangle = W_Q(\mathbf{x}, \mathbf{x}) \end{aligned} \tag{15}$$

where the subscript Q indicates that this is a primary source spectrum, and the subscript U indicates that this is a field spectrum. The spectrum for the primary source is a function of the phasor $\rho_\omega(\mathbf{x})$ which represents the currents and charges in this source as discussed under "Primary Sources" in the next section. It is also useful to normalize these spectra in the manner

$$s_A(\mathbf{x}, \omega) = \frac{S_A(\mathbf{x}, \omega)}{\displaystyle\int_0^\infty S_A(\mathbf{x}, \omega)\, d\omega} \tag{16}$$

where the subscript A can indicate either U or Q, and the normalized spectrum has the property

$$\int_0^\infty s_A(\mathbf{x}, \omega)\, d\omega = 1 \tag{17}$$

so that it is independent of the total intensity.

Angular Correlation Function

A new coherence function, introduced for use with the angular spectrum expansion of a monochromatic component of the field,[28] is the angular correlation function defined by

$$\mathscr{A}_\omega(\mathbf{p}_1, \mathbf{p}_2) = \langle A_\omega(\mathbf{p}_1), A^*_\omega(\mathbf{p}_2) \rangle \tag{18}$$

where $A_\omega(\mathbf{p}_i)$ is the angular spectrum which gives the complex amplitude of the plane wave component of the field which propagates in the direction given by the unit vector $\mathbf{p}_i$. This is related to the cross-spectral density function over the $z = 0$ plane by the equation

$$\mathscr{A}(\mathbf{p}_1, \mathbf{p}_2) = \frac{1}{\lambda^4} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} W^{(0)}_\omega(\mathbf{x}'_1, \mathbf{x}'_2) e^{-ik(\mathbf{p}_1 \cdot \mathbf{x}'_1 - \mathbf{p}_2 \cdot \mathbf{x}'_2)}\, d^2\mathbf{x}'_1\, d^2\mathbf{x}'_2 \tag{19}$$

This is the four-dimensional Fourier transform of the cross-spectral density function over the $z = 0$ plane. It represents a correlation function between the complex amplitudes of two plane wave components of the field propagating in the directions given by the unit vectors $\mathbf{p}_1$ and $\mathbf{p}_2$, respectively. It can be used to calculate the cross-spectral density function (as described later under "Angular Spectrum Representation") between any pair of points away from the $z = 0$ plane, assuming that the field propagates in a source-free homogeneous medium. In this article we will use single-primed vectors, as in Eq. (19), to represent radius vectors from the origin to points within the $z = 0$ plane, i.e., $\mathbf{x}' = (x', y', 0)$, as shown in Fig. 1.

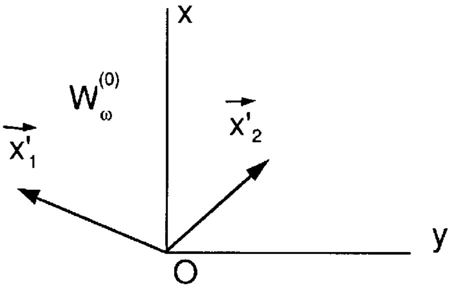

FIGURE 1 Illustrating the coordinate system and notation used for planar sources in the $z = 0$ plane.

All other vectors, such as $\mathbf{x}$ or $\mathbf{x}''$, are to be taken as three-dimensional vectors. Generally $\mathbf{s}$ and $\mathbf{p}$ are three-dimensional unit vectors indicating directions from the origin, a superscript (0) on a function indicates that it is the boundary condition for that function over the $z = 0$ plane, and a superscript (∞) on a function indicates that it is the asymptotic value for that function on a sphere of constant radius R from the origin as $R \rightarrow \infty$.

Intensity

The intensity is usually considered to be the observable quantity in coherence theory. Originally it was defined to be the trace of the mutual coherence function as defined by Eq. (8), i.e.,

$$I(\mathbf{x}_1) \triangleq \Gamma_{11}(0) \underset{T\rightarrow\infty}{\approx} \frac{1}{2T}\int_{-T}^{T} u(\mathbf{x}_1, t)u^*(\mathbf{x}_1, t)\, dt \tag{20}$$

which is always real. Thus it is the time-averaged square magnitude of the analytic signal. This represents the measurement obtained by the electromagnetic power detectors always used to detect light fields. Since the change to ensemble averages in coherence theory, it is almost always assumed that the analytic signal is an ergodic random process so that the intensity can be obtained from the equation

$$I(\mathbf{x}_1) \triangleq \Gamma_{11}(0) = \langle u(\mathbf{x}_1, t)u^*(\mathbf{x}_1, t)\rangle \tag{21}$$

where the sharp brackets indicate an ensemble average. Usually, in most recent coherence-theory papers, the intensity calculated is actually the spectrum, which is equivalent to the intensity of a single monochromatic component of the field which is defined as the trace of the cross-spectral density function as given by

$$I_\omega(\mathbf{x}_1) \triangleq W_\omega(\mathbf{x}_1, \mathbf{x}_1) = \langle U(\mathbf{x}_1, \omega)U^*(\mathbf{x}_1, \omega)\rangle \tag{22}$$

Since different monochromatic components of the field are mutually incoherent and cannot interfere, we can always calculate the intensity of the total field as the sum over the intensities of its monochromatic components in the manner

$$I(\mathbf{x}_1) \triangleq \int_0^\infty I_\omega(\mathbf{x}_1)\, d\omega \tag{23}$$

Since in most papers on coherence theory the subscript omega is usually dropped, the reader should be careful to observe whether or not the intensity calculated is for a monochromatic component of the field only. If it is, the total measurable intensity can be obtained simply by summing over all omega, as indicated in Eq. (23).

Radiant Emittance

In classical radiometry the *radiant emittance* is defined to be the power radiated into the far field by a planar source per unit area. A wave function with some of the properties of radiant emittance has been defined by Marchand and Wolf using coherence theory (see Ref. 29, eq. (32), and Ref. 30). However, because of interference effects, the far-field energy cannot be subdivided into components that can be traced back to the area of the source that produced them. The result is that the radiant emittance defined by Marchand and Wolf is not nonnegative definite (as it is in classical radiometry) except for the special case of a completely incoherent source. Since, as discussed in the next section under ''Perfectly Incoherent Source,'' perfectly incoherent sources exist only as a limiting case, radiant emittance has not been found to be a very useful concept in coherence theory.

Radiant Intensity

In classical radiometry the *radiant intensity* is defined to be the power radiated from a planar source into a unit solid angle with respect to an origin at the center of the surface. This can be interpreted in coherence theory as the field intensity over a portion of a surface in the far field of the source, in some direction given by the unit vector **s**, which subtends a unit solid angle from the source. Thus the radiant intensity for a monochromatic component of the field can be defined in coherence theory as

$$J_\omega(\mathbf{s}) \underset{R\to\infty}{\approx} W_\omega^{(\infty)}(R\mathbf{s}, R\mathbf{s})R^2 \tag{24}$$

To obtain the total radiant intensity we need only sum this function over all omega.

Radiance

In classical coherence theory the radiance function is the power radiated from a unit area on a planar source into a unit solid angle with respect to an origin at the center of the source. In the geometrical optics model, from which this concept originally came, it is consistent to talk about particles of light leaving an area at a specified point on a surface to travel in some specified direction. However, in a wave theory, wave position and wave direction are Fourier conjugate variables. We can have a configuration space wave function (position) or a momentum space wave function (direction), but not a wave function that depends independently on both position and direction. Thus the behavior of a wave does not necessarily conform to a model which utilizes a radiance function.[31] Most naturally occurring sources are quasi-homogeneous (discussed later). For such sources, a radiance function for a typical monochromatic component of the field can be defined as the Wigner distribution function[32–35] of the cross-spectral density function over the $z = 0$ plane, which is given by

$$B_\omega(\mathbf{x}'_+, \mathbf{s}) = \frac{\cos\theta}{\lambda^2} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} W_\omega^{(0)}(\mathbf{x}'_+ + \mathbf{x}'_-/2, \mathbf{x}'_+ - \mathbf{x}'_-/2)e^{-ik\mathbf{s}\cdot\mathbf{x}'_-}\, d^2\mathbf{x}'_- \tag{25}$$

where θ is the angle that the unit vector **s** makes with the $+z$ axis. For quasi-homogeneous fields this can be associated with the energy radiated from some point $\mathbf{x}'_+$ into the far field in the direction **s**. Such a definition for radiance also works approximately for some other light fields, but for light which does not come from a quasi-homogeneous source, no such definition is either completely equivalent to a classical radiance function[31] or unique as an approximation to it. Much progress has been made toward representing a more general class of fields using a radiance function.[36] In general, waves do not have radiance functions.

Higher-Order Coherence Functions

In general, the statistical properties of a random variable are uniquely defined by the probability density function which can be expanded into a series which contains correlation functions of all orders. Thus, in general, all orders of correlation functions are necessary to completely define the statistical properties of the field. In classical coherence theory we usually assume that the partially coherent fields arise from many independent sources so that, by the central limit theorem of statistics, the probability distribution function for the real and imaginary components of the phasor field amplitude are zero-mean gaussian random variables (See Ref. 8, sec. 2.72*e*). Thus, from the gaussian moment theorem, the field correlation functions of any order can be calculated from the second-order correlation functions, for example,

$$\langle U(\mathbf{x}_1, \omega) U^*(\mathbf{x}_1, \omega) U(\mathbf{x}_2, \omega) U^*(\mathbf{x}_2, \omega)\rangle = I_\omega(\mathbf{x}_1) I_\omega(\mathbf{x}_2) + |W_\omega(\mathbf{x}_1, \mathbf{x}_2)|^2 \tag{26}$$

Thus, for gaussian fields, the second-order correlation functions used in coherence theory completely define the statistical properties of the field. Some experiments, such as those involving intensity interferometry, actually measure fourth- or higher-order correlation functions.[37]

4.5 MODEL SOURCES

Primary Sources

In coherence theory it is useful to talk about primary and secondary sources. A primary source distribution is the usual source represented by the actual charge and current distribution which give rise to the field. For propagation from a primary source through a source-free media, the field amplitude is defined by the inhomogeneous Helmholtz equation [see Ref. 38, eq. (6.57)], i.e.,

$$\left(\nabla^2 + \frac{\omega^2}{c^2}\right) U_\omega(\mathbf{x}) = -4\pi\rho_\omega(\mathbf{x}) \tag{27}$$

where $\rho_\omega(\mathbf{x})$ represents the charge-current distribution in the usual manner. A solution to this wave equation gives

$$W_U(\mathbf{x}_1, \mathbf{x}_2) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} W_Q(\mathbf{x}_1'', \mathbf{x}_2'') K(\mathbf{x}_1, \mathbf{x}_1'') K^*(\mathbf{x}_2, \mathbf{x}_2'')\, d^3\mathbf{x}_1''\, d^3\mathbf{x}_2'' \tag{28}$$

for the cross-spectral density function, where $k = \omega/c = 2\pi/\lambda$

$$K(\mathbf{x}, \mathbf{x}'') = \frac{e^{ik|\mathbf{x}-\mathbf{x}''|}}{|\mathbf{x} - \mathbf{x}''|} \tag{29}$$

is the free-space propagator for a primary source, $W_U(\mathbf{x}_1, \mathbf{x}_2)$ is the cross-spectral density function for the fields (with suppressed ω-dependence), as defined by Eq. (11), and

$$W_Q(\mathbf{x}_1'', \mathbf{x}_2'') = \langle \rho_\omega(\mathbf{x}_1'') \rho_\omega^*(\mathbf{x}_2'')\rangle \tag{30}$$

is the cross-spectral density function for the source. This three-dimensional primary source can be easily reduced to a two-dimensional source over the $z = 0$ plane by simply defining the charge current distribution to be

$$\rho_\omega(\mathbf{x}) = \rho'_\omega(x, y)\delta(z) \tag{31}$$

where $\delta(z)$ is the Dirac delta function.

Secondary Sources

Often, however, it is more convenient to consider a field which arises from sources outside of the region in space in which the fields are of interest. Then it is sometime useful to work with boundary conditions for the field amplitude over some surface bounding the region of interest. In many coherence problems these boundary conditions are called a *planar secondary source* even though they are actually treated as boundary conditions. For example, most conventional diffraction equations assume the boundary condition over the $z = 0$ plane is known and use it to calculate the fields in the $z > 0$ half-space. Then the field obeys the homogeneous Helmholtz equation [See Ref. 38, eq. (7.8)], i.e.,

$$\left(\nabla^2 + \frac{\omega^2}{c^2}\right)U_\omega(\mathbf{x}) = 0 \tag{32}$$

which has the solution

$$W_\omega(\mathbf{x}_1, \mathbf{x}_2) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} W_\omega^{(0)}(\mathbf{x}'_1, \mathbf{x}'_2)h(\mathbf{x}_1, \mathbf{x}'_1)h^*(\mathbf{x}_2, \mathbf{x}'_2)\, d^2\mathbf{x}'_1\, d^2\mathbf{x}'_2 \tag{33}$$

where $W_\omega^{(0)}(\mathbf{x}'_1, \mathbf{x}'_2)$ is the boundary condition for the cross-spectral density function of the fields over the $z = 0$ plane (as shown in Fig. 1), $W_\omega(\mathbf{x}_1, \mathbf{x}_2)$ is the cross-spectral density function anywhere in the $z > 0$ half-space, and

$$h(\mathbf{x}, \mathbf{x}') = \frac{-1}{2\pi}\frac{d}{dz}\frac{e^{ik|\mathbf{x}-\mathbf{x}'|}}{|\mathbf{x}-\mathbf{x}'|} \tag{34}$$

is the free-space propagator for the field amplitude. This is a common example of a secondary source over the $z = 0$ plane.

Perfectly Coherent Source

The definition of a perfectly coherent source, within the theory of partial coherence, is somewhat complicated. The light from an ideal monochromatic source is, of course, always perfectly coherent. Such a field produces high-contrast interference patterns when its intensity is detected by any suitable instrument. However, it is possible that light fields exist that are not monochromatic but can also produce similar interference patterns and therefore must be considered coherent. The ability of light fields to produce interference patterns at a detector is measured most directly by the complex degree of coherence

$\gamma_{12}(\tau)$, defined by Eq. (10). If a field has a complex degree of coherence that has unit magnitude for every value of τ and for every point pair throughout some domain D, then light from all points in D will combine to produce high-contrast interference fringes.[39] Such a field is defined to be perfectly coherent within D. Mandel and Wolf[27] have shown that the mutual coherence function for such a field factors within D in the manner

$$\Gamma_{12}(\tau) = \psi(\mathbf{x}_1)\psi^*(\mathbf{x}_2)e^{-i\omega\tau} \tag{35}$$

We will take Eq. (35) to be the definition of a perfectly coherent field. Coherence is not as easily defined in the space-frequency domain because it depends on the spectrum of the light as well as on the complex degree of spectral coherence. For example, consider a field for which every monochromatic component is characterized by a complex degree of spectral coherence which has unit magnitude between all point pairs within some domain D. Mandel and Wolf[40] have shown that for such a field the cross-spectral density function within D factors is

$$W_\omega(\mathbf{x}_1''\mathbf{x}_2'') = \bar{U}(\mathbf{x}_1'', \omega)\bar{U}^*(\mathbf{x}_2'', \omega) \tag{36}$$

However, even if Eq. (36) holds for this field within D, the field may not be perfectly coherent [as perfect coherence is defined by Eq. (35)] between all points within the domain. In fact it can be completely incoherent between some points within D.[41] A secondary source covering the $z = 0$ plane with a cross-spectral density function over that plane which factors as given by Eq. (36) will produce a field in the $z > 0$ half-space (filled with free space or a homogeneous, isotopic dielectric) which has a cross-spectral density function that factors in the same manner everywhere in the half-space. This can be easily shown by substitution from Eq. (36) into Eq. (28), using Eq. (29). But, even if this is true for every monochromatic component of the field, Eq. (35) may not hold within the half-space for every point pair, so we cannot say that the field is perfectly coherent there. Perfectly coherent light sources never actually occur, but sometimes the light from a laser can behave approximately in this way over some coherence volume which is usefully large. Radio waves often behave in this manner over very large coherence volumes.

Quasi-Monochromatic Source

In many problems it is more useful not to assume that a field is strictly monochromatic but instead to assume that it is only quasi-monochromatic so that the time-dependent field amplitude can be approximated by

$$u(\mathbf{x}, t) = u_0(\mathbf{x}, t)e^{-i\omega t} \tag{37}$$

where $u_0(\mathbf{x}, t)$ is a random process which varies much more slowly in time than $e^{-i\omega t}$. Then the mutual coherence function and the complex degree of spatial coherence can be usefully approximated by (see Ref. 15, sec. 10.4.1)

$$\begin{aligned} \Gamma_{12}(\tau) &= \Gamma_{12}(0)e^{-i\omega\tau} \\ \gamma_{12}(\tau) &= \gamma_{12}(0)e^{-i\omega\tau} \end{aligned} \tag{38}$$

within coherence times much less than the reciprocal bandwidth of the field, i.e., $\Delta\tau \ll 1/\Delta\omega$. In the pre-1960 coherence literature, $\Gamma_{12}(0)$ was called the *mutual intensity*. Monochromatic diffraction theory was then used to define the propagation properties of this monochromatic function. It was used instead of the cross-spectral density function to formulate the theory for the propagation of a partially coherent quasi-monochromatic field. While this earlier form of the theory was limited by the quasi-monochromatic approximation and was therefore not appropriate for very wideband light, the newer formulation (in terms of the cross-spectral density function) makes no assumptions about the spectrum of the light and can be applied generally. The quasi-monochromatic approximation is still very useful when dealing with radiation of very high coherence.[42]

Schell Model Source

Other, more general, source models have been developed. The most general of these is the Schell model source (see Ref. 43, sec. 7.5, and Ref. 44), for which we only assume that the complex degree of spectral coherence for either a primary or secondary source is stationary in space, so that from Eq. (14) we have

$$W_A(\mathbf{x}_1, \mathbf{x}_2) = \mu_A(\mathbf{x}_1 - \mathbf{x}_2)\sqrt{W_A(\mathbf{x}_1, \mathbf{x}_1)W_A(\mathbf{x}_2, \mathbf{x}_2)} \tag{39}$$

where the subscript A stands for U in the case of a Schell model secondary source and Q in the case of a Schell model primary source. The Schell model does not assume low coherence and, therefore, can be applied to spatially stationary light fields of any state of coherence. The Schell model of the form shown in Eq. (39) has been used to represent both three-dimensional primary sources[45,46] and two-dimensional secondary sources.[43,47,48]

Quasi-Homogeneous Source

If the intensity of a Schell model source is essentially constant over any coherence area, then Eq. (39) may be approximated by

$$W_A(\mathbf{x}_1, \mathbf{x}_2) = \mu_A(\mathbf{x}_1 - \mathbf{x}_2)I_A[(\mathbf{x}_1 + \mathbf{x}_1)/2] \tag{40}$$

where the subscript A can be either U, for the case of a quasi-homogeneous secondary source or Q, for the case of a quasi-homogeneous primary source. This equation is very useful in coherence theory because of the important exact mathematical identity.[49]

$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \mu_\omega^{(0)}(\mathbf{x}_1' - \mathbf{x}_2')I_\omega^{(0)}[(\mathbf{x}_1' + \mathbf{x}_2')/2]e^{-ik(\mathbf{x}_1'\cdot\mathbf{p}_1 - \mathbf{x}_2'\cdot\mathbf{p}_2)}\, dx_1'\, dy_1'\, dx_2'\, dy_2'$$

$$= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \mu_\omega^{(0)}(\mathbf{x}_-')e^{-ik(\mathbf{x}_-'\cdot\mathbf{p}_+)}\, dx_-'\, dy_-' \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} I_\omega^{(0)}(\mathbf{x}_+')e^{-ik(\mathbf{x}_+'\cdot\mathbf{p}_-)}\, dx_+'\, dy_+' \tag{41}$$

where

$$\mathbf{x}_+' = (\mathbf{x}_1' + \mathbf{x}_2')/2 \qquad \mathbf{x}_-' = \mathbf{x}_1' - \mathbf{x}_2'$$

and

$$\mathbf{p}_+ = (\mathbf{p}_1 + \mathbf{p}_2)/2 \qquad \mathbf{p}_- = \mathbf{p}_1 - \mathbf{p}_2$$

which allows the four-dimensional Fourier transforms that occur in propagating the correlation functions for secondary sources [for example, Eqs. (49) or (54)] to be factored into a product of two-dimensional Fourier transforms. An equivalent identity also holds for the six-dimensional Fourier transform of the cross-spectral density function for a primary source, reducing it to the product of two three-dimensional Fourier transforms. This is equally useful in dealing with propagation from primary sources [for example, Eq. (53)]. This model is very good for representing two-dimensional secondary sources with sufficiently low coherence that the intensity does not vary over the coherence area on the input plane.[49,50] It has also been applied to primary three-dimensional sources.[45,46] to primary and secondary two-dimensional sources,[51,52] and to three-dimensional scattering potentials.[53,54]

Perfectly Incoherent Source

If the coherence volume of a field becomes much smaller than any other dimensions of interest in the problem, then the field is said to be *incoherent.* It is believed that no field can be incoherent over dimensions smaller than the order of a light wavelength. An incoherent field can be taken as a special case of a quasi-homogeneous field for which the complex degree of spectral coherence is approximated by a Dirac delta function, i.e.,

$$\begin{aligned} W_A(\mathbf{x}_1, \mathbf{x}_2) &= I(\mathbf{x}_1)\delta^2(\mathbf{x}_1 - \mathbf{x}_2) \\ W_Q(\mathbf{x}_1, \mathbf{x}_2) &= I(\mathbf{x}_1)\delta^3(\mathbf{x}_1 - \mathbf{x}_2) \end{aligned} \tag{42}$$

where the two-dimensional Dirac delta function is used for any two-dimensional source and a three-dimensional Dirac delta function is used only for a three-dimensional primary source. Even though this approximation is widely used, it is not a good representation for the thermal sources that predominate in nature. For example, the radiant intensity from a planar, incoherent source is not in agreement with Lambert's law. For thermal sources the following model is much better.

Thermal (Lambertian) Source

For a planar, quasi-homogeneous source to have a radiant intensity in agreement with Lambert's law it is necessary for the complex degree of spectral coherence to have the form

$$\mu_A(\mathbf{x}_1 - \mathbf{x}_2) = \frac{\sin(k\,|\mathbf{x}_1 - \mathbf{x}_2|)}{k\,|\mathbf{x}_1 - \mathbf{x}_2|} \tag{43}$$

to which arbitrary spatial frequency components with periods less than a wavelength can be added since they do not affect the far field.[55] It can also be shown that, under frequently obtained conditions, blackbody radiation has such a complex degree of spectral coherence.[56] It is believed that most naturally occurring light can be modeled as quasi-homogeneous with this correlation function.

4.6 PROPAGATION

Perfectly Coherent Light

Perfectly coherent light propagates according to conventional diffraction theory. By substitution from Eq. (36) into Eq. (33) using Eq. (34) we obtain

$$U_\omega(\mathbf{x}) = \frac{1}{2\pi}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} U_\omega^{(0)}(\mathbf{x}')\,\frac{1}{2\pi}\frac{d}{dz'}\frac{e^{ik|\mathbf{x}-\mathbf{x}'|}}{|\mathbf{x}-\mathbf{x}'|}\,d^2\mathbf{x}' \tag{44}$$

which is just Rayleigh's diffraction integral of the first kind. Perfectly coherent light does not lose coherence as it propagates through any medium which is time-independent. For perfectly coherent light propagating in time-independent media, coherence theory is not needed.

Hopkin's Formula

In 1951 Hopkins[57] published a formula for the complex degree of spatial coherence for the field from a planar, secondary, incoherent, quasi-monochromatic source after propagating through a linear optical system with spread function $h(\mathbf{x}, \mathbf{x}')$, i.e.,

$$\gamma_{12}(0) = \frac{1}{\sqrt{I(\mathbf{x}_1)I(\mathbf{x}_2)}} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} I_\omega^{(0)}(\mathbf{x}_1')h(\mathbf{x}_1 - \mathbf{x}_1')h^*(\mathbf{x}_2 - \mathbf{x}_1')\, d^2\mathbf{x}_1' \tag{45}$$

where $I_\omega^{(0)}(\mathbf{x}')$ is the intensity over the source plane. This formula can be greatly generalized to give the complex degree of spectral coherence for the field from any planar, quasi-homogeneous, secondary source[58] after transmission through this linear optical system, i.e.,

$$\mu_{12}(\mathbf{x}_1, \mathbf{x}_2) = \frac{1}{\sqrt{I(\mathbf{x}_1)I(\mathbf{x}_2)}} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} I_\omega^{(0)}(\mathbf{x}')h(\mathbf{x}_1, \mathbf{x}')h^*(\mathbf{x}_2, \mathbf{x}')\, d^2\mathbf{x}' \tag{46}$$

provided that the spread function $h(\mathbf{x}, \mathbf{x}')$ can be assumed to be constant in its $\mathbf{x}'$ dependence over any coherence area in the source plane.

van Cittert–Zernike Theorem

Hopkins' formula can be specialized for free-space propagation to calculate the far-field coherence properties of planar, secondary, quasi-homogeneous sources of low coherence. In 1934 van Cittert[59] and, later, Zernike[60] derived a formula equivalent to

$$\mu_\omega(\mathbf{x}_1, \mathbf{x}_2) = \frac{1}{\sqrt{I(\mathbf{x}_1)I(\mathbf{x}_2)}} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} I_\omega^{(0)}(\mathbf{x}')\frac{e^{ik[|\mathbf{x}_1-\mathbf{x}'|-|\mathbf{x}_2-\mathbf{x}'|]}}{|\mathbf{x}_1 - \mathbf{x}'|\,|\mathbf{x}_2 - \mathbf{x}'|} d^2\mathbf{x}' \tag{47}$$

for the complex degree of spectral coherence between any pair of points in the field radiated from an incoherent planar source, assuming that the points are not within a few wavelengths of the source. We can obtain Eq. (47) by substitution from Eq. (34) into Eq. (46) and then approximating the propagator in a standard manner [see Ref. 61, eq. (7)]. Assume next, that the source area is contained within a circle of radius a about the origin in the source plane as shown in Fig. 4. Then, if the field points are both located on a sphere of radius R, which is outside of the Rayleigh range of the origin (i.e., $|\mathbf{x}_1| = |\mathbf{x}_2| = R \gg ka^2$), we can apply the Fraunhofer approximation to Eq. (47) to obtain

$$\mu_{12}(\mathbf{x}_1, \mathbf{x}_2) = \frac{1}{\sqrt{I(\mathbf{x}_1)I(\mathbf{x}_2)}} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} I_\omega^{(0)}(\mathbf{x}')e^{ik\mathbf{x}'\cdot(\mathbf{x}_1-\mathbf{x}_2)/R}\, d^2\mathbf{x}' \tag{48}$$

This formula is very important in coherence theory. It shows that the complex degree of spectral coherence from any planar, incoherent source with an intensity distribution $I_\omega^{(0)}(\mathbf{x}')$ has the same dependence on $(\mathbf{x}_1 - \mathbf{x}_2)$, over a sphere of radius R in the far field, as the diffraction pattern from a closely related perfectly coherent planar source with a real amplitude distribution proportional to $I_\omega^{(0)}(\mathbf{x}')$ (see Ref. 15, sec. 10.4.2*a*). Equation (48) can also be applied to a planar, quasi-homogeneous source[49] that is not necessarily incoherent, as will be shown later under "Reciprocity Theorem."

Angular Spectrum Representation

Much more general equations for propagation of the cross-spectral density function can be obtained. Equation (33) is one such expression. Another can be found if we expand the fields in a source-free region of space into an angular spectrum of plane waves. Then we find that the cross-spectral density function over any plane can be calculated from the same function over a parallel plane using a linear systems approach. For an example, consider the two planes illustrated in Fig. 2.

We assume that the cross-spectral density function is known over the $z = 0$ plane in the figure, and we wish to calculate this function over the $z = d$ plane. To do this we first take the Fourier transform of the cross-spectral density function over the $z = 0$ plane according to Eq. (19)

$$\mathscr{A}_{\text{in}}(\mathbf{p}_1, \mathbf{p}_2) = \frac{1}{\lambda^4}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} W_\omega^{(0)}(\mathbf{x}_1', \mathbf{x}_2') e^{-ik(\mathbf{p}_1\cdot\mathbf{x}_1' - \mathbf{p}_2\cdot\mathbf{x}_2')}\, d^2\mathbf{x}_1'\, d^2\mathbf{x}_2' \tag{49}$$

to obtain the angular correlation function in which all of the phase differences between the plane wave amplitudes are given relative to the point at the origin. Second, we shift the phase reference from the origin to the point on the z axis in the output plane by multiplying the angular correlation function by a transfer function, i.e.,

$$\mathscr{A}_{\text{out}}(\mathbf{p}_1, \mathbf{p}_2) = \mathscr{A}_{\text{in}}(\mathbf{p}_1, \mathbf{p}_2) \exp\,[ik(m_1 - m_2)d] \tag{50}$$

where d is the distance from the input to the output plane along the z axis (for back propagation d will be negative) and m_i is the third component of the unit vector $\mathbf{p}_i = (p_i, q_i, m_i)$, $i = 1$ or 2, which is defined by

$$\begin{aligned} m_i &= \sqrt{1 - p_i^2 - q_i^2}, \text{ if } p_i^2 + q_i^2 \le 1 \\ &= i\sqrt{p_i^2 + q_i^2 - 1}, \text{ if } p_i^2 + q_i^2 > 1 \end{aligned} \tag{51}$$

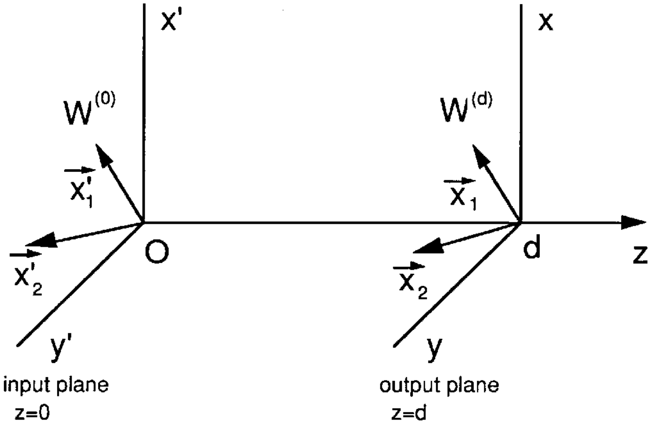

FIGURE 2 Illustrating the coordinate system for propagation of the cross-spectral density function using the angular spectrum of plane waves.

and is the cosine of the angle that $\mathbf{p}_i$ makes with the $+z$ axis for real m_i. Finally, to obtain the cross-spectral density function over the output plane, we simply take the Fourier inverse of $\mathscr{A}_{\text{out}}(\mathbf{p}_1, \mathbf{p}_2)$, i.e.,

$$W_\omega^{(d)}(\mathbf{x}_1\mathbf{x}_2) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \mathscr{A}_{\text{out}}(\mathbf{p}_1, \mathbf{p}_2) e^{ik(\mathbf{p}_1\cdot\mathbf{x}_1 - \mathbf{p}_2\cdot\mathbf{x}_2)}\, d^2\mathbf{p}_1\, d^2\mathbf{p}_2 \tag{52}$$

where, in this equation only, we use $\mathbf{x}_i$ to represent a two-dimensional radius vector from the point $(0, 0, d)$ to a field point in the $z = d$ plane, as shown in Fig. 2. This propagation procedure is similar to the method usually used to propagate the field amplitude in Fourier optics. In coherence theory, it is the cross-spectral density function for a field of any state of coherence that is propagated between arbitrary parallel planes using the linear systems procedure. The only condition for the validity of this procedure is that the volume between the planes must either be empty space or a uniform dielectric medium.

Radiation Field

The cross-spectral density function far away from any source, which has finite size, can be calculated using a particularly simple equation. Consider a primary, three-dimensional source located within a sphere of radius a, as shown in Fig. 3. For field points, $\mathbf{x}_1$ and $\mathbf{x}_2$ which are much farther from the origin than the Rayleigh range ($|\mathbf{x}_i| \gg ka^2$), in any direction, a form of the familiar Fraunhofer approximation can be applied to Eq. (28) to obtain [see Ref. 62, eq. (2.5)]

$$W_U^{(\infty)}(\mathbf{x}_1, \mathbf{x}_2) = \frac{e^{ik(|\mathbf{x}_1| - |\mathbf{x}_2|)}}{|\mathbf{x}_1|\,|\mathbf{x}_2|} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} W_Q(\mathbf{x}_1'', \mathbf{x}_2'') \times e^{-ik[\mathbf{x}_1\cdot\mathbf{x}_1''/|\mathbf{x}_1| - \mathbf{x}_2\cdot\mathbf{x}_2''/|\mathbf{x}_2|]}\, d^3\mathbf{x}_1''\, d^3\mathbf{x}_2'' \tag{53}$$

Thus the cross-spectral density function of the far field is proportional to the six-dimensional Fourier transform of the cross-spectral density function of its sources. A very

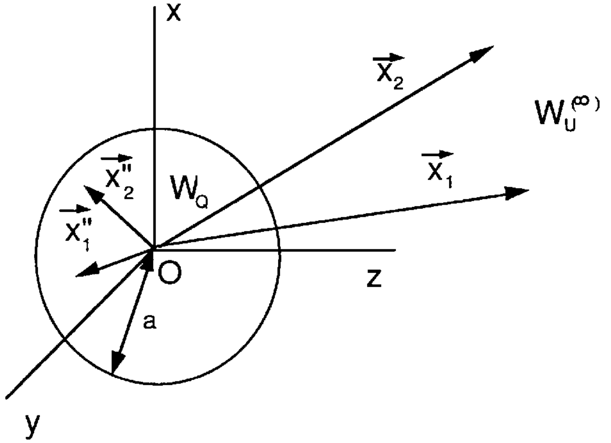

FIGURE 3 Illustrating the coordinate system used to calculate the cross-spectral density function in the far field of a primary, three-dimensional source.

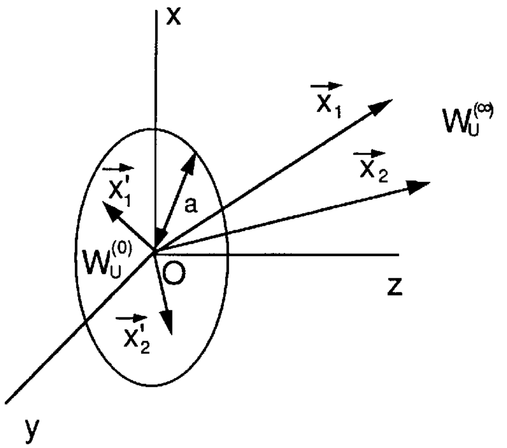

FIGURE 4 Illustrating the coordinate system for calculating the far field cross-spectral density function for a planar, secondary source distribution in the $z = 0$ plane. Single-primed coordinates indicate radius vectors from the origin to points within the $z = 0$ plane.

similar expression can also be found for a two-dimensional, secondary source distribution over the $z = 0$ plane, as illustrated in Fig. 4.

If the sources are all restricted to the area within a circle about the origin of radius *a,* then the cross-spectral density function for all points which are outside of the Rayleigh range ($|\mathbf{x}_i| \gg ka^2$) from the origin and also in the $z > 0$ half-space can be found by using a different form of the Fraunhofer approximation in Eq. (33) [see Ref. 62, eq. (3.3)] to get

$$W_U^{(\infty)}(\mathbf{x}_1, \mathbf{x}_2) = \frac{1}{\lambda^2} \frac{z_1}{|\mathbf{x}_1|} \frac{z_2}{|\mathbf{x}_2|} \frac{e^{ik(|\mathbf{x}_1| - |\mathbf{x}_2|)}}{|\mathbf{x}_1|\,|\mathbf{x}_2|} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} W_U^{(0)}(\mathbf{x}'_1, \mathbf{x}'_2) \times e^{-ik[\mathbf{x}_1 \cdot \mathbf{x}'_1/|\mathbf{x}_1| - \mathbf{x}_2 \cdot \mathbf{x}'_2/|\mathbf{x}_2|]}\, d^2\mathbf{x}'_1\, d^2\mathbf{x}'_2 \tag{54}$$

Because of both their relative simplicity (as Fourier transforms) and great utility, Eqs. (53) and (54) are very important in coherence theory for calculating both the radiant intensity and the far-field coherence properties of the radiation field from any source.

Representations

Several equations have been described here for propagating the cross-spectral density function. The two most general are Eq. (33), which uses an expansion of the field into spherical Huygens wavelets, and Eqs. (49), (50), and (52), which use an expansion of the field into an angular spectrum of plane waves. These two formulations are completely equivalent. Neither uses any approximation not also used by the other method. The choice of which to use for a particular calculation can be made completely on a basis of convenience. The far-field approximations given by Eqs. (53) and (54), for example, can be derived from either representation. There are two bridges between the spherical and plane wave representations, one given by Weyl's integral, i.e.,

$$\frac{e^{ik|\mathbf{x} - \mathbf{x}''|}}{|\mathbf{x} - \mathbf{x}''|} = \frac{i}{\lambda} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \frac{1}{m} e^{ik[p(x - x'') + q(y - y'') + m|z - z''|]}\, dp\, dq \tag{55}$$

where

$$m = \sqrt{1 - p^2 - q^2} \text{ if } p^2 + q^2 \leq 1, \\ = i\sqrt{p^2 + q^2 - 1} \text{ if } p^2 + q^2 > 1 \tag{56}$$

and the other by a related integral

$$\frac{-1}{2\pi} \frac{d}{dz} \frac{e^{ik|\mathbf{x}-\mathbf{x}''|}}{|\mathbf{x}-\mathbf{x}''|} = \frac{\pm 1}{\lambda^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} e^{ik[p(x-x'')+q(y-y'')+m|z-z''|]}\, dp\, dq \tag{57}$$

which can be easily derived from Eq. (55). In Eq. (57) the ± sign holds according to whether $(z - z'') \gtrless 0$. With these two equations it is possible to transform back and forth between these two representations.

Reciprocity Theorem

The radiation pattern and the complex degree of spectral coherence obey a very useful reciprocity theorem for a quasi-homogeneous source. By substituting from Eq. (40) into Eq. (53), and using Eq. (24) and the six-dimensional form of Eq. (41), it has been shown that the radiant intensity in the direction of the unit vector **s** from any bounded, three-dimensional, quasi-homogeneous primary source distribution is given by [see Ref. 45, eq. (3.11)]

$$J_\omega(\mathbf{s}) = J_0 \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \mu_Q(\mathbf{x}''_-) e^{-ik\mathbf{x}''_-\cdot\mathbf{s}}\, d^3\mathbf{x}''_- \tag{58}$$

where $\mu_Q(\mathbf{x}''_-)$ is the (spatially stationary) complex degree of spectral coherence for the source distribution as defined in Eq. (40), and

$$J_0 = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} I_Q(\mathbf{x}''_+)\, d^3\mathbf{x}''_+ \tag{59}$$

where $I_Q(\mathbf{x}''_+)$ is the intensity defined in Eq. (40). Note that the far-field radiation pattern depends, not on the source intensity distribution, but only on the source coherence. We also find from this calculation that the complete degree of spectral coherence between any two points in the far field of this source is given by [see Ref. 45, eq. (3.15)]

$$\mu^{(\infty)}u(R_1\mathbf{s}_1, R_2\mathbf{s}_2) = \frac{e^{ik(R_1-R_2)}}{J_0} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} I_Q(\mathbf{x}''_+) e^{ik\mathbf{x}''_+\cdot(\mathbf{s}_1-\mathbf{s}_2)}\, d^3\mathbf{x}''_+ \tag{60}$$

Note that the coherence of the far field depends, not on the source coherence, but rather on the source intensity distribution, $I_Q(\mathbf{x}''_+)$. Equation (60) is a generalization of the van Cittert–Zernike theorem to three-dimensional, primary quasi-homogeneous sources, which are not necessarily incoherent. Equation (59) is a new theorem, reciprocal to the van Cittert–Zernike theorem, which was discovered by Carter and Wolf.[45,49] Equations (58) and (60), taken together, give a reciprocity relation. For quasi-homogeneous sources, far-field coherence is determined by source intensity alone and the far-field intensity pattern is determined by source coherence alone. Therefore, coherence and intensity are reciprocal when going from the source into the far field. Since most sources which occur naturally are believed to be quasi-homogeneous, this is a very useful theorem. This reciprocity theorem has been found to hold much more generally than just for three-dimensional primary sources. For a planar, secondary source, by substitution from Eq. (40) into Eq. (54) and then using Eq. (41), we obtain[49]

$$J_\omega(\mathbf{s}) = J'_0 \cos^2 \theta \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \mu_U^{(0)}(\mathbf{x}'_-) e^{-ik\mathbf{x}'_- \cdot \mathbf{s}}\, d^2\mathbf{x}'_- \tag{61}$$

where θ is the angle that **s** makes with the $+z$ axis, and where

$$J'_0 = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} I_U^{(0)}(\mathbf{x}'_+)\, d^2\mathbf{x}'_+ \tag{62}$$

and we also obtain

$$\mu_U^{(\infty)}(R_1\mathbf{s}_1, R_2\mathbf{s}_2) = \frac{1}{J'_0} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} I_U^{(0)}(\mathbf{x}'_+) e^{-ik\mathbf{x}'_+ \cdot (\mathbf{s}_1 - \mathbf{s}_2)}\, d^2\mathbf{x}'_+ \tag{63}$$

Very similar reciprocity relations also hold for scattering of initially coherent light from quasi-homogeneous scattering potentials,[53,54] and for the scattering of laser beams from quasi-homogeneous sea waves.[63] Reciprocity relations which apply to fields that are not necessarily quasi-homogeneous have also been obtained.[64]

Nonradiating Sources

One additional important comment must be made about Eq. (58). The integrals appearing in this equation form a three-dimensional Fourier transform of $\mu_Q(\mathbf{x}''_-)$. However, $J_\omega(\mathbf{s})$, the radiant intensity that this source radiates into the far field at radial frequency ω, is a function of only the direction of **s**, which is a unit vector with a constant amplitude equal to one. It then follows that only the values of this transform over a spherical surface of unit radius from the origin affect the far field. Therefore, sources which have a complex degree of spectral coherence, $\mu_Q(\mathbf{x}''_-)$, which do not have spatial frequencies falling on this sphere, do not radiate at frequency ω. It appears possible from this fact to have sources in such a state of coherence that they do not radiate at all. Similar comments can also be made in regard to Eq. (53) which apply to all sources, even those that are not quasi-homogeneous. From Eq. (53) it is clear that only sources which have a cross-spectral density function with spatial frequencies (with respect to both $\mathbf{x}''_1$ and $\mathbf{x}''_2$) on a unit sphere can radiate. It is believed that this is closely related to the phase-matching condition in nonlinear optics.

Perfectly Incoherent Sources

For a completely incoherent primary source the far-field radiant intensity, by substitution from Eq. (42) into Eq. (58), is seen to be the same in all directions, independent of the shape of the source. By substitution from Eq. (40) into Eq. (28), and then using Eqs. (14), (29), and (42), we find that the complex degree of spectral coherence for this incoherent source is given by

$$\mu_U(\mathbf{x}_1, \mathbf{x}_2) = \frac{1}{\sqrt{I(\mathbf{x}_1)/(\mathbf{x}_2)}} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} I_Q(\mathbf{x}'') \frac{e^{ik[|\mathbf{x}_1 - \mathbf{x}''| - |\mathbf{x}_2 - \mathbf{x}''|]}}{|\mathbf{x}_1 - \mathbf{x}''|\, |\mathbf{x}_2 - \mathbf{x}''|} d^3\mathbf{x}'' \tag{64}$$

Thus it is only the source intensity distribution that affects the field coherence. Comparison of this equation with Eq. (47) shows that this is a generalization of the van Cittert–Zernike theorem to primary sources. It is clear from this equation that the complex degree of spectral coherence depends only on the shape of the source and not the fact that the source is completely incoherent. For a completely incoherent, planar, secondary source the radiant intensity is given by

$$J_\omega(\mathbf{s}) = J'_0 \cos^2 \theta \tag{65}$$

independent of the shape of the illuminated area on the source plane, where θ is the angle that $\mathbf{s}$ makes with the normal to the source plane. This can be proven by substitution from Eq. (42) into Eq. (61). Note that such sources do not obey Lambert's law. The far-field coherence, again, depends on the source intensity as given by the van Cittert–Zernike theorem [see Eq. (47)] and not on the source coherence.

Spectrum

For a quasi-homogeneous, three-dimensional primary source the spectrum of the radiation $S_U^{(\infty)}(R\mathbf{s}, \omega)$ at a point $R\mathbf{s}$ in the direction $\mathbf{s}$ (unit vector) and at a distance R from the origin, in the far field of the source, can be found, as a function of the source spectrum $S_Q^{(0)}(\omega)$, by substitution from Eqs. (24) and (15) into Eq. (58) to get

$$S_U^{(\infty)}(R\mathbf{s}, \omega) = \frac{c^3 S_Q(\omega)}{\omega^3 R^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \mu_Q(\mathbf{x}''_-, \omega) e^{-ik\mathbf{x}''_- \cdot \mathbf{s}} \, d^3(k\mathbf{x}''_-) \tag{66}$$

where we explicitly indicate the dependence of the complex degree of spectral coherence on frequency. Notice that the spectrum of the field is not necessarily the same as the spectrum of the source and, furthermore, that it can vary from point to point in space. The field spectrum depends on the source coherence as well as on the source spectrum. A very similar propagation relation can be found for the far-field spectrum from a planar, secondary source in the $z = 0$ plane. By substitution from Eqs. (24) and (15) into Eq. (61) we get

$$S_U^{(\infty)}(R\mathbf{s}, \omega) = \frac{S_U^{(0)}(\omega)}{R^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \mu_U^{(0)}(\mathbf{x}'_-, \omega) e^{-ik\mathbf{x}'_- \cdot \mathbf{s}} \, d^2(k\mathbf{x}'_-) \tag{67}$$

This shows that the spectrum for the field itself is changed upon propagation from the $z = 0$ plane into the far field and is different in different directions $\mathbf{s}$ from the source.[65]

4.7 SPECTRUM OF LIGHT

Limitations

The complex analytic signal for a field that is not perfectly coherent, as defined in Eq. (3), is usually assumed to be a time-stationary random process. Therefore, the integral

$$\int_{-\infty}^{\infty} u(\mathbf{x}, t) e^{i\omega t} \, dt \tag{68}$$

does not converge, so that the analytic signal does not have a Fourier transform. Therefore, it is only possible to move freely from the space-time domain to the

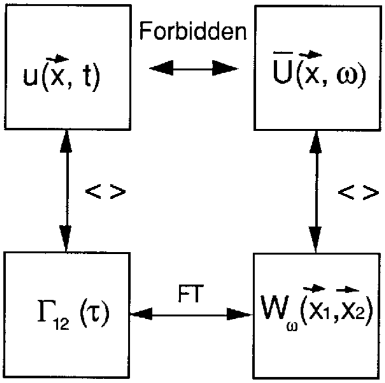

FIGURE 5 Illustrating the transformations which are possible between four functions that are used in coherence theory.

space-frequency domain along the path shown in Fig. 5. Equation (3) does not apply to time-stationary fields within the framework of ordinary function theory.

Coherent Mode Representation

Coherent mode representation (see Wolf[66,67]) has shown that any partially coherent field can be represented as the sum over component fields that are each perfectly self-coherent, but mutually incoherent with each other. Thus the cross-spectral density function for any field can be represented in the form

$$W_A(\mathbf{x}_1, \mathbf{x}_2) = \sum_n \lambda_n \phi_{A,n}(\mathbf{x}_1) \phi^*_{A,n}(\mathbf{x}_2) \tag{69}$$

where $\phi_{A,n}(\mathbf{x}_i)$ is a phasor amplitude for its nth coherent component. This representation can be used either with primary $(A = Q)$, or secondary $(A = U)$ sources. The phasor amplitudes $\phi_{A,n}(\mathbf{x}_i)$ and the complex expansion coefficients λ_n in Eq. (69) are eigenfunctions and eigenvalues of $W_A(\mathbf{x}_1, \mathbf{x}_2)$, as given by the equation

$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} W_A(\mathbf{x}_1, \mathbf{x}_2) \phi_{A,n}(\mathbf{x}_2)\, d^3\mathbf{x}_2 = \lambda_n(\omega) \phi_{A,n}(\mathbf{x}_1) \tag{70}$$

Since $W_A(\mathbf{x}_1, \mathbf{x}_2)$ is hermitian, the eigenfunctions are complete and orthogonal, i.e.,

$$\sum_n \phi_{A,n}(\mathbf{x}_1) \phi^*_{A,n}(\mathbf{x}_2) = \delta^3(\mathbf{x}_1 - \mathbf{x}_2) \tag{71}$$

and

$$\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \phi_{A,n}(\mathbf{x}_1) \phi^*_{A,m}(\mathbf{x}_1)\, d^3\mathbf{x}_1 = \delta_{nm} \tag{72}$$

where δ_{nm} is the Kronecker delta function, and the eigenvalues are real and nonnegative definite, i.e.,

$$\begin{aligned} \text{Real}\,\{\lambda_n(\omega)\} &\geq 0 \\ \text{Imag}\,\{\lambda_n(\omega)\} &= 0 \end{aligned} \tag{73}$$

This is a very important concept in coherence theory. Wolf has used this representation to show that the frequency decomposition of the field can be defined in a different manner than was done in Eq. (3). A new phasor,

$$\bar{U}_A(\mathbf{x}, \omega) = \sum_n a_n(\omega)\phi_{A,n}(\mathbf{x}, \omega) \tag{74}$$

where $a_n(\omega)$ are random coefficients such that

$$\langle a_n(\omega)a_m^*(\omega)\rangle = \lambda_n(\omega)\delta_{nm} \tag{75}$$

can be introduced to represent the spectral components of the field. It then follows[66] that, if the $\phi_{A,n}(\mathbf{x}_i)$ are eigenfunctions of the cross-spectral density function, $W_A(\mathbf{x}_1, \mathbf{x}_2)$, then the cross-spectral density function can be represented as the correlation function between these phasors at the two spatial points $\mathbf{x}_1$ and $\mathbf{x}_2$, i.e.,

$$W_A(\mathbf{x}_1, \mathbf{x}_2) = \langle \bar{U}_A(\mathbf{x}_1, \omega)\bar{U}_A^*(\mathbf{x}_2, \omega)\rangle \tag{76}$$

in a manner very similar to the representation given in Eq. (11) in respect to the older phasors. Notice, by comparison of Eqs. (11) and (76), that the phasors $\bar{U}_A(\mathbf{x}_i, \omega)$ and $U_A(\mathbf{x}_i, \omega)$ are not the same. One may formulate coherence theory either by defining $u(\mathbf{x}, t)$ in Fig. 5 and then moving in a counterclockwise direction in this figure to derive the correlation functions using the Wiener-Khintchene theory or, alternatively, defining $\bar{U}_A(\mathbf{x}_i, \omega)$ and moving in a clockwise direction to define the correlation functions using the coherent mode expansion.

Wolf Shift and Scaling law

From Eqs. (66) and (67) it is clear that the spectrum of a radiation field may change as the field propagates. It is not necessarily equal to the source spectrum as it is usually assumed. This brings up an important question. Why do the spectra for light fields appear so constant, experimentally, that a change with propagation was never suspected? Wolf[65] has provided at least part of the answer to this question. He discovered a scaling law that is obeyed by most natural fields and under which the normalized spectrums for most fields do remain invariant as they propagate. We can derive this scaling law by substitution from Eqs. (66) and (67) into Eq. (16). We then find that, if the complex degree of spectral coherence for the source is a function of $k\mathbf{x}_-$ only, i.e.,

$$\mu_A(\mathbf{x}_-, \omega) = f(k\mathbf{x}_-) \tag{77}$$

(so that this function is the same for each frequency component of the field, provided that the spatial separations of the two test points are always scaled by the wavelength), then the normalized spectrum in the far field is given by

$$s_U^{(\infty)}(R\mathbf{s}, \omega) = \frac{S_Q(\omega)/\omega^3}{\displaystyle\int_0^\infty S_Q(\omega)/\omega^3\, d\omega} \neq f(R\mathbf{s}) \tag{78}$$

if $S_Q(\omega)$ is the complex degree of spectral coherence for a primary, quasi-homogeneous source [see Ref. 90, Eq. (65)], and

$$s_U^{(\infty)}(R\mathbf{s}, \omega) = \frac{S_U^{(0)}(\omega)}{\displaystyle\int_0^\infty S_U^{(0)}(\omega)\, d\omega} = s_U^{(0)}(\omega) \neq f(R\mathbf{s}) \tag{79}$$

if $s_U^{(0)}(\omega)$ is the normalized spectrum for a secondary, quasi-homogeneous source [see Ref. 90, Eq. (51)]. In each case the field spectrum does not change as the field propagates. Since the cross-spectral density function for a thermal source [see Eq. (43)] obeys this scaling law, it is not surprising that these changes in the spectrum of a propagating light field were never discovered experimentally. The fact that the spectrum can change was verified experimentally only after coherence theory pointed out the possibility.[68–72]

4.8 POLARIZATION EFFECTS

Explicit Vector Representations

As discussed earlier under "Scalar Field Amplitude", the scalar amplitude is frequently all that is required to treat the vector electromagnetic field. If polarization effects are important, it might be necessary to use two scalar field amplitudes to represent the two independent polarization components. However, in some complicated problems it is necessary to consider all six components of the vector field explicitly. For such a theory, the correlation functions between vector components of the field become tensors,[73,74] which propagate in a manner very similar to the scalar correlation functions.

4.9 APPLICATIONS

Speckle

If coherent light is scattered from a stationary, rough surface, the phase of the light field is randomized in space. The diffraction patterns observed with such light displays a complicated granular pattern usually called *speckle* (see Ref. 8, sec. 7.5). Even though the light phase can be treated as a random variable, the light is still perfectly coherent. Coherence theory deals with the effects of time fluctuations, not spatial variations in the field amplitude or phase. Despite this, the same statistical tools used in coherence theory have been usefully applied to studying speckle phenomena.[75,76] To treat speckle, the ensemble is usually redefined, not to represent the time fluctuations of the field but, rather, to represent all of the possible speckle patterns that might be observed under the conditions of a particular experiment. An observed speckle pattern is usually due to a single member of this ensemble (unless time fluctuations are also present), whereas the intensity observed in coherence theory is always the result of a weighted average over all of the ensemble. To obtain the intensity distribution over some plane, as defined in coherence theory, it would be necessary to average over all of the possible speckle patterns explicitly. If this is done, for example, by moving the scatterer while the intensity of a diffraction pattern is time-averaged, then time fluctuations are introduced into the field during the measurement; the light becomes partially coherent; and coherence theory can be properly used to model the measured intensity. One must be very careful in applying the coherence theory model to treat speckle phenomena, because coherence theory was not originally formulated to deal with speckle.

Statistical Radiometry

Classical radiometry was originally based on a mechanical treatment of light as a flux of particles. It is not totally compatible with wave theories. Coherence theory has been used to incorporate classical radiometry into electromagnetic theory as much as has been found possible. It has been found that the usual definitions for the radiance function and the radiant emittance cause problems when applied to a wave theory. Some of this work is discussed earlier (pp. 4.8 to 4.10, 4.12, 4.13, 4.15 to 4.16, 4.18). Other radiometric functions, such as the radiant intensity, have clear meaning in a wave theory.

Spectral Representation

It was discovered, using coherence theory, that the spectrum of a light field is not the same as that of its source and that it can change as the light field propagates away from its source into the radiation field. Some of this work was discussed earlier under ‘‘Perfectly Incoherent Sources’’ and ‘‘Coherent Mode Representation.’’ This work has been found very useful for explaining troublesome experimental discrepancies in precise spectroradiometry.[71]

Laser Modes

Coherence theory has been usefully applied to describing the coherence properties of laser modes.[77] This theory is based on the coherent mode representation discussed under ‘‘Spectrum of Light.’’

Radio Astronomy

Intensity interferometry was used to apply techniques from radio astronomy to observation with light.[37] A lively debate ensued as to whether optical interference effects (which indicate partial coherence) could be observed from intensity correlations.[78] From relations like Eq. (26) and similar calculations using quantum coherence theory, it quickly became clear that they could.[79,80] More recently, coherence theory has been used to model a radio telescope[42] and to study how to focus an instrument to observe emitters that are not in the far field of the antenna array.[81] It has been shown[82] that a radio telescope and a conventional optical telescope are very similar, within a coherence theory model, even though their operation is completely different. This model makes the similarities between the two types of instruments very clear.

Noncosmological Red Shift

Cosmological theories for the structure and origin of the universe make great use of the observed red shift in the spectral lines of the light received from distant radiating objects, such as stars.[83] It is usually assumed that the spectrum of the light is constant upon propagation and that the observed red shift is the result of simple Doppler shift due to the motion of the distant objects away from the earth in all directions. If this is true, then clearly the observed universe is expanding and must have begun with some sort of explosion, called "the big bang." The size of the observable universe is estimated based on the amount of this red shift. A new theory by Wolf[84–87] shows that red shifts can occur naturally without Doppler shifts as the light propagates from the source to an observer if the source is not in thermal equilibrium, i.e., a thermal source as discussed earlier under "Thermal (Lambertian) Source." The basis of Wolf's theory was discussed on pp. 4: 32–33 and 34–36.

CHAPTER 5
POLARIZATION[†]

Jean M. Bennett
Senior Scientist (Optics),
Research Department,
Michelson Laboratory,
Naval Air Warfare Center,
China Lake, California

GLOSSARY

c	velocity of light
d	thickness
E	electric field
$\mathbf{k}$	wave vector ($k = 2\pi/\lambda$)
k	extinction coefficient
m	number of reflections
N	retardation per wavelength
n	real refractive index
$\tilde{n}$	complex refractive index
$\hat{\mathbf{n}}$	unit normal vector
p	degree of polarization
p	parallel polarization
R	intensity reflection coefficient
r	amplitude reflection coefficient
$\mathbf{r}$	position vector
s	senkrecht or perpendicular polarization
t	amplitude transmission coefficient
t	time
z	cartesian coordinate

[†] This material was originally prepared under the auspices of the U.S. government and is not subject to copyright.

$\alpha, \beta, a, b, c, d$	intermediate parameters
α	absorption coefficient
γ	$2\pi nd \cos\theta/\lambda$
δ	phase angle
ε	dielectric constant
η	effective refractive index
θ_B	Brewster angle
θ	angle
κ	absorption index
λ	wavelength
ρ	extinction ratio
σ	conductivity
ω	radian or angular frequency
∇	laplacian operator
0	first medium
1	second medium

The material on polarization is abridged from the much more complete treatment by Bennett and Bennett.[1] Information on polarizers is found in Volume 2, Chapter 3, "Polarizers."

1. Basic Concepts and Conventions Optical polarization was discovered by E. L. Malus in 1808. A major triumph of nineteenth- and early twentieth-century theoretical physics was the development of electromagnetic theory and the demonstration that optical polarization is completely described by it. This theory is phenomenological in that instead of trying to explain why materials have certain fundamental characteristics, it concentrates on the resulting properties which any material with those characteristics will display. In the optical case, the polarization and all other optical properties of a material are determined by two or more phenomenological parameters called *optical constants.* Electromagnetic theory has little or nothing to say about *why* a material should have these particular optical constants or *how* they are related to its atomic character. This problem has been extensively investigated in twentieth-century solid-state physics and is still only partially understood. It is clear, however, that the optical constants are a function not only of the atomic nature of the material, i.e., its position in the periodic table, but are also quite sensitive to how it is prepared. Perhaps *optical parameters* would be a better term than optical constants. Nevertheless, the concept of optical constants is an extremely useful one and makes it possible to predict quantitatively the optical behavior of a material and, under certain conditions, to relate this behavior to nonoptical parameters.

Since the optical constants are so fundamental, differences in their definition are particularly unfortunate. The most damaging of these differences arises from an ambiguity in the initial derivation. Maxwell's equations, which form the basis of electromagnetic theory, result in the wave equation, which in mks units is

$$\nabla^2 \mathbf{E} = \frac{\varepsilon}{c^2}\frac{\partial^2 \mathbf{E}}{\partial t^2} + \frac{4\pi\sigma}{c^2}\frac{\partial \mathbf{E}}{\partial t} \tag{1}$$

where ∇^2 = laplacian operator
$\mathbf{E}$ = electric field vector of traveling wave
t = time
c = velocity of light
σ = conductivity of material at frequency of wave motion
ε = dielectric constant of material at frequency of wave motion

A solution to this equation is

$$\mathbf{E} = \mathbf{E}_0 \exp\left[i(\omega t + \delta)\right] \exp\left(-i\mathbf{k} \cdot \mathbf{r}\right) \exp\left(-\frac{\alpha z}{2}\right) \tag{2}$$

where $\mathbf{E}_0$ = amplitude of wave
ω = angular frequency of wave
δ = phase vector
$\mathbf{k}$ = wave vector
$\mathbf{r}$ = position vector
z = direction wave is traveling
α = absorption coefficient

The wave vector $\mathbf{k}$ is assumed to be real and equal to $(2\pi/\lambda_m)\hat{\mathbf{n}}$, where λ_m is the wavelength in the medium in which the wave is traveling and $\mathbf{n}$ is a unit vector in the k direction.† Equation (2) can also be written in terms of $\tilde{n}$, the complex index of refraction, defined as

$$\tilde{n} = n - ik \tag{3}$$

where n is the index of refraction and k the extinction coefficient. In this form, Eq. (2) is

$$E = E_0 \exp\left[i\omega\left(t - \frac{\tilde{n}z}{c}\right)\right] \tag{4}$$

when $\delta = 0$. By setting the imaginary part of the exponent equal to zero one obtains

$$z = \frac{c}{n}t \tag{5}$$

To show that Eq. (4) represents a wave traveling in the positive z direction with phase velocity c/n, we note that the phase ϕ of the wave in Eq. (4) is $\omega t - (\omega\tilde{n}z)/c = \phi$. For a wave propagating with a constant phase, $d\phi = 0$, so that $\omega\, dt - (\omega\tilde{n}/c)\, dz = d\phi = 0$, and hence the phase velocity $v_p = dz/dt = c/n$.[2] The amplitude of the wave at z is, from Eq. (4),

$$|E| = E_0 e^{-2\pi kz/\lambda} \tag{6}$$

where λ is the wavelength in vacuum. The wave is thus exponentially damped, and the amplitude penetration depth, or distance below an interface at which the *amplitude* of the wave falls to $1/e$ times its initial value, is $z = \lambda/2\pi k$. The absorption coefficient α, or

† Frequently the wave vector is taken to be complex, that is, $\tilde{\mathbf{k}} = (2\pi/\lambda_m - i\alpha/2)\mathbf{n}$, and Eq. (2) is written $\mathbf{E} = \mathbf{E}_0 \exp\left[i(\omega t + \delta)\right] \exp\left(-i\mathbf{k}' \cdot \mathbf{r}\right)$.

the reciprocal of the distance in which the *intensity* of the wave falls to $1/e$ times its initial value, is

$$\alpha = \frac{4\pi k}{\lambda} \tag{7}$$

This development follows that commonly given by those working at optical or radio frequencies. The confusion in the definition of the optical constants arises because an equally valid solution to Eq. (1) is

$$E' = E_0 \exp\left[-i\omega\left(t - \frac{\tilde{n}'z}{c}\right)\right] \tag{8}$$

which also represents an exponentially damped wave traveling in the $+z$ direction *provided that the complex index of refraction is defined to be*

$$\tilde{n}' = n + ik \tag{9}$$

where the primes indicate the alternative solution. When the wave equation arises in quantum mechanics, the solution chosen is generally the negative exponential, i.e. Eq. (8) rather than Eq. (4). Solid-state physicists working in optics thus often define the complex index of refraction as the form given in Eq. (9) rather than that in Eq. (3). Equally valid, self-consistent theories can be built up using either definition, and as long as only intensities are considered, the resulting expressions are identical. However, when phase differences are calculated, the two conventions usually lead to contradictory results. Even worse, an author who is not extremely careful may not consistently follow either convention, and the result may be pure nonsense. Some well-known books might be cited in which the authors are not even consistent from chapter to chapter.

There are several other cases in optics in which alternative conventions are possible and both are found in the literature. Among these, the most distressing are the use of a left-handed rather than a right-handed coordinate system, which makes the p and s components of polarized light have the same phase change at normal incidence (see Par. 2), and defining the optical constants so that they depend on the angle of incidence, which makes the angle of refraction given by Snell's law real for an absorbing medium. There are many advantages to be gained by using a single set of conventions in electromagnetic theory. In any event, an author should *clearly* state the conventions being used and then *stay with them.*

Finally, the complex index of refraction is sometimes written

$$\tilde{n} = n(1 - i\kappa) \tag{10}$$

In this formulation the symbol κ is almost universally used instead of k, which is reserved for the imaginary part of the refractive index. Although k is more directly related to the absorption coefficient α than κ [see Eq. (7)] and usually makes the resulting expressions slightly simpler, in areas such as attenuated total reflection the use of κ results in a simplification. To avoid confusion between k and κ, if Eq. (10) is used, κ could be called the *absorption index* to distinguish it from the extinction coefficient k, and the absorption coefficient α.

2. Fresnel Equations The Fresnel equations are expressions for the reflection and transmission coefficients of light at nonnormal incidence. In deriving these equations, the coordinate system assumed determines the signs in the equations and therefore the phase changes on reflection of the p and s components. In accordance with the Muller

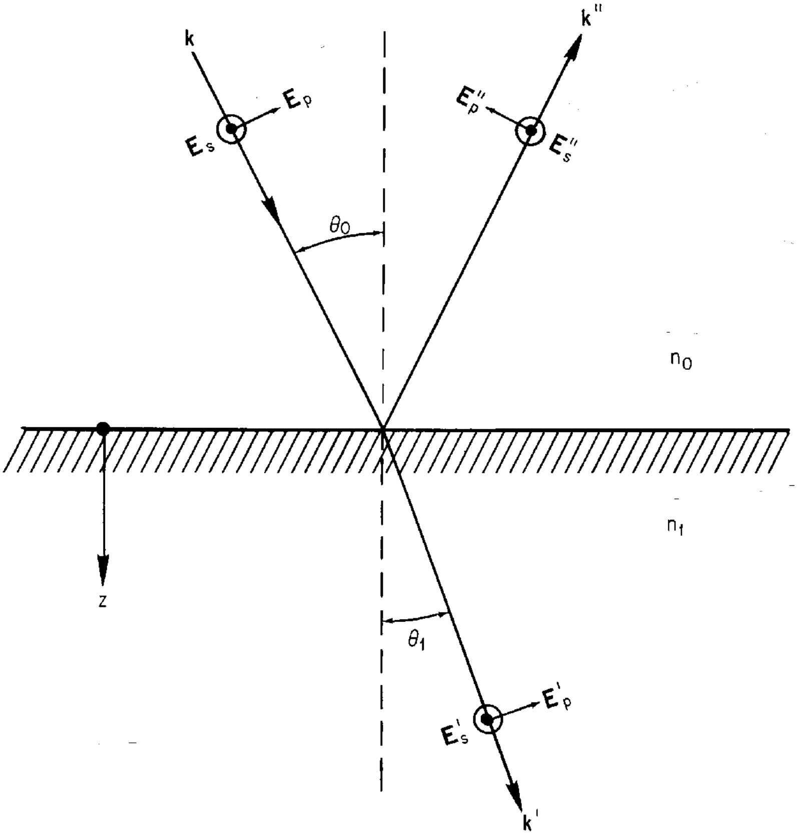

FIGURE 1 Coordinate system for measuring the E vectors of a plane wave reflected and refracted at a boundary between a medium of refractive index n_0 and a medium of refractive index n_1 (may be absorbing). The positive direction for the coordinates of the E_s, E_s', and E_s'' components is out of the paper, and that for the coordinates of the E_p components is in the plane of the paper, as indicated by the arrows. The wave vector **k**, the direction the wave is traveling z, and angles of incidence and refraction θ_0 and θ_1 are also shown. [*Modified from Muller, Ref.* 3.]

convention,[3] we shall assume that the coordinate system is as shown in Fig. 1. In this system, the angle of incidence is θ_0, and the angle of refraction is θ_1. The *s component* of polarization is the plane of vibration of the E wave which is perpendicular to the plane of the paper, and the *p component* is the plane of vibration which is in the plane of the paper.† (The plane of incidence is in the plane of the paper.) The positive directions for the vibrations are indicated in Fig. 1 by the dots for E_s, E_s', and E_s'' and by the arrows for the corresponding p components. Note that the positive direction for E_p'' is as shown in the

† Unfortunately, when Malus discovered that light reflected at a certain angle from glass is, as he said, "polarized," he defined the plane of polarization" of the reflected light as the plane of incidence. Since the reflected light in this case has its E vector perpendicular to the plane of incidence, the "plane of polarization" is perpendicular to the plane in which the E vector vibrates. This nomenclature causes considerable confusion and has been partially resolved in modern terminology by discussing the *plane of vibration* of the E vector and avoiding, insofar as possible, the term *plane of polarization.* In this chapter, when specifying the direction in which light is polarized, we shall give the direction of vibration, *not* the direction of polarization.

figure because of the *mirror-image effect.* By convention, one always looks *against the direction of propagation of the wave* so that the positive direction of E_p is to the right and the positive direction of E''_p is also to the right. The positive directions of the reflected E vectors are not the same as the actual directions of the reflected E vectors. These latter directions will depend on the refractive index of the material and may be either positive or negative. For example, if $n_1 > n_0$, at normal incidence E''_s will be in the negative direction and E''_p will be in the positive direction. Thus we say that there is a phase change on reflection of 180° for the s wave and a phase change of 0° for the p wave.

With this coordinate system, the Fresnel amplitude reflection coefficients for a single interface, obtained from Eq. (4) by setting up and solving the boundary-value problem, can be written

$$\frac{E''_s}{E_s} \equiv r_s = \frac{n_0 \cos\theta_0 - n_1 \cos\theta_1}{n_0 \cos\theta_0 + n_1 \cos\theta_1} \tag{11}$$

and

$$\frac{E''_p}{E_p} \equiv r_p = \frac{n_1 \cos\theta_0 - n_0 \cos\theta_1}{n_1 \cos\theta_0 + n_0 \cos\theta_1} \tag{12}$$

The amplitude transmission coefficients are

$$\frac{E'_s}{E_s} \equiv t_s = \frac{2n_0 \cos\theta_0}{n_0 \cos\theta_0 + n_1 \cos\theta_1} \tag{13}$$

and

$$\frac{E'_p}{E_p} \equiv t_p = \frac{2n_0 \cos\theta_0}{n_1 \cos\theta_0 + n_0 \cos\theta_1} \tag{14}$$

Other forms of the Fresnel amplitude reflection and transmission coefficients containing only the angles of incidence and refraction are somewhat more convenient. These relations can be derived using Snell's law

$$\frac{\sin\theta_0}{\sin\theta_1} = \frac{n_1}{n_0} \tag{15}$$

to eliminate n_0 and n_1 from Eqs. (1) to (14):

$$r_s = \frac{-\sin(\theta_0 - \theta_1)}{\sin(\theta_0 + \theta_1)} \tag{16}$$

$$r_p = \frac{\tan(\theta_0 - \theta_1)}{\tan(\theta_0 + \theta_1)} \tag{17}$$

$$t_s = \frac{2\sin\theta_1 \cos\theta_0}{\sin(\theta_0 + \theta_1)} \tag{18}$$

$$t_p = \frac{2\sin\theta_1 \cos\theta_1}{\sin(\theta_0 + \theta_1)\cos(\theta_0 - \theta_1)} \tag{19}$$

For nonabsorbing materials the intensity reflection coefficients R_s and R_p are simply the squares of Eqs. (16) and (17):

$$R_s = r_s^2 = \frac{\sin^2(\theta_0 - \theta_1)}{\sin^2(\theta_0 + \theta_1)} \tag{20}$$

$$R_p = r_p^2 = \frac{\tan^2(\theta_0 - \theta_1)}{\tan^2(\theta_0 + \theta_1)} \tag{21}$$

and, at normal incidence,

$$R_s = R_p = \frac{(n_0 - n_1)^2}{(n_0 + n_1)^2} \tag{22}$$

from Eqs. (11) and (12). In the lower part of Fig. 2, R_s and R_p are given as a function of angle of incidence for various values of the refractive-index ratio n_1/n_0 with k_1 for the material equal to zero. The curves for $n_1/n_0 = 1.3$, 1.8, and 2.3 show that the normal-incidence reflectance increases as n_1 increases. The curves for $n_1/n_0 = 0.3$ and 0.8 and $k_1 = 0$ have no physical significance as long as the incident medium is air. However,

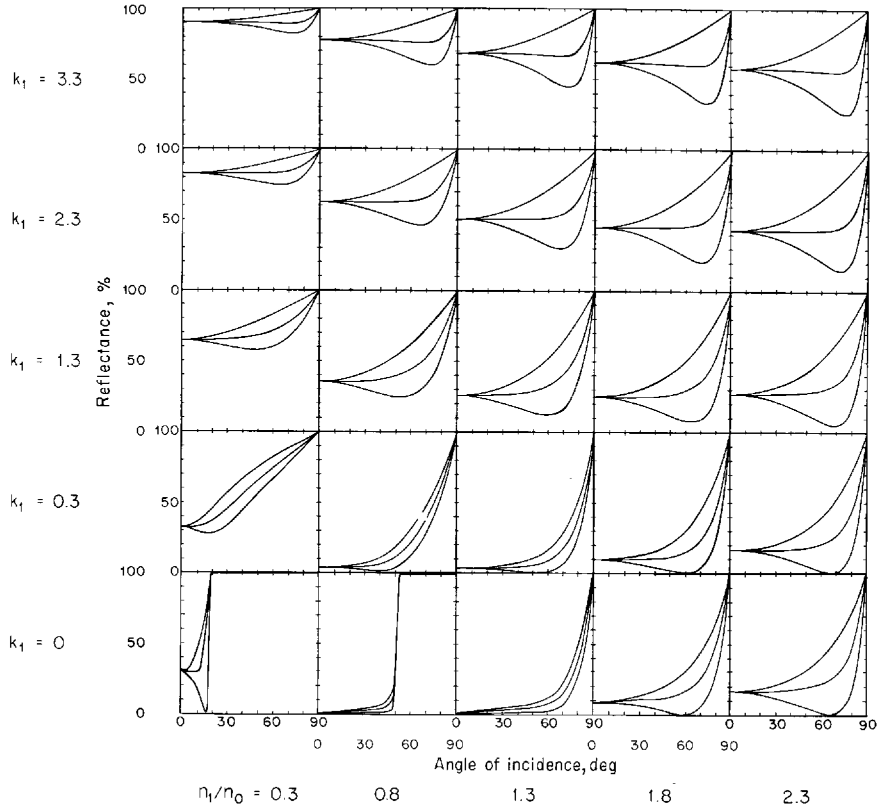

FIGURE 2 R_s (upper curves), R_p (lower curves), and $R_{av} = (R_s + R_p)/2$ as a function of angle of incidence for various values of the refractive-index ratio n_1/n_0 and k_1. The incident medium, having refractive index n_0, is assumed to be nonabsorbing. [*Modified from Hunter, Ref. 4.*]

they are representative of *intenal reflections* in materials of refractive index $n_0 = 3.33$ and 1.25, respectively, when the *other* medium is air ($n_1 = 1$).

The intensity transmission coefficients T_s and T_p are obtained from the Poynting vector and for nonabsorbing materials are

$$T_s = 1 - R_s = \frac{n_1 \cos \theta_1}{n_0 \cos \theta_0} t_s^2 = \frac{4 n_0 n_1 \cos \theta_0 \cos \theta_1}{(n_0 \cos \theta_0 + n_1 \cos \theta_1)^2} = \frac{\sin 2\theta_0 \sin 2\theta_1}{\sin^2 (\theta_0 + \theta_1)} \tag{23}$$

$$T_p = 1 - R_p = \frac{n_1 \cos \theta_1}{n_0 \cos \theta_0} t_p^2 = \frac{4 n_0 n_1 \cos \theta_0 \cos \theta_1}{(n_1 \cos \theta_0 + n_0 \cos \theta_1)^2}$$

$$= \frac{\sin 2\theta_0 \sin 2\theta_1}{\sin^2 (\theta_0 + \theta_1) \cos^2 (\theta_0 - \theta_1)} \tag{24}$$

These coefficients are for light passing through a single boundary and hence are of limited usefulness. In actual cases, the light is transmitted through a slab of material where there are two boundaries, generally multiple reflections within the material, and sometimes interference effects when the boundaries are smooth and plane-parallel.

The intensity transmission coefficient T_{sample} for a slab of transparent material in air is given by the well-known Airy equation[5] when the sample has smooth, plane-parallel sides and coherent multiple reflections occur within it:

$$T_{\text{sample}} = \frac{1}{1 + [4R_{s,p}/(1 - R_{s,p})^2] \sin^2 \gamma} \tag{25}$$

where

$$\gamma = \frac{2\pi n_1 d \cos \theta_1}{\lambda} \tag{26}$$

The values of R_s and R_p can be determined from Eqs. (20) to (22); d is the sample thickness, λ the wavelength, n_1 the refractive index of the material, and θ_1 the angle of refraction. Equation (25) holds for all angles of incidence including the Brewster angle, where $R_p = 0$ [see Eq. (48)]. The Airy equation predicts that at a given angle of incidence the transmission of the sample will vary from a maximum value of 1 to a minimum value of $(1 - R_{s,p})^2/(1 + R_{s,p})^2$ as the wavelength or the thickness is changed. If the sample is very thick, the oscillations in the transmittance will occur at wavelengths very close together and hence will be unresolved. A complete oscillation occurs every time γ changes by π, so that the wavelength interval $\Delta\lambda$ between oscillations is

$$\Delta\lambda \approx \frac{\lambda^2}{2 n_1 d \cos \theta_1} \tag{27}$$

An an example, a sample 1 mm thick with an index of 1.5 at 5000 Å will have transmission maxima separated by 0.83 Å when measured at normal incidence ($\cos \theta_1 = 1$). These maxima would not be resolved by most commercial spectrophotometers. In such a case, one would be measuring the average transmission $T_{\text{sample,av}}$:

$$T_{\text{sample,av}} = \frac{1 - R_{s,p}}{1 + R_{s,p}} \tag{28}$$

For nonabsorbing materials, this is the same value as that which would be obtained if the multiply reflected beams did not coherently interfere within the sample. If the sample is wedge-shaped, so that no multiply reflected beams contribute to the measured transmittance, T_{sample} is simply T_s^2 or T_p^2 and can be calculated from Eq. (23) or (24).

When the material is absorbing, i.e., has a complex refractive index, it is not so easy to calculate the reflectance and transmittance since the angle of refraction is complex. However, Snell's law [Eq. (15)] and Fresnel's equations (11) and (12) are sometimes used with complex values of n_1 and θ_1. The resulting amplitude reflection coefficients are written

$$r_s = |r_s|\, e^{i\delta_s} \tag{29}$$

and

$$r_p = |r_p|\, e^{i\delta_p} \tag{30}$$

where $|r_s|$ and $|r_p|$ are the magnitudes of the reflectances and δ_s and δ_p are the phase changes on reflection. The intensity reflection coefficients are

$$R_{s,p} = r_{s,p} r^*_{s,p} \tag{31}$$

An alternative approach is to use the method of effective indexes to calculate R_s and R_p. In the medium of incidence, which is assumed to be nonabsorbing, the effective indexes η_{0s} and η_{0p} for the s and p components are

$$\eta_{0s} = n_0 \cos \theta_0 \tag{32}$$

$$\eta_{0p} = \frac{n_0}{\cos \theta_0} \tag{33}$$

where n_0 generally equals 1 for air. In the absorbing material both η's are complex and can be written, according to the Bernings,[6,7]

$$\tilde{\eta}_{1s} = \tilde{n}_1 \cos \theta_1 \tag{34}$$

$$\tilde{\eta}_{1p} = \frac{\tilde{n}_1}{\cos \theta_1} \tag{35}$$

where $\tilde{n}_1 = n_1 - ik_1$ is the complex refractive index of the material, and

$$\cos \theta_1 = \left[\frac{(\alpha_1^2 + \beta_1^2)^{1/2} + \alpha_1}{2}\right]^{1/2} - i\left[\frac{(\alpha_1^2 + \beta_1^2)^{1/2} - \alpha_1}{2}\right]^{1/2} \tag{36}$$

$$\alpha_1 = 1 + \left(\frac{n_0 \sin \theta_0}{n_1^2 + k_1^2}\right)^2 (k_1^2 - n_1^2) \tag{37}$$

and

$$\beta_1 = -2n_1 k_1 \left(\frac{n_0 \sin \theta_0}{n_1^2 + k_1^2}\right)^2 \tag{38}$$

Abelès' method[8] also uses effective indexes for the absorbing material, but they are calculated differently:

$$\tilde{\eta}_{1s} = a - ib \tag{39}$$

$$\tilde{\eta}_{1p} = c - id \tag{40}$$

where

$$a^2 - b^2 = n_1^2 - k_1^2 - n_0^2 \sin^2 \theta_0 \tag{41}$$

$$ab = n_1 k_1 \tag{42}$$

$$c = a\left(1 + \frac{n_0^2 \sin^2 \theta_0}{a^2 + b^2}\right) \tag{43}$$

$$d = b\left(1 - \frac{n_0^2 \sin^2 \theta_0}{a^2 + b^2}\right) \tag{44}$$

In both methods employing effective indexes, the amplitude reflection coefficients are

$$r_s = \frac{\eta_{0s} - \eta_{1s}}{\eta_{0s} + \eta_{1s}} \tag{45}$$

$$r_p = \frac{\eta_{1p} - \eta_{0p}}{\eta_{1p} + \eta_{0p}} \tag{46}$$

which are equivalent to Eqs. (29) and (30) and reduce to Eqs. (11) and (12) when $k_1 = 0$. The intensity reflection coefficients are given by Eq. (31), as before. At normal incidence,

$$R_s = R_p = \frac{(n_0 - n_1)^2 + k_1^2}{(n_0 + n_1)^2 + k_1^2} \tag{47}$$

Values of R_s and R_p are plotted as a function of angle of incidence in Fig. 2 for various values of n_1 and k_1. (The incident medium is assumed to be air with $n_0 = 1$ unless otherwise noted.) As n_1 increases with $k_1 > 0$ held constant, the magnitudes of R_s and R_p at normal incidence both decrease. As k_1 increases with n_1 held constant, the magnitudes of R_s and R_p at normal incidence both increase. Tables of R_s and R_p for various values of n_1 and k_1 are given for angles of incidence from 0 to 85° by Holl.[9]

The absolute phase changes on reflection δ_s and δ_p are also of interest in problems involving polarization. When the material is nonabsorbing, the phase changes can be determined from the amplitude reflection coefficients, Eqs. (11) and (12); when $\theta_0 = 0$ and $n_1 > n_0$, $\delta_s = 180°$ and $\delta_p = 360°$.† This is an apparent contradiction since at normal incidence the s and p components should be indistinguishable. However, the problem is resolved by recalling that by convention we are always looking against the direction of propagation of the light (see Fig. 1). To avoid complications, the phase change on reflection at normal incidence (often defined as β) is identified with δ_s.

For a dielectric, if $n_0 < n_1$, δ_s remains 180° for all angles of incidence from 0 to 90°, as can be seen from the numerator of Eq. (11). However, there is an abrupt discontinuity in δ_p, as can be seen from Eq. (12). If $n_0 < n_1$, $\delta_p = 360°$† at normal incidence and at larger angles for which the numerator of Eq. (12) is positive. Since $\cos\theta_0$ becomes increasingly less than $\cos\theta_1$ as θ_0 increases, and since $n_1 > n_0$, there will be an angle for which $n_1 \cos\theta_0 = n_0 \cos\theta_1$. At this angle δ_p undergoes an abrupt change from 360 to 180°, and it remains 180° for larger angles of incidence. At the transition value of θ_0, which is called the *Brewster angle* θ_B since $R_p = 0$,

$$\tan\theta_B = \frac{n_1}{n_0} \tag{48}$$

(This angle is also called the *polarizing angle* since $\theta_0 + \theta_1 = 90°$.)

The phase changes δ_s and δ_p are not simply 360 or 180° for an absorbing material. At normal incidence it follows from Eq. (45) that

$$\tan\delta_s = \frac{2n_0k_1}{n_0^2 - n_1^2 - k_1^2} \tag{49}$$

† Since 360° and 0° are indistinguishable, many optics books state that $\delta_p = 0°$ for dielectrics at normal incidence, but this makes the ellipsometric parameter $\Delta = \delta_p - \delta_s < 0$, which is incompatible with ellipsometric conventions—see the section on Ellipsometry.

so that $\delta_s = 180°$ only if $k_1 = 0$. As before, $\delta_p = \delta_s + 180°$, as seen by comparing Eqs. (45) and (46). At nonnormal incidence

$$\tan \delta_s = \frac{2\eta_{0s} b}{\eta_{0s}^2 - a^2 - b^2} \tag{50}$$

and

$$\tan \delta_p = \frac{-2\eta_{0p} d}{c^2 + d^2 - \eta_{0p}^2} \tag{51}$$

where the relations for *a, b, c,* and *d* have been given in Eqs. (41) to (44). The following relations between these quantities may also prove helpful:

$$a^2 + b^2 = [(n_1^2 - k_1^2 - n_0^2 \sin^2 \theta_0)^2 + 4n_1^2 k_1^2]^{1/2} \tag{52}$$

$$c^2 + d^2 = \frac{(n_1^2 + k_1^2)^2}{a^2 + b^2} \tag{53}$$

$$b^2 = \frac{n_1^2 - k_1^2 - n_0^2 \sin^2 \theta_0}{2} + \frac{a^2 + b^2}{2} \tag{54}$$

Figure 3 shows how δ_s and δ_p change as a function of angle of incidence for an absorbing material. At normal incidence they are 180° apart because of the mirror-image effect, mentioned previously. As the angle of incidence increases, δ_p approaches δ_s, and at the *principal angle* $\bar{\theta}$ the two quantities differ by only 90°. At grazing incidence they coincide.

The reflectance R_p does not reach zero for an absorbing material as it does for a dielectric, but the angle for which it is a minimum is called the *pseudo Brewster angle* θ_B'. Two other angles closely associated with the pseudo Brewster are also of interest. The angle for which the ratio R_p/R_s is a minimum is sometimes called the *second Brewster*

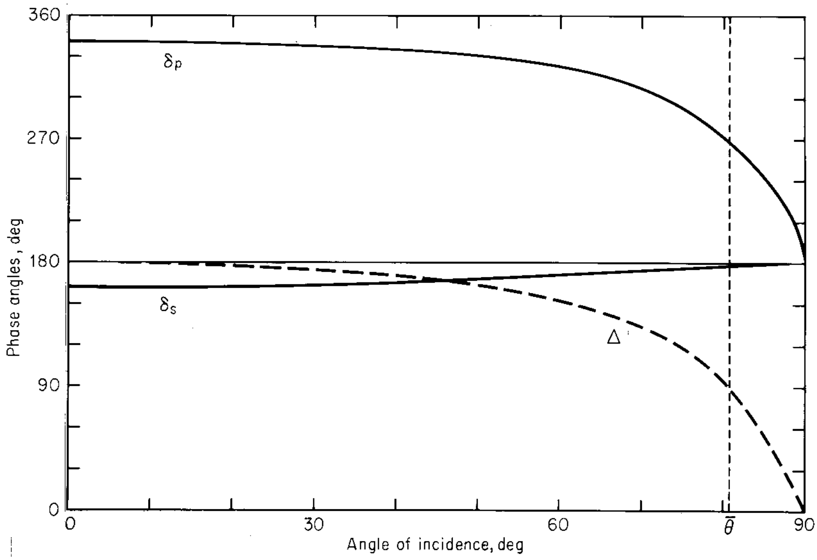

FIGURE 3 Phase changes on reflection δ_s and δ_p and phase difference $\Delta = \delta_p - \delta_s$ as a function of angle of incidence for an absorbing material. The principal angle, for which $\Delta = 90°$, is also shown. [*Bennett and Bennett, Ref.* 10.]

angle. It is generally only slightly larger than θ_B'. The *principal angle* $\bar{\theta}$, at which $\delta_p - \delta_s = 90°$, is always larger than the second Brewster angle and θ_B'. For most metals θ_B' and $\bar{\theta}$ are only a fraction of a degree apart, but it is possible for them to differ by as much as 45°.[9] There is no polarizing angle as such for an absorbing material because the angle of refraction is complex.

3. Basic Relations for Polarizers A linear[†] polarizer is anything which when placed in an incident unpolarized beam produces a beam of light whose electric vector is vibrating primarily in one plane, with only a small component vibrating in the plane perpendicular to it. If a polarizer is placed in a plane-polarized beam and is rotated about an axis parallel to the beam direction, the transmittance T will vary between a maximum value T_1 and a minimum value T_2 according to the law

$$T = (T_1 - T_2)\cos^2\theta + T_2 \tag{55}$$

Although the quantities T_1 and T_2 are called the *principal transmittances,* in general $T_1 \gg T_2$; θ is the angle between the plane of the principal transmittance T_1 and the plane of vibration (of the electric vector) of the incident beam. If the polarizer is placed in a beam of unpolarized light, its transmittance is

$$T = \tfrac{1}{2}(T_1 + T_2) \tag{56}$$

so that a perfect polarizer would transmit only 50 percent of an incident unpolarized beam.[‡]

When two identical polarizers are placed in an unpolarized beam, the resulting transmittance will be

$$T_\parallel = \tfrac{1}{2}(T_1^2 + T_2^2) \tag{57}$$

when their principal transmittance directions are parallel and will be

$$T_\perp = T_1 T_2 \tag{58}$$

when they are perpendicular. In general, if the directions of principal transmittance are inclined at an angle θ to each other, the transmittance of the pair will be

$$T_\theta = \tfrac{1}{2}(T_1^2 + T_2^2)\cos^2\theta + T_1 T_2 \sin^2\theta \tag{59}$$

The polarizing properties of a polarizer are generally defined in terms of its *degree of polarization* P[§,‖]

$$P = \frac{T_1 - T_2}{T_1 + T_2} \tag{60}$$

or its *extinction ratio* ρ_p

$$\rho_p = \frac{T_2}{T_1} \tag{61}$$

When one deals with nonnormal-incidence reflection polarizers, one generally writes P

[†] Circular polarizers are discussed in Par. 6.

[‡] Jones[11] has pointed out that a perfect polarizer can transmit more than 50 percent of an incident unpolarized beam under certain conditions.

[§] Bird and Shurcliff[12] distinguish between *degree of polarization,* which is a constant of the light beam, and *polarizance,* which is a constant of the polarizer. The polarizance is defined as being equal to the degree of polarization the polarizer produces in an incident monochromatic beam that is unpolarized. In practice, incident beams are often slightly polarized, so that the polarizance values differ slightly from the ideal degree of polarization. Other authors have not followed this distinction.

[‖] Authors dealing with topics such as scattering from aerosols sometimes define *degree of polarization* (of the scattered light) in terms of the Stokes vectors (Par. 7) as $P = (S_1^2 + S_2^2 + S_3^2)^{1/2}/S_0$.

and ρ_p in terms of R_p and R_s, the reflectances of light polarized parallel and perpendicular to the plane of incidence, respectively. As will be shown in Par. 4, R_s can be equated to T_1 and R_p to T_2, so that Eqs. (60) and (61) become $P = (R_s - R_p)/(R_s + R_p)$ and $\rho_p = R_p/R_s$. If either ρ_p or P is known, the other can be deduced since

$$P = \frac{1 - \rho_p}{1 + \rho_p} \tag{62}$$

and

$$\rho_p = \frac{1 - P}{1 + P} \tag{63}$$

If one is determining the degree of polarization or the extinction ratio of a polarizer, the ratio of $T_\perp$ to $T_\parallel$ can be measured for two identical polarizers in unpolarized light. From Eqs. (57) and (58),

$$\frac{T_\perp}{T_\parallel} = \frac{T_1 T_2}{(T_1^2 + T_2^2)/2} \approx \frac{2T_2}{T_1} = 2\rho_p \tag{64}$$

if $T_2^2 \ll T_1^2$. If a perfect polarizer or a source of perfectly plane-polarized light is available, T_2/T_1 can be determined directly by measuring the ratio of the minimum to the maximum transmittance of the polarizer. Other relations for two identical partial polarizers are given by West and Jones,[13] as well as the transmittance $T_{\theta ab}$ of two dissimilar partial polarizers *a* and *b* whose principal axes are inclined at an angle θ with respect to each other. This latter expression is

$$T_{\theta ab} = \tfrac{1}{2}(T_{1a}T_{1b} + T_{2a}T_{2b}) \cos^2\theta + \tfrac{1}{2}(T_{1a}T_{2b} + T_{1b}T_{2a}) \sin^2\theta \tag{65}$$

where the subscripts 1 and 2 refer to the principal transmittances, as before.

Spectrophotometric measurements can involve polarizers and dichroic samples. Dichroic (optically anisotropic) materials are those which absorb light polarized in one direction more strongly than light polarized at right angles to that direction. (Dichroic materials are to be distinguished from birefringent materials, which may have different refractive indices for the two electric vectors vibrating at right angles to each other but similar, usually negligible, absorption coefficients.) When making spectrophotometric measurements, one should know the degree of polarization of the polarizer and how to correct for instrumental polarization. This latter quantity may arise from nonnormal-incidence reflections from a grating, dispersing prism, or mirrors. Light sources are also sometimes polarized. Simon,[14] Charney,[15] Gonatas *et al.*,[16] and Wizinowich[17] suggest methods for dealing with imperfect polarizers, dichroic samples, and instrumental polarization. In addition, when a dichroic sample is placed between a polarizer and a spectrophotometer which itself acts like an imperfect polarizer, one has effectively three polarizers in series. This situation has been treated by Jones,[18] who showed that anomalies can arise when the phase retardation of the polarizers takes on certain values. Mielenz and Eckerle[19] have discussed the accuracy of various types of polarization attenuators.

4. Polarization by Nonnormal-Incidence Reflection (Pile of Plates) Pile-of-plates polarizers make use of reflection or transmission of light at nonnormal incidence, frequently near the Brewster or polarizing angle [Eq. (48) in Par. 2]. The extinction ratio and "transmittance" of these polarizers can be calculated directly from the Fresnel equations. Some simplifications occur for nonabsorbing or slightly absorbing plates. Equations (20) and (21) give the values of the intensity reflection coefficients R_s and R_p for light vibrating perpendicular to the plane of incidence (*s* component) and parallel to the plane of incidence (*p* component). The angle of refraction θ_1 in those equations is related

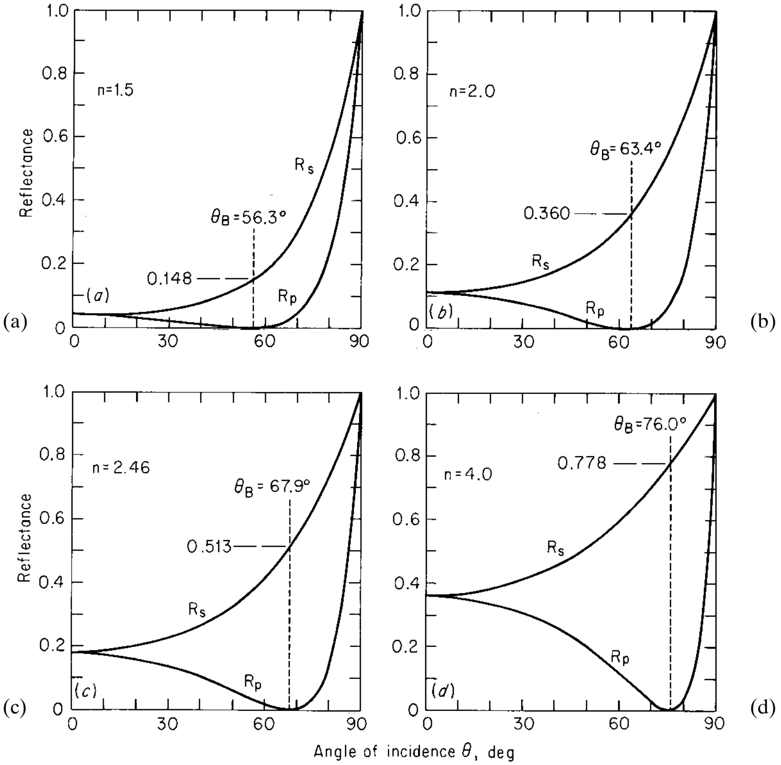

FIGURE 4 Reflectance of light polarized parallel R_p and perpendicular R_s to the plane of incidence from materials of different refractive index n as a function of angle of incidence: (*a*) $n = 1.5$ (alkali halides in ultraviolet and sheet plastics in infrared), (*b*) $n = 2.0$ (AgCl in infrared), (*c*) $n = 2.46$ (Se in infrared), and (*d*) $n = 4.0$ (Ge in infrared). The Brewster angle θ_B (at which R_p goes to 0) and the magnitude of R_s at θ_B are also indicated.

to the refractive index n of the material by Snell's law [Eq. (15)†]. At the Brewster angle $R_p = 0$, so that the reflected light is, in principle, completely plane-polarized. This is the basis for all Brewster angle reflection polarizers.

Let us now see how the characteristics of a reflection polarizer depend on its refractive index. In Fig. 4 the reflectances R_s and R_p have been plotted for different values of the refractive index, roughly representing alkali halides in the ultraviolet and sheet-plastic materials, silver chloride, selenium, and germanium in the infrared. The Brewster angle, given by Eq. (48), is also indicated, as well as the magnitude of R_s at the Brewster angle. We note from these graphs that if light is polarized by a single reflection from a nonabsorbing material, the polarizer with the highest refractive index will have the largest throughput. In reflection polarizers, the quantity R_s is essentially the principal "transmittance" of the polarizer [T_1 in Eqs. (55) to (65)] except that it must be multipled by the reflectance of any other mirrors used to return the beam to its axial position.

The reflectance R_p can be equated to T_2, the minimum "transmittance" of the polarizer, so that the extinction ratio ρ_p of a reflection polarizer [Eq. (61)] is $\rho_p = R_p/R_s$. If R_p is

† Since we are assuming that the medium of incidence is air, $n_0 = 1$ and $n_1 = n$, the refractive index of the material.

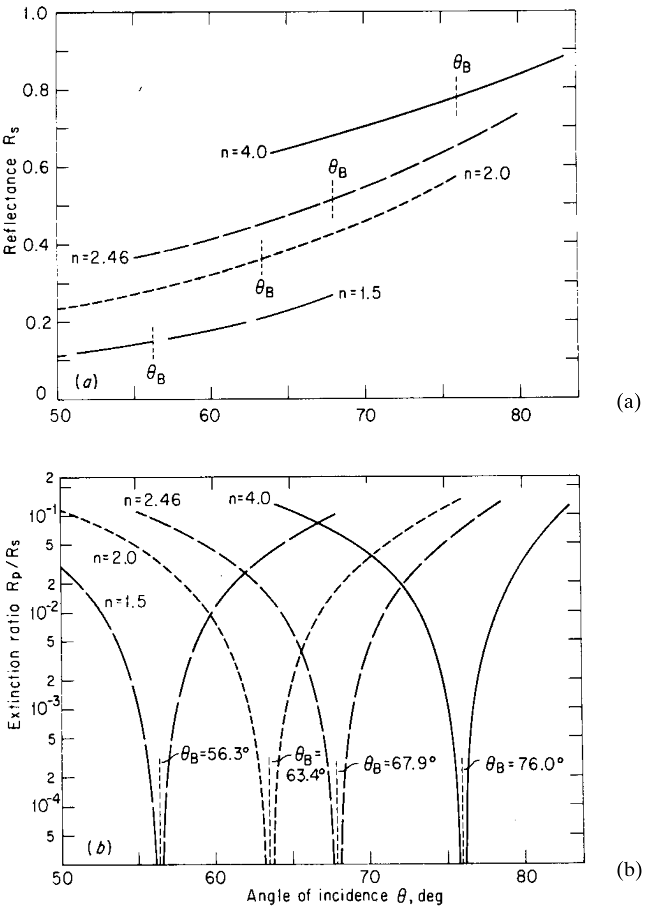

FIGURE 5 (*a*) Reflectance R_s and (*b*) extinction ratio R_p/R_s for materials of different refractive index at angles near the Brewster angle θ_B. A single surface of the material is assumed.

really zero at the Brewster angle, the extinction ratio will be zero for all materials *independent of the value of n.* If a given extinction ratio is desired, for example, 10^{-3} [corresponding to 99.8 percent polarization; see Eq. (62)], then the convergence angle of the light beam must be small so that all the angles of incidence lie within about ±1° of the Brewster angle. The convergence angle depends only weakly on the refractive index for this case, varying from ±1.2° for $n = 1.5$ to ±0.8° for $n = 4.0$.

If a good extinction ratio is required for a beam of larger convergence angle, two polarizing reflections may be used. Then all the exponents in Fig. 5*b* are doubled, and the convergence angles for a given extinction ratio are greatly increased. To obtain a value of 10^{-3} with two reflections, the angle of incidence must be within about ±6° of the Brewster angle for values of n less than 3.5; for $n = 4$ it is reduced slightly and becomes more asymmetric (+4.0 and −5.2°). A disadvantage of having two reflections from the polarizing materials is that the throughput is reduced. All the values of R_s in Fig. 5*a* are squared, so that for $n = 4$, $R_s = 0.78$ but $R_s^2 = 0.61$; for smaller refractive indexes the reduction in throughput is much greater.

The information shown graphically in Figs. 4 and 5 is given analytically in a paper by Azzam[20] who is concerned about the angular sensitivity of Brewster-angle reflection polarizers, particularly those made with silicon or germanium plates. Also, Murty and Shukla[21] show analytically that the shadowy extinction patterns sometimes seen with a crossed Brewster angle reflection polarizer and analyzer are caused by light incident on the surfaces at angles different from the Brewster angle.

Although in many cases multiple reflections within a plate degrade its polarizing properties, this is not true for Brewster angle reflection polarizers. For multiple reflections within a plane-parallel plate of material

$$(R_{s,p})_{\text{plate}} = \frac{2R_{s,p}}{1 + R_{s,p}} \tag{66}$$

assuming no interference or absorption; R_s and R_p are given by Eqs. (20) and (21). Multiple reflections have a minor effect on the extinction ratio but the increase in R_s is appreciable. To fulfill the conditions of Eq. (66), the plate must have plane-parallel sides and be unbacked. We are also assuming that the plate is thick or nonuniform enough for interference effects within it to be neglected.

All the preceding discussion applies only to nonabsorbing materials. If a small amount of absorption is present, R_p will have a minimum that is very close to zero and the material will still make a good reflection polarizer. However, if the extinction coefficient k becomes appreciable, the minimum in R_p will increase and the polarizing efficiency will be degraded. By referring to Fig. 2 one can see roughly what the ratio of R_p to R_s will be for a given set of optical constants. Exact values of R_p and R_s can be calculated from n and k using Eqs. (45), (46), (31), and the other pertinent relations in Par. 2. When choosing materials for possible use as metallic reflection polarizers, one wants the largest difference between R_s and R_p and the smallest magnitude of R_p at the minimum. Thus, ideally n should be much larger than k.

The Abelès condition[22] applies to the amplitude reflectances r_s and r_p for either dielectrics or metals at 45° angle of incidence. At this angle

$$r_s^2 = r_p \tag{67}$$

and

$$2\delta_s = \delta_p \tag{68}$$

where the δ's are the absolute phase changes on reflection for the p and s components (see Par. 2). Relation (67) is frequently applied to the intensity reflectances R_s and R_p, which are directly related to the amplitude reflectances [Eqs. (20), (21), and (31)].

5. Polarization by Nonnormal-Incidence Transmission (Pile of Plates) The theory of Brewster angle transmission polarizers follows directly from that given for reflection polarizers. Table 1 lists the relations giving the s and p transmittances of the polarizers with various assumptions about multiple reflections, interference, absorption, etc.† All these relations contain R_s and R_p, the reflectances at a single interface, which are given at the bottom of the table.

At the Brewster angle, R_p at a single interface equals zero, and the transmittances of the plates can be expressed in terms of the refractive index of the material and the number of plates. The relations for the s and p transmittances at this angle are given in Table 2. Most references that contain an expression for the degree of polarization of a pile of plates give the formula of Provostaye and Desains,[23] which assumes an infinite series of multiple reflections between all surfaces, i.e., multiple reflections within and between plates. This

† Transmission polarizers in which the multiply internally reflected beams are coherent and produce interference effects are discussed in Chap. 3, "Polarizers," in Vol. II of this Handbook.

§ Multiple reflections between plates.

‖ Formula of Provostaye and Desains, Ref. 23.

¶ Also holds for coherent multiple reflections averaged over one period of $\sin^2\gamma$.

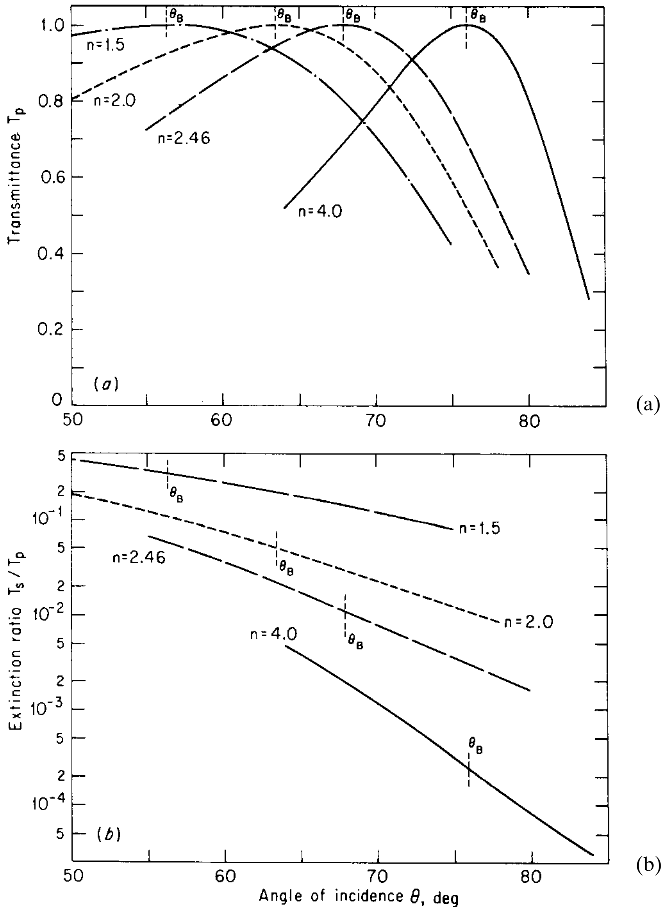

FIGURE 6 (*a*) Transmittance and (*b*) extinction ratio of four plane-parallel plates of refractive index *n* as a function of angle of incidence, for angles near the Brewster angle. Assumptions are multiple reflections but no interference within each plate and no reflections between plates.

assumption is not valid for most real transmission polarizers (see Chap. 3, "Polarizers," in Vol. II of this Handbook, specifically Brewster Angle Transmission Polarizers).

For most parallel-plate polarizers it is reasonable to assume incoherent multiple reflections within each plate and no reflections between plates. Figure 6 shows the principal transmittance (*p* component) and extinction ratio for several four-plate polarizers having the refractive indexes indicated.† The extinction ratio improves considerably with increasing refractive index. It is also improved by using the plates at an angle of incidence slightly above the Brewster angle. This procedure, which is most helpful for high refractive index plates, reduces the transmission per plate so that a trade-off is required between losses resulting from absorption or scattering when many plates are used and the

† The extinction ratio of a pile of *m* plates (no multiple reflections between plates) is simply the product of the extinction ratios of the individual plates.

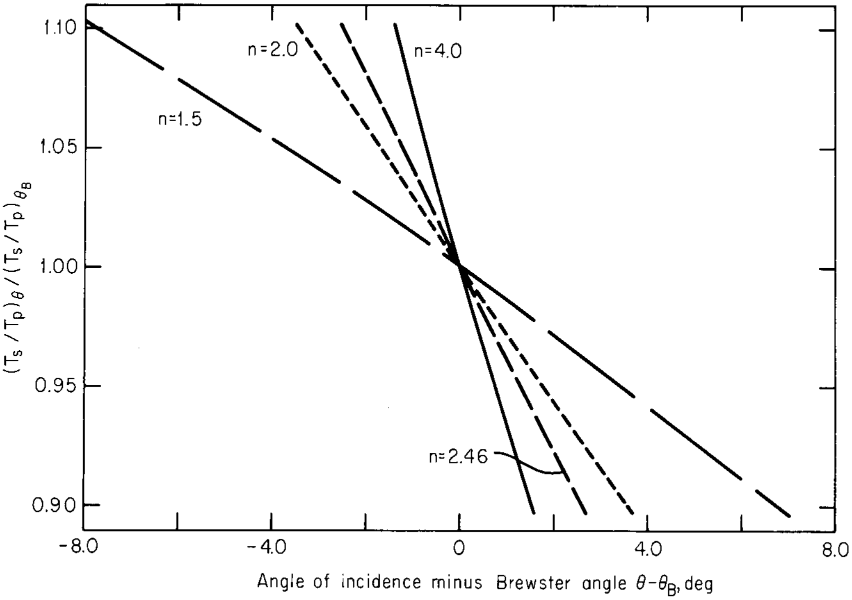

FIGURE 7 Variation of extinction ratio (per film) as a function of angle near the Brewster angle $\theta - \theta_B$. The ordinate is the extinction ratio at θ divided by the extinction ratio at θ_B.

reflectance loss per plate when only a few plates are used above the Brewster angle. In some cases significant improvements have been achieved by following the latter course.[24]

When the number of plates of a given refractive index is increased, the transmittance is unaffected (in the absence of absorption) and the extinction ratio is greatly increased, as shown in the earlier Polarization chapter.[1] In the absence of absorption, comparable transmittances and extinction ratios are obtained with a large number of low-refractive-index plates or a small number of high refractive index plates. Small amounts of absorption decrease the transmittance, but have little effect on the extinction ratio.[1] Tuckerman[25] has derived exact expressions for light reflected from or transmitted through a pile of absorbing plates. He has also noted mistakes that have been perpetuated in some of the formulas for light reflected from or transmitted through a pile of nonabsorbing plates.

A figure of merit giving the variation of the extinction ratio with angle of incidence can be defined as in Fig. 7, where the ordinate is the extinction ratio at a given angle of incidence divided by the extinction ratio at the Brewster angle. The angles of incidence are referred to the Brewster angle, and curves for different values of the refractive index are shown. These curves are calculated from the ratio

$$\frac{\left(\dfrac{T_s}{T_p}\right)_\theta}{\left(\dfrac{T_s}{T_p}\right)_{\theta_B}} = \frac{\left(\dfrac{1-R_s}{1+R_s}\,\dfrac{1+R_p}{1-R_p}\right)_\theta}{\left(\dfrac{1-R_s}{1+R_s}\right)^{\theta_B}} \tag{69}$$

and are for a single transparent film or plate having multiple incoherent internal reflections within the material. As an example of how to use the graphs, consider an optical system having a two-plate germanium polarizer with a refractive index of 4.0. If the angles of incidence vary from −1.4 to +1.5° around the Brewster angle, the ratio of the extinction ratios will vary between $1.10^2 = 1.21$ and $0.90^2 = 0.81$, respectively. (For *m* plates it would be 1.10^m and 0.90^m.) Thus, in order to restrict the percent variation of the extinction ratio to a given value, one must use a smaller acceptance angle when using more plates.

We have assumed that there are multiple incoherent reflections within each plate and no multiple reflections between plates. The difference in extinction ratios for a series of four plates with and without internal reflections is shown in Fig. 8. The principal transmittance is essentially the same as in Fig. 6 for values of T_p above 0.70 (and only about 0.025 lower when T_p drops to 0.30). However, the extinction ratio of high-refractive-index

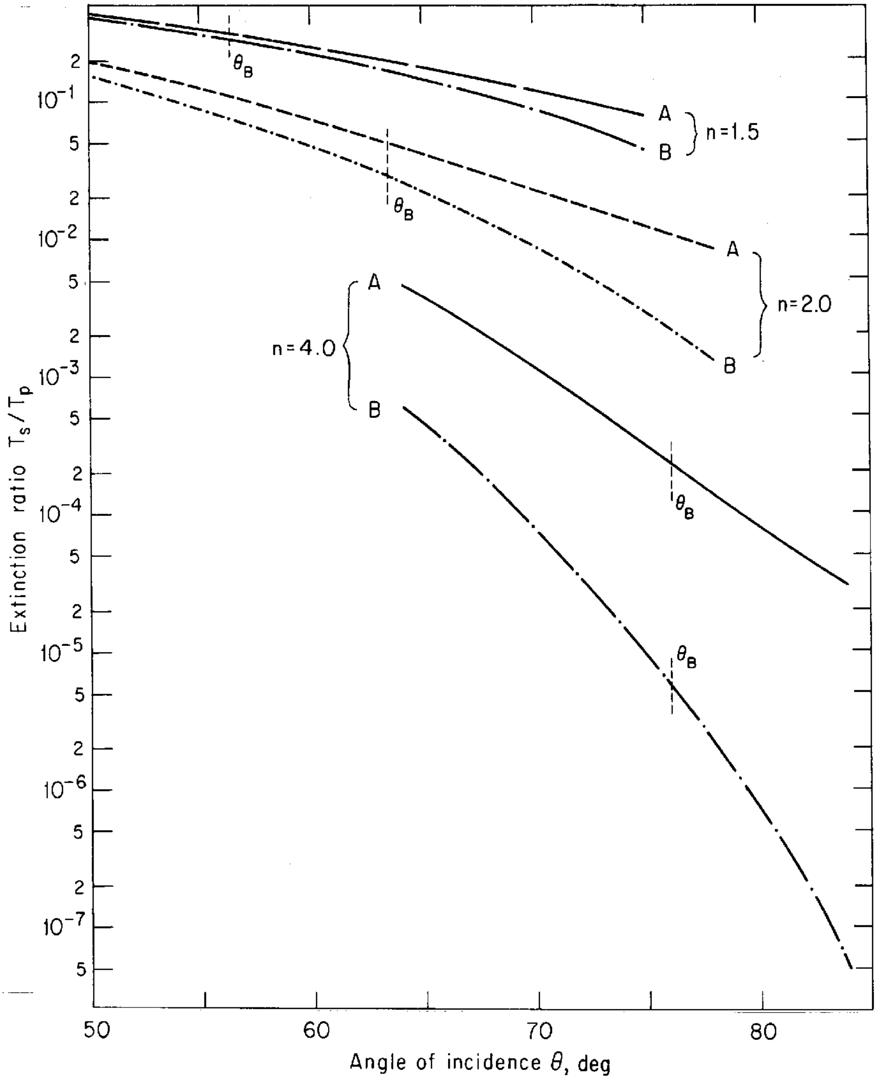

FIGURE 8 Extinction ratio of four plane-parallel plates of refractive index n as a function of angle of incidence for angles near the Brewster angle. Assumptions are A, multiple reflections but no interference within each plate and no reflections between plates; B, no multiple reflections within each plate or between plates. The transmittances for conditions A and B are essentially identical (see Fig. 6a).

materials is much better without multiple internal reflections; for low-refractive-index materials the difference in extinction ratios is small.

The effect of multiple reflections on the extinction ratio can readily be seen from the three relations for the transmittances of the *p* and *s* components:

No multiple reflections:

$$(T_{s,p})_{\text{sample}} = (1 - R_{s,p})^{2m} = 1 - 2mR_{s,p} + 2m^2R_{s,p}^2 - mR_{s,p}^2 + \cdots \tag{70}$$

Multiple reflections within plates:

$$(T_{s,p})_{\text{sample}} = \left(\frac{1 - R_{s,p}}{1 + R_{s,p}}\right)^m = 1 - 2mR_{s,p} + 2m^2R_{s,p}^2 + \cdots \tag{71}$$

Multiple reflections within and between plates:

$$(T_{s,p})_{\text{sample}} = \frac{1 - R_{s,p}}{1 + (2m - 1)R_{s,p}} = 1 - 2mR_{s,p} + 4m^2R_{s,p} - 2mR_{s,p}^2 + \cdots \tag{72}$$

At the Brewster angle, $R_p = 0$, $T_p = 1$, and the extinction ratio will be smallest, i.e., highest degree of polarization, for the smallest values of the *s* transmittance. The first three terms in Eqs. (70) and (71) are identical, but Eq. (70) has an additional negative term in R_s^2 and so it will give a slightly smaller value of the *s* transmittance. Equation (72), from which the formula of Provostaye and Desains was derived, has twice as large a third term as the other two equations, and the negative fourth term is only $1/2m$ of the third term, so that it does not reduce the overall value of the expression appreciably. Thus, Eq. (72) gives an appreciably larger value of the *s* transmittance, but fortunately it is a limiting case and is rarely encountered experimentally.

6. Quarter-Wave Plates and Other Phase Retardation Plates A retardation plate is a piece of birefringent, uniaxial (or uniaxial-appearing) material in which the ordinary and extraordinary rays travel at different velocities. Thus, one ray is retarded relative to the other, and the path $N\lambda$ between the two rays is given by

$$N\lambda = \pm d(n_e - n_o) \tag{73}$$

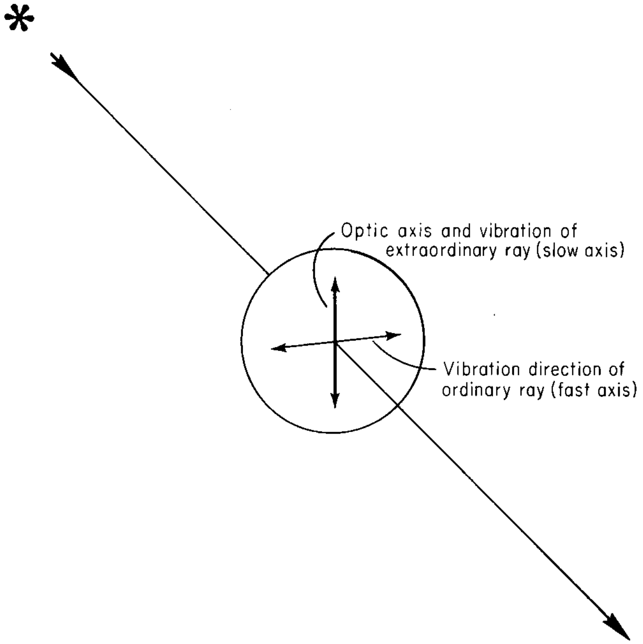
where n_o = refractive index of ordinary ray
n_e = refractive index of extraordinary ray
d = physical thickness of plate
λ = wavelength

The positive sign is used when $n_e > n_o$, that is, a positive uniaxial crystal, and the negative sign is used for a negative uniaxial crystal, for which $n_e < n_o$. Since $N\lambda$ is the path difference between the two rays, N can be considered the retardation expressed in fractions of a wavelength. For example, $N = 1/4$ for a quarter-wave (or $\lambda/4$) plate, 1/2 for a half-wave (or $\lambda/2$) plate, 3/4 for a three-quarter-wave (or $3\lambda/4$) plate, etc.

The phase difference between two rays traveling through a birefringent material is $2\pi/\lambda$ times the path difference, so that the phase retardation δ is

$$\delta = 2\pi N = \pm \frac{2\pi d(n_e - n_o)}{\lambda} \tag{74}$$

Thus, phase differences of $\pi/2$, π, and $3\pi/2$ are introduced between the two beams in quarter-wave, half-wave, and three-quarter-wave plates, respectively.



Optic axis and vibration of extraordinary ray (slow axis)
Vibration direction of ordinary ray (fast axis)

FIGURE 9 Light incident normally on the front surface of a retardation plate showing the vibration directions of the ordinary and extraordinary rays. In a positive uniaxial crystal, the fast and slow axes are as indicated in parentheses; in a negative uniaxial crystal, the two axes are interchanged.

A retardation plate can be made from a crystal which is cut so that the optic axis lies in a plane parallel to the face of the plate, as shown in Fig. 9. Consider a beam of unpolarized or plane-polarized light normally incident on the crystal. It can be resolved into two components traveling along the same path through the crystal but vibrating at right angles to each other. The ordinary ray vibrates in a direction perpendicular to the optic axis, while the extraordinary ray vibrates in a direction parallel to the optic axis. In a positive uniaxial crystal $n_e > n_o$, so that the extraordinary ray travels more slowly than the ordinary ray. The fast axis is defined as the direction in which the faster-moving ray vibrates; thus in a positive uniaxial crystal, the fast axis (ordinary ray) is perpendicular to the optic axis, while the slow axis (extraordinary ray) coincides with the optic axis. For a negative uniaxial crystal, the fast axis coincides with the optic axis.

Figure 10 shows how the state of polarization of a light wave changes after passing through retardation plates of various thicknesses when the incident light is plane-polarized at an azimuth of 45° to the fast axis of the plate. If the plate has a retardation of $\lambda/8$, which means that the ordinary and extraordinary waves are out of phase by $\pi/4$ with each other, the transmitted light will be elliptically polarized with the major axis of the ellipse coinciding with the axis of the original plane-polarized beam. As the retardation gradually increases (plate gets thicker for a given wavelength or wavelength gets shorter for a given plate thickness), the ellipse gradually turns into a circle, but its major axis remains at 45° to the fast axis of the retardation plate. For a retardation of $\lambda/4$, the emerging light is right circularly polarized. As the retardation continues to increase, the transmitted light becomes elliptically polarized with the major axis of the ellipse lying perpendicular to the plane of the incident polarized beam, and then the minor axis of the ellipse shrinks to zero

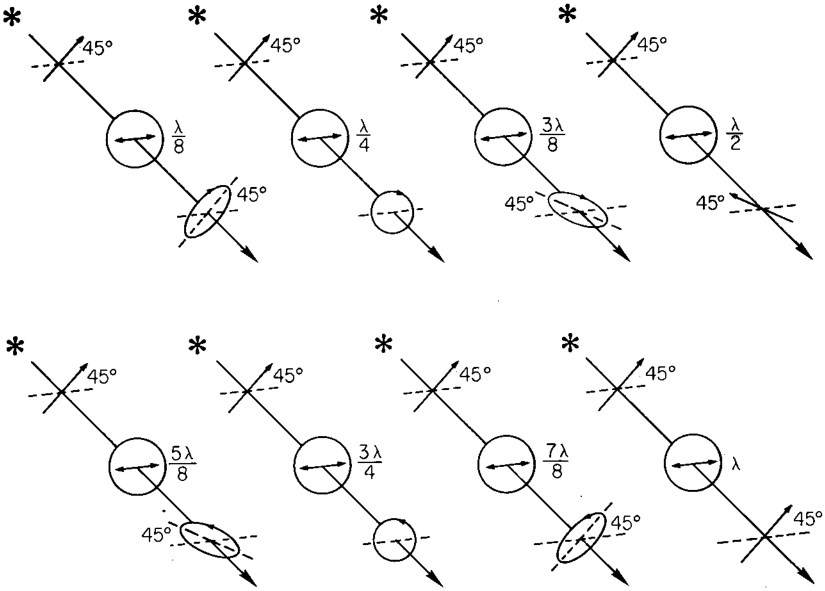


FIGURE 10 State of polarization of a light wave after passing through a crystal plate whose retardation is indicated in fractions of a wavelength (phase retardation $2\pi/\lambda$ times these values) and whose fast axis is indicated by the double arrow. In all cases the incident light is plane-polarized at an azimuth of 45° to the direction of the fast axis.

and plane-polarized light is produced when the retardation becomes $\lambda/2$. As the retardation increases further, the patterns change in opposite order and the polarized light is left circularly polarized when the retardation equals $3\lambda/4$. Finally, when the retardation is a full wave, the incident plane-polarized light is transmitted unchanged although the slow wave has now been retarded by a full wavelength relative to the fast wave.

The most common type of retardation plate is the quarter-wave plate. Figure 11 shows how this plate affects the state of polarization of light passing through it when the fast axis is positioned in the horizontal plane and the azimuth of the incident plane-polarized light is changed from $\theta = 0°$ to $\theta = 90°$. When $\theta = 0°$, only the ordinary ray (for a positive birefringent material) passes through the plate, so that the state of polarization of the beam is unchanged. When θ starts increasing, the transmitted beam is elliptically polarized with the major axis of the ellipse lying along the fast axis of the $\lambda/4$ plate; $\tan\theta = b/a$, the

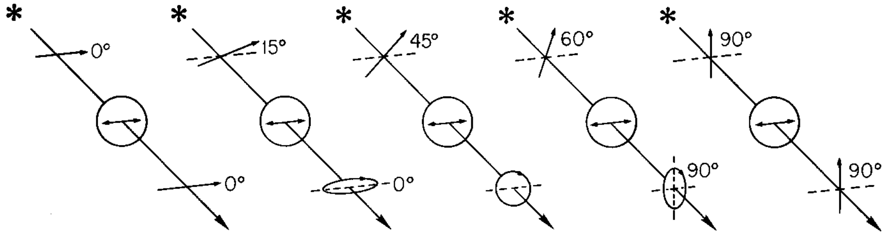

FIGURE 11 State of polarization of a light wave after passing through a $\lambda/4$ plate (whose fast axis is indicated by the double arrow) for different azimuths of the incident plane-polarized beam.

ratio of the minor to the major axis of the ellipse. In the next case, $\theta = 15°$ and $\tan\theta = 0.268$, and so the ellipse is long and narrow. When the plane of vibration has rotated to an azimuth of 45°, the emerging beam is right circularly polarized (the same situation as that shown in the second part of Fig. 10). For values of θ between 45 and 90°, the light is again elliptically polarized, this time with the major axis of the ellipse lying along the direction of the slow axis of the $\lambda/4$ plate. The angle shown in the figure is 60°, and $\tan 60° = 1.732$, so that b/a (referred to the fast axis) is greater than unity. When θ increases to 90°, the plane of vibration coincides with the slow axis and the transmitted light is again plane-polarized. As θ continues to increase, the transmitted patterns repeat those already described and are symmetric about the slow axis, but the direction of rotation in the ellipse changes from right-handed to left-handed, so that left-circularly polarized light is produced when $\theta = 135°$.

The definition of right- and left-circularly polarized light should be clear from Figs. 10 and 11. When the rotation is *clockwise* with the observer looking *opposite to the direction of propagation,* the light is called *right-circularly polarized*; if the rotation is *counterclockwise,* the light is called *left-circularly polarized.*[26] When circularly polarized light is reflected from a mirror, the direction of propagation is reversed, so that the sense of the circular polarization changes; i.e., left-circularly polarized light changes on reflection into right-circularly polarized light and vice versa. Therefore, in experiments involving magnetic fields in which the sense of the circularly polarized light is important,[27,28] it is important to know which kind one started with and how many mirror reflections occurred in the rest of the light path. Cyclotron resonance experiments can sometimes be used to determine the sense of the circular polarization.[28] Another method utilizing a polarizer and $\lambda/4$ plate has been described by Wood.[29]

The behavior of a half-wave plate in a beam of plane-polarized light is completely different from that of a quarter-wave plate; the transmitted light is always plane-polarized. If the incident plane of vibration is at an azimuth θ with respect to the fast axis of the $\lambda/2$ plate, the transmitted beam will be rotated through an angle 2θ relative to the azimuth of the incident beam. The case showing $\theta = 45°$ where the phase of vibration is rotated through 90° is illustrated in the fourth part of Fig. 10. In this situation the extraordinary beam is retarded by half a wavelength relative to the ordinary beam (for a positive birefringent material), hence the name, half-wave plate. If the polarizer is fixed and the $\lambda/2$ plate is rotated (or vice versa), the plane of vibration of the transmitted beam will rotate at twice the frequency of rotation of the $\lambda/2$ plate.

Quarter-wave plates are useful for analyzing all kinds of polarized light. In addition, they are widely employed in experiments using polarized light, e.g., measurements of the thickness and refractive index of thin films by ellipsometry or measurements of optical rotary dispersion, circular dichroism, or strain birefringence. Polarizing microscopes, interference microscopes, and petrographic microscopes are usually equipped with $\lambda/4$ plates. In some applications the $\lambda/4$ plate is needed only to produce circularly polarized light, e.g., for optical pumping in some laser experiments, or to convert a partially polarized light source into one which appears unpolarized, i.e., has equal amplitudes of vibration in all azimuths. For these and similar applications, one can sometimes use a circular polarizer which does not have all the other properties of a $\lambda/4$ plate (see Pars. 73 to 76 in Ref. 1).

The customary application for a $\lambda/2$ plate is to rotate the plane of polarization through an angle of 90°. In other applications the angle of rotation can be variable. Automatic setting ellipsometers or polarimeters sometimes employ rotating $\lambda/2$ plates in which the azimuth of the transmitted beam rotates at twice the frequency of the $\lambda/2$ plate.

7. Matrix Methods for Computing Polarization In dealing with problems involving polarized light, it is often necessary to determine the effect of various types of polarizers (linear, circular, elliptical, etc.), rotators, retardation plates, and other polarization-sensitive devices on the state of polarization of a light beam. The Poincaré sphere construction is helpful for giving a qualitative understanding of the problem; for quantitative calculations, one of several forms of matrix calculus can be used. The matrix methods are based on the fact that the effect of a polarizer or retarder is to perform a linear transformation (represented by a matrix) on the vector representation of a polarized light beam. The advantage of these methods over conventional techniques is that problems are reduced to simple matrix operations; thus since one does not have to think through the physics of every problem, the probability of making an error is greatly reduced. The most common forms of matrix calculus are the Mueller calculus and the Jones calculus, but the coherency-matrix formulation is also gaining popularity for dealing with problems involving partially polarized light. We give here a brief description of the Poincaré sphere and the different matrix methods, indicating how they are used, the different types of problems for which they are helpful, and where complete descriptions of each may be found.

The *Poincaré sphere* is a useful device for visualizing the effects of polarizers and retarders on a beam of polarized light. The various states of polarization are represented on the sphere as follows. The equator represents various forms of linear polarization, the poles represent right- and left-circular polarization,[†] and other points on the sphere represent elliptically polarized light. Every point on the sphere corresponds to a different polarization form. The radius of the sphere indicates the intensity of the light beam (which is usually assumed to be unity). The effects of polarizers and retarders are determined by appropriate displacements on the sphere. Partially polarized light or absorption may be dealt with approximately by ignoring the intensity factor, since one is generally interested only in the state of polarization; however, the construction is most useful when dealing with nonabsorbing materials. Good introductory descriptions of the Poincaré sphere, including references, can be found in *Polarized Light* by Shurcliff,[30‡] *Ellipsometry and Polarized Light* by Azzam and Bashara,[31] and *Polarized Light in Optics and Spectroscopy* by Kliger, Lewis, and Randall;[32§] illustrative examples and problems are given in Sutton and Panati.[33] More comprehensive treatments are given by Ramachandran and Ramaseshan[34§] and Jerrard[35§] and include numerous examples of applications to various types of problems. The new book *Polarized Light, Fundamentals and Applications* by Collett[36] has a comprehensive 35-page chapter on the mathematical aspects of the Poincaré sphere; this material can be best understood after reading some of the introductory descriptions of the Poincaré sphere. The main advantage of the Poincaré sphere, like other graphical methods, is to reveal by essentially a physical argument which terms in exceedingly complex equations are negligible or can be made negligible by modifying the experiment. It is characteristic of problems in polarized light that the trigonometric equations are opaque to inspection and yield useful results only after exact calculation with the aid of a computer or after complex manipulation and rather clever trigonometric identities. The Poincaré sphere thus serves as a guide to the physical intrepretation of otherwise obscure polarization phenomena. It can be used for solving problems involving retarders or combinations of retarders,[30,32,36–39] compensators, half-shade devices, and depolarizers,[34] and it has also been applied to ellipsometric problems[40] and stress-optical measurements.[41]

The Poincaré sphere is based on the Stokes vectors, which are sometimes designated S_0, S_1, S_2, and S_3. The physical interpretation of the vectors is as follows. S_0 is the intensity of the light beam, corresponding to the radius of the Poincaré sphere. S_1 is the difference in intensities between the horizontal and vertical polarization components of the beam; when S_1 is positive, the preference is for horizontal polarization, and when it is negative, the

[†] Right-circularly polarized light is defined as a *clockwise* rotation of the electric vector when the observer is looking *against the direction the wave is traveling.*

[‡] Schurcliff and Kliger, Lewis, and Randall have the S_3 axis pointing down, so that the upper pole represents left-circular polarization. The more logical convention, followed by most others, is for the upper pole to represent right-circular polarization.

[§] The notation is similar to that used by Schurcliff,[30] with the upper pole representing left-circular polarization.

preference is for vertical polarization.† S_2 indicates preference for +45° or −45° polarization, depending upon whether it is positive or negative, and S_3 gives the preference for right or left circular polarization. The Stokes vectors S_1, S_2, and S_3 are simply the three cartesian coordinates of a point on the Poincaré sphere: S_1 and S_2 are perpendicular to each other in the equatorial plane, and S_3 points toward the north pole of the sphere.‡ Thus, any state of polarization of a light beam can be specified by these three Stokes vectors. The intensity vector S_0 is related to the other three by the relation $S_0^2 = S_1^2 + S_2^2 + S_3^2$ when the beam is completely polarized. If the beam is partially polarized, $S_0^2 > S_1^2 + S_2^2 + S_3^2$. Good introductory material on Stokes vectors is given by Shurcliff,[30] Azzam and Bashara,[31] Kliger *et al.,*[32] Sutton and Panati,[33] and Walker.[42] A comprehensive discussion of the Stokes vectors has been given by Collett.[36] Rigorous definitions of the simple vectors and those for partially coherent light can be found in Born and Wolf;[43] other authors are cited by Shurcliff[30] and Collett.[36] Stokes vectors are generally used in conjunction with the Mueller calculus, and some examples of applications will be given there. We note here that Budde[44] has demonstrated a method for experimentally determining the Stokes vectors and other polarization parameters from a Fourier analysis of measured quantities. Ioshpa and Obridko[45] have proposed a photoelectric method for simultaneously and independently measuring the four Stokes parameters. Collett[46] has developed a method for measuring the four Stokes vectors using a single circular polarizer. Azzam and coworkers[47–51] have built, tested, analyzed, and calibrated a four-detector photopolarimeter for measuring normalized Stokes vectors of a large number of polarization states, and have given a physical meaning to the rows and columns in the instrument matrix. Other methods for measuring Stokes parameters are discussed by Collett.[36] Hauge[52] has surveyed different types of methods for completely determining the state of polarization of a light beam using combinations of Stokes vectors.

The matrix methods for solving problems involving polarized light have certain properties in common. All use some type of representation for the original light beam (assumed to be a plane wave traveling in a given direction) that uniquely describes its state of polarization. Generally the beam is completely polarized, but for some of the matrix methods it can also be unpolarized or partially polarized or its phase may be specified. The beam encounters one or more devices which change its state of polarization. These are called *instruments* and are represented by appropriate matrices. After the instruments operate on the light beam, it emerges as an outgoing plane wave in an altered state of polarization. The basic problem for all the methods is to find a suitable representation for the incident plane wave (usually a two- or four-component column vector), and the correct matrices (2 × 2 or 4 × 4) to represent the instruments. Once the problem is set up, one can perform the appropriate matrix operations to obtain a representation for the outgoing plane wave. Its properties are interpreted in the same way as the properties of the incident plane wave.

An introduction to the Jones and Mueller calculus is given by Shurcliff,[30] Azzam and Bashara,[31] and Kliger *et al.,*[32] and an excellent systematic and rigorous discussion of all the matrix methods has been given by O'Neill[53] and Collett.[36] All references contain tables of vectors for the various types of polarized beams and tables of instrument matrices. More complete tables are given by Sutton and Panati.[33] In the Mueller calculus the beam is represented by the four-component Stokes vector, written as a column vector. This vector has all real elements and gives information about *intensity* properties of the beam. Thus it is not able to handle problems involving phase changes or combinations of two beams that are coherent. The instrument matrix is a 4 × 4 matrix with all real elements. In the Jones calculus, the Jones vector is a two-component column vector that generally has complex elements. It contains information about the *amplitude* properties of the beam and hence is

† Some authors dealing with light scattering from aerosols define S_1 as positive when the preference is for vertical polarization.

‡ See Shurcliff and Kliger, Lewis, and Randall footnote, p. 5.26.

well suited for handling coherency problems. However, it cannot handle problems involving depolarization, as the Mueller calculus can. The Jones instrument matrix is a 2×2 matrix whose elements are generally complex.

Shurcliff[30] has noted some additional differences between Jones calculus and Mueller calculus. The Jones calculus is well suited to problems involving a large number of similar devices arranged in series in a regular manner and permits an investigator to arrive at an answer expressed explicitly in terms of the number of such devices. The Mueller calculus is not suited for this type of problem. The Jones instrument matrix of a train of transparent or absorbing nondepolarizing polarizers and retarders contains no redundant information. The matrix contains four elements each of which has two parts, so that there are a total of eight constants, none of which is a function of any other. The Mueller instrument matrix of such a train contains much redundancy; there are 16 constants but only 7 of them are independent.

In order to handle problems involving partially coherent polarized light, coherency-matrix formalism has been developed. In this system the beam is represented by a 4×4 matrix called a *coherency* or *density matrix,* which is the time average of the product of the Jones vector with its hermitian conjugate. The instrument matrices are the same as those used in the Jones calculus. O'Neill[53] and Born and Wolf[43] have good basic descriptions of coherency-matrix formalism; later extensions of the theory are given by Marathay.[54,55]

There have been some modifications of the various matrix methods. Priebe[56] has introduced an operational notation for the Mueller matrices that facilitates the analysis by simplifying the functional description of a train of optical components. Collins and Steele[57] have suggested a modification of the Jones calculus in which the light vector is expressed as the sum of two circularly polarized (rather than linearly polarized) components. Schmieder[58] has given a unified treatment of Jones calculus and Mueller calculus including the coherency matrix and has shown that if the Stokes parameters are ordered in a different way from that customarily used, familiar relationships are preserved and the rotation matrix looks like a rotation matrix rather than like a rearranged one. Tewarson[59] presents a generalized reciprocity equation expressing an algebraic relationship between the parameters of an optical system and its reciprocal system and has verified the equation for both plane-polarized and circularly polarized light beams. Since his equation follows from the reciprocity law in the Mueller calculus, that law is verified also. Cernosek[60] presents a simple geometric method based on the properties of quaternions to give a quick, quantitative analysis of the effect of any combination of linear retarders and rotators on the state of polarization of a system.

Among the applications of Mueller calculus and Jones calculus to problems involving polarized light, McCrackin[61] has used both matrix methods to analyze instrumental errors in ellipsometry, and Hellerstein[62] has used Mueller calculus to study the passage of linearly, circularly, and elliptically polarized light through a Sénarmont polariscope. Azzam and Bashara[63] have used Jones calculus to give a unified analysis of errors in ellipsometry, including effects of birefringence in cell windows, imperfect components, and incorrect azimuth angles. Azzam[64] also describes a simple photopolarimeter with rotating polarizer and analyzer for measuring Jones and Mueller matrices.

CHAPTER 6
SCATTERING BY PARTICLES

Craig F. Bohren
Pennsylvania State University
University Park, Pennsylvania

6.1 GLOSSARY

a	radius
a_n, b_n	scattering coefficients
C	cross section
D_n	logarithmic derivative, $d/d\rho[\ln \psi_n(\rho)]$
E	Electric field strength
$\mathbf{e}_x$	unit vector in the x direction
f	Nv
G	projected particle area
h	thickness
I	irradiance
I, Q, U, V	Stokes parameters
j	running index
k	$2\pi/\lambda$
k	imaginary part of the refractive index
m	relative complex refractive index
N	number
n	running index
P_n	associated Legendre functions of the first kind
p	phase function, normalized differential scattering cross section
Q	efficiencies or efficiency factors
r	distance
S	element of the amplitude scattering matrix
v	volume

W	power
X	scattering amplitude
x	size parameter, ka
α	absorption coefficient
θ	angle
λ	wavelength
π_n	$P_n^1/\sin\theta$
τ_n	$dP_n^1/d\theta$
ψ, ξ	Riccati-Bessel functions
Ω	solid angle
ω	radian frequency
$\parallel$	parallel
$\perp$	perpendicular
Re	real part of

Subscripts

abs	absorbed
ext	extinction
sca	scattered

6.2 INTRODUCTION

Light scattering by particles plays starring and supporting roles on a variety of stages: astronomy, cell biology, colloid chemistry, combustion engineering, heat transfer, meteorology, paint technology, solid-state physics—the list is almost endless. The best evidence of the catholicity of scattering by particles is the many journals that publish papers about it.

Scattering by single particles is the subject of monographs by van de Hulst,[1] Deirmendjian,[2] Kerker,[3] Bayvel and Jones,[4] Bohren and Huffman,[5] Barber and Hill[6] and of a collection edited by Kerker.[7] Two similar collections contain papers on scattering by atmospheric particles[8] and by chiral particles[9] (ones not superposable on their mirror images); scattering by chiral particles is also treated by Lakhtakia et al.[10] Papers on scattering by particles are included in collections edited by Gouesbet and Gréhan[11] and by Barber and Chang.[12] Within this *Handbook* scattering by particles is touched upon in chaps. 44 and 45. A grand feast is available for those with the juices to digest it. What follows is a mere snack.

A particle is an aggregation of sufficiently many molecules that it can be described adequately in macroscopic terms (i.e., by constitutive parameters such as permittivity and permeability). It is a more or less well-defined entity unlike, say, a density fluctuation in a gas or a liquid. Single molecules are not particles, even though scattering by them is in some ways similar (for a clear but dated discussion of molecular scattering, see Martin[13]).

Scattering by single particles is discussed mostly in the wave language of light, although multiple scattering by incoherent arrays of many particles can be discussed intelligibly in the photon language. The distinction between single and multiple scattering is observed more readily on paper than in laboratories and in nature. Strict single scattering can exist only in a boundless void containing a lone scatterer illuminated by a remote source, although single scattering often is attained to a high degree of approximation. A distinction made less frequently is that between scattering by coherent and by incoherent arrays. In treating scattering by coherent arrays, the wave nature of light cannot be ignored: phases *must* be taken into account. But in treating scattering by incoherent arrays, phases *may* be ignored.

Pure water is a coherent array of water molecules; a cloud is an incoherent array of water droplets. In neither of these arrays is multiple scattering negligible, although the theories used to describe them may not explicitly invoke it.

The distinction between incoherent and coherent arrays is not absolute. Although a cloud of water droplets is usually considered to be an incoherent array, it is not such an array for scattering in the forward direction. And although most of the light scattered by pure water is accounted for by the laws of specular reflection and refraction, it also scatters light—weakly yet measurably—in directions not accounted for by these laws.[13]

A single particle is itself a coherent array of many molecules, but can be part of an incoherent array of many particles, scattering collectively in such a way that the phases of the waves scattered by each one individually are washed out. Although this section is devoted to single scattering, it must be kept in mind that multiple scattering is not always negligible and is not just scaled-up single scattering. Multiple scattering gives rise to phenomena inexplicable by single-scattering arguments.[14]

6.3 SCATTERING: AN OVERVIEW

Why is light scattered? No single answer will be satisfactory to everyone, yet because scattering by particles has been amenable to treatment mostly by classical electromagnetic theory, our answer lies within this theory.

Although palpable matter may appear to be continuous and is often electrically neutral, it is composed of discrete electric charges. Light is an oscillating electromagnetic field, which can excite the charges in matter to oscillate. Oscillating charges radiate electromagnetic waves, a fundamental property of such charges with its origins in the finite speed of light. These radiated electromagnetic waves are scattered waves, waves excited or driven by a source external to the scatterer: an incident wave from the source excites secondary waves from the scatterer; the superposition of all these waves is what is observed. If the frequency of the secondary waves is (approximately) that of the source, these waves are said to be *elastically* scattered (the term *coherently* scattered is also used).

Scientific knowledge grows like the accumulation of bric-a-brac in a vast and disorderly closet in a house kept by a sloven. Few are the attempts at ridding the closet of rusty or obsolete gear, at throwing out redundant equipment, at putting things in order. For example, spurious distinctions are still made between reflection, refraction, scattering, interference, and diffraction despite centuries of accumulated knowledge about the nature of light and matter.

Countless students have been told that specular reflection is localized at smooth surfaces, that photons somehow rebound from them. Yet this interpretation is shaky given that even the smoothest surface attainable is, on the scale of a photon, as wrinkled as the back of a cowboy's neck. Photons conceived of as tiny balls would be scattered in all directions by such a surface, for which it is difficult even to define what is meant by an angle of incidence.

Why do we think of reflection occurring at surfaces rather than because of them whereas we usually do not think of scattering by particles in this way? One reason is that we can see the surfaces of mirrors and ponds. Another is the dead hand of traditional approaches to the laws of specular reflection and refraction.

The empirical approach arrives at these laws as purely geometrical summaries of what is observed—and a discreet silence is maintained about underlying causes. The second approach is by way of continuum electromagnetic theory: reflected and refracted fields satisfy the Maxwell equations. Perhaps because this approach, which also yields the Fresnel formulas, entails the solution of a boundary-value problem, reflected and refracted fields are mistakenly thought to originate from boundaries rather than from all the illuminated matter they enclose. This second approach comes to grips with the nature of light but not of matter, which is treated as continuous. The third approach is to explicitly recognize that reflection and refraction are consequences of scattering by discrete matter. Although this scattering interpretation was developed by Paul Ewald and Carl Wilhelm Oseen early in this century, it has diffused with glacial slowness. According to this interpretation, when the optically smooth interface between optically homogeneous dissimilar media is illuminated, the reflected and refracted waves are superpositions of vast numbers of secondary waves excited by the incident wave. Thus reflected and refracted light is, at heart, an interference pattern of scattered light. Doyle[15] showed that although the Fresnel equations are obtained from macroscopic electromagnetic theory, they can be dissected to reveal their microscopic underpinnings.

No optics textbook would be complete without sections on interference and diffraction, a distinction without a difference: there is no diffraction without interference. Moreover, diffraction is encumbered with many meanings. Van de Hulst[1] lists several: small deviations from rectilinear propagation; wave motion in the presence of an obstacle; scattering by a flat particle such as a disk; an integral relation for a function satisfying the wave equation. To these may be added scattering near the forward direction and by a periodic array.

Van de Hulst stops short of pointing out that a term with so many meanings has no meaning. Even the etymology of diffraction is of little help: it comes from a Latin root meaning to break.

There is no fundamental distinction between diffraction and scattering. Born and Wolf[16] refer to scattering by a sphere as diffraction by a sphere. I leave it as a penance for the reader to devise an experiment to determine whether a sphere scatters light or diffracts it.

The only meaningful distinction is that between approximate theories. Diffraction theories obtain answers at the expense of obscuring the physics of the interaction of light with matter. For example, an illuminated slit in an opaque screen may be the mathematical source but it is not the physical source of a diffraction pattern. Only the screen can give rise to secondary waves that yield the observed pattern. Yet generations of students have been taught that empty space is the source of the radiation diffracted by a slit. To befuddle them even more, they also have been taught that two slits give an interference pattern whereas one slit gives a diffraction pattern.

If we can construct a mathematical theory (diffraction theory) that enables us to avoid having to explicitly consider the nature of matter, all to the good. But this mathematical theory and its quantitative successes should not blind us to the fact that we are pretending. Sometimes this pretense cannot be maintained, and when this happens a finger is mistakenly pointed at "anomalies," whereas what is truly anomalous is that a theory so devoid of physical content could ever give adequate results.

A distinction must be made between a physical process and the superficially different theories used to describe it. There is no fundamental difference between specular reflection and refraction by films, diffraction by slits, and scattering by particles. All are consequences of light interacting with matter. They differ only in their geometries and the approximate theories that are sufficient for their quantitative description. The different terms used to describe them are encrustations deposited during the slow evolution of our understanding of light and matter.

6.4 SCATTERING BY PARTICLES: BASIC CONCEPTS AND TERMINOLOGY

A single particle can be considered a collection of tiny dipolar antennas driven to radiate (scatter) by an incident oscillating electric field. Scattering by such a coherent array of antennas depends on its size and shape, the observation angle (scattering angle), the response of the individual antennas (composition), and the polarization state and frequency of the incident wave. Geometry, composition, and the properties of the illumination are the determinants of scattering by particles.

Perhaps the only real difference between optics and electrical engineering is that electrical engineers can measure amplitudes and phases of fields whereas the primary observable quantity in optics is the time-averaged Poynting vector (irradiance), an amplitude squared. Several secondary observables are inferred from measurements of this primary observable. Consider, for example, a single particle illuminated by a beam with irradiance I_i. The total power scattered by this particle is W_{sca}. Within the realm of linear optics, the scattered power is proportional to the incident irradiance. This proportionality can be transformed into an equality by means of a factor C_{sca}:

$$W_{\text{sca}} = C_{\text{sca}} I_i \tag{1}$$

For Eq. (1) to be dimensionally homogeneous C_{sca} must have the dimensions of area, hence C_{sca} has acquired the name *scattering cross section.*

Particles absorb as well as scatter electromagnetic radiation. The rate of absorption W_{abs} by an illuminated particle, like scattered power, is proportional to the incident irradiance:

$$W_{\text{abs}} = C_{\text{abs}} I_i \tag{2}$$

where C_{abs} is the *absorption cross section.* The sum of these cross sections is the *extinction cross section*:

$$C_{\text{ext}} = C_{\text{sca}} + C_{\text{abs}} \tag{3}$$

Implicit in these definitions of cross sections is the assumption that the irradiance of the incident light is constant over lateral dimensions large compared with the size of the illuminated particle. This condition is necessarily satisfied by a plane wave infinite in lateral extent, which, much more often than not, is the source of illumination in light-scattering theories.

The extinction cross section can be determined (in principle) by measuring transmission by a slab populated by N identical particles per unit volume. Provided that multiple scattering is negligible, the incident and transmitted irradiances I_i and I_t are related by

$$I_t = I_i e^{-NC_{\text{ext}}h} \tag{4}$$

where h is the thickness of the slab. Only the sum of scattering and absorption can be obtained from transmission measurements. To separate extinction into its components requires additional measurements.

Equation (4) requires that all particles in the slab be identical. They are different if they differ in size, shape, composition, or orientation (incident beams are different if they differ in wavelength or polarization state). Equation (4) is generalized to a distribution of particles by replacing NC_{ext} with

$$\sum_j N_j C_{\text{ext},j} \tag{5}$$

where j denotes all parameters distinguishing one particle from another.

Instead of cross sections, normalized cross sections called *efficiencies* or *efficiency factors,* Q_{sca}, Q_{abs}, and Q_{ext}, often are presented. The normalizing factor is the particle's area G projected onto a plane perpendicular to the incident beam. No significance should be attached to efficiency used as shorthand for normalized cross section. The normalization factor is arbitrary. It could just as well be the total area of the particle or, to honor Lord Rayleigh, the area of his thumbnail.

Proper efficiencies ought to be less than unity, whereas efficiencies for scattering, absorption, and extinction are not so constrained. Moreover, some particles—soot aggregates, for example—do not have well-defined cross-sectional areas. Such particles have cross sections for scattering and absorption but the corresponding efficiencies are nebulous.

If any quantity deserves the designation efficiency it is the cross section per particle volume v. Equation (4) can be rewritten to display this:

$$I_t = I_i e^{-fh(C_{\text{ext}}/v)} \tag{6}$$

where $f = Nv$ is the total volume of particles per unit slab volume. For a given particle loading, specified by fh (volume of particles per unit slab area), transmission is a minimum when C_{ext}/v is a maximum.

Each way of displaying extinction (or scattering) versus particle size or wavelength of the incident beam tells a different story. This is illustrated in Fig. 1, which shows the scattering cross section, scattering efficiency, and scattering cross section per unit volume of a silicate sphere in air illuminated by visible light. These curves were obtained with van de Hulst's simple *anomalous diffraction* approximation[1] (all that is anomalous about it is that it gives such good results). Each curve yields a different answer to the question, what size particle is most efficient at scattering light? And comparison of Figs. 1*c* and 2 shows that scattering by a particle and specular reflection are similar.

At sufficiently large distances r from a scatterer of bounded extent, the scattered field $\mathbf{E}_s$ decreases inversely with distance and is transverse:

$$\mathbf{E}_s \sim \frac{e^{ik(r-z)}}{-ikr} \mathbf{X} E \qquad (kr \gg 1) \tag{7}$$

where $k = 2\pi/\lambda$ is the wave number of the incident plane harmonic wave $\mathbf{E}_{\text{i}} = \mathbf{e}_x E$, $E = E_0 \exp(ikz)$ propagating along the z axis. The *vector scattering amplitude* is written as $\mathbf{X}$ as a reminder that the incident wave is linearly polarized along the x axis. Here and elsewhere the time-dependent factor $\exp(-i\omega t)$ is omitted.

The extinction cross section is related in a simple way to the scattering amplitude;

$$C_{\text{ext}} = \frac{4\pi}{k^2} \operatorname{Re}\{(\mathbf{X} \cdot \mathbf{e}_x)_{\theta=0}\} \tag{8}$$

This remarkable result, often called the *optical theorem,* implies that plane-wave extinction depends only on scattering in the forward direction $\theta = 0$, which seems to contradict the

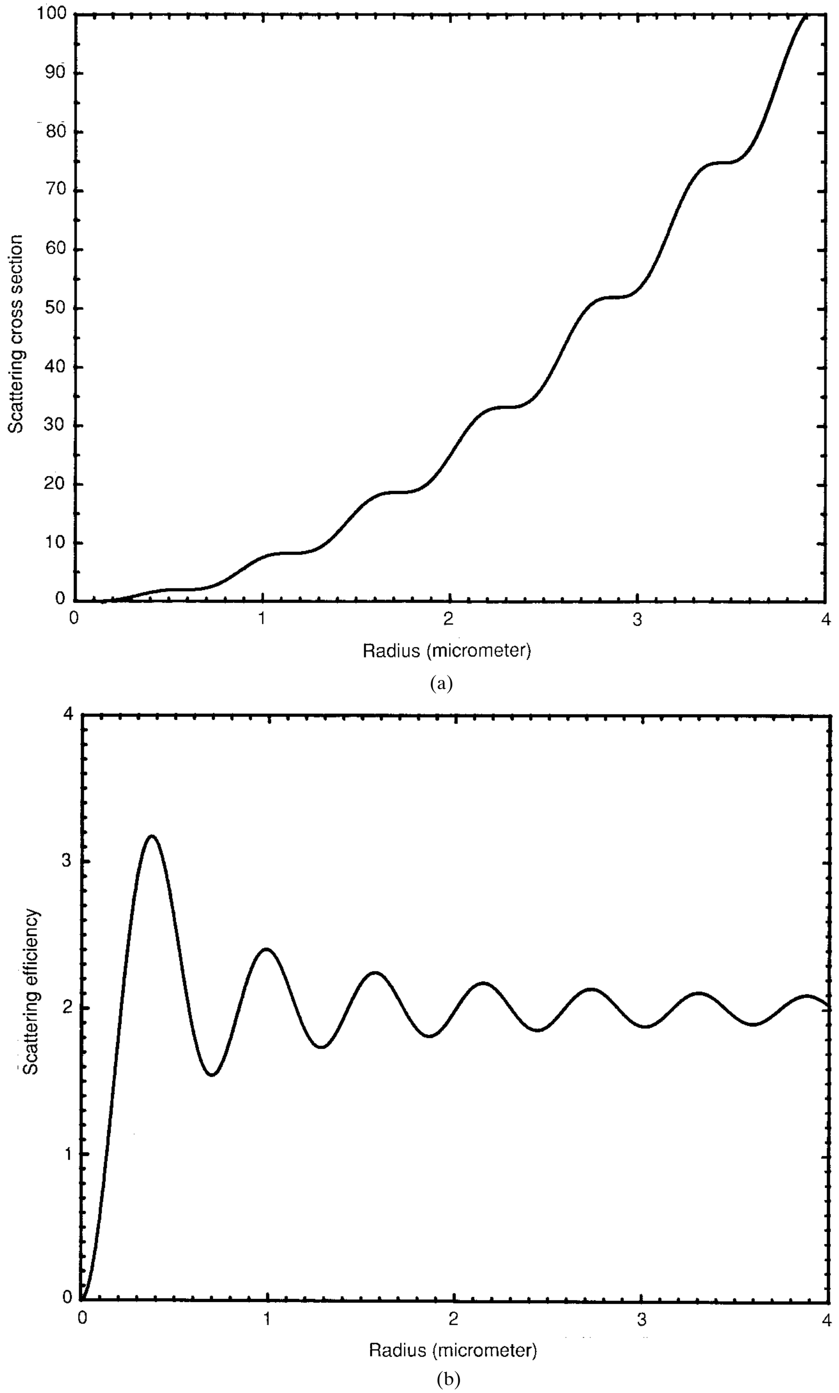

FIGURE 1 Scattering of visible light by a silicate sphere calculated using the anomalous diffraction approximation: (*a*) scattering cross section; (*b*) scattering efficiency (cross section normalized by projected area); (*c*) volumetric scattering cross section (cross section per unit particle volume).

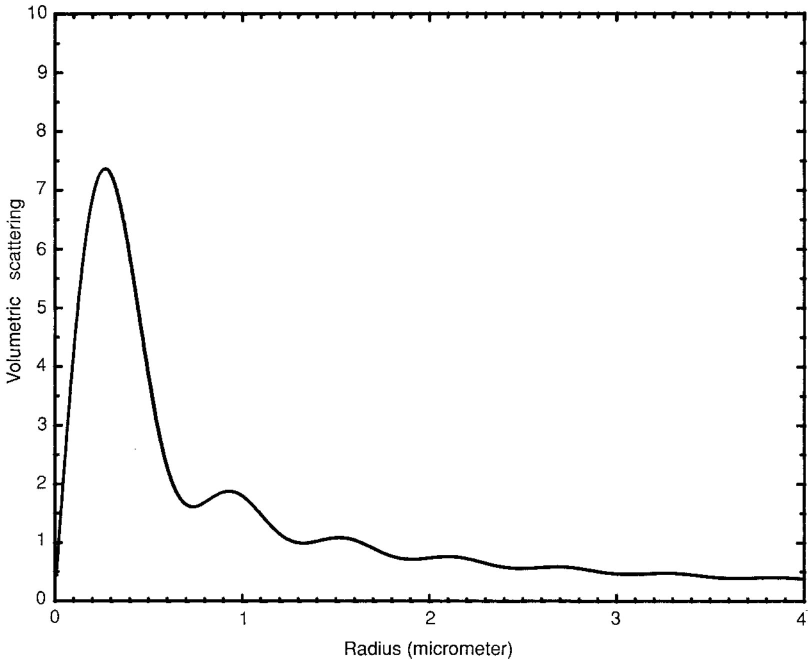

(c)

FIGURE 1 (*Continued*)

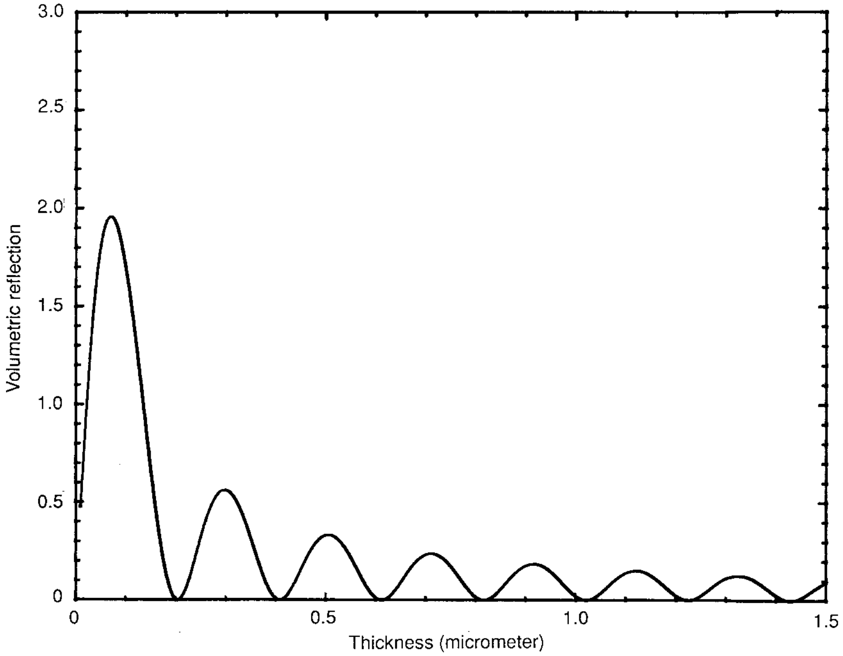

FIGURE 2 Reflected power per unit incident irradiance and unit volume of a silicate slab normally illuminated by visible light (reflectance divided by slab thickness).

interpretation of extinction as the sum of scattering in *all* directions and absorption. Yet extinction has two interpretations, the second manifest in the optical theorem: extinction is interference between incident and forward-scattered waves.

The scattering cross section is also obtained from the vector scattering amplitude by an integration over all directions:

$$C_{\text{sca}} = \int_{4\pi} \frac{|\mathbf{X}|^2}{k^2}\, d\Omega \tag{9}$$

At wavelengths far from strong absorption bands, the scattering cross section of a particle small compared with the wavelength satisfies (approximately)

$$C_{\text{sca}} \propto \frac{v^2}{\lambda^4} \qquad (ka \rightarrow 0) \tag{10}$$

where a is a characteristic linear dimension of the particle. This result was first obtained by Lord Rayleigh in 1871 by dimensional analysis (his paper is included in Ref. 8).

The extinction cross section of a particle large compared with the wavelength approaches the limit

$$C_{\text{ext}} \rightarrow 2G \qquad (ka \rightarrow \infty) \tag{11}$$

The fact that C_{ext} approaches *twice* G instead of G is sometimes called the *extinction paradox.* This alleged paradox arises from the expectation that geometrical optics should become a better approximation as a particle becomes larger. But all particles have edges because of which extinction by them always has a component unaccounted for by geometrical optics. This additional component, however, may not be observed because it is associated with light scattered very near the forward direction and because all detectors have finite acceptance angles. Measured extinction is theoretical extinction reduced by the scattered light collected by the detector.

No particle scatters light equally in all directions; isotropic scatterers exist only in the dreams of inept theorists. The angular dependence of scattering can be specified by the *differential scattering cross section,* written symbolically as $dC_{\text{sca}}/d\Omega$ as a reminder that the *total* scattering cross section is obtained from it by integrating over all directions:

$$C_{\text{sca}} = \int_{4\pi} \frac{dC_{\text{sca}}}{d\Omega}\, d\Omega \tag{12}$$

The normalized differential scattering cross section p

$$p = \frac{1}{C_{\text{sca}}} \frac{dC_{\text{sca}}}{d\Omega} \tag{13}$$

is sometimes called the *phase function.* This coinage of astronomers (after the phases of astronomical bodies) confuses those who are perplexed by phase attached to a quantity from which phase in the usual optical sense is absent. To add to the confusion, the phase function is sometimes normalized to 4π instead of to unity.

A salient characteristic of scattering by particles is strong forward-backward asymmetry. Small metallic particles at far infrared wavelengths provide one of the few examples in which backscattering is larger than forward scattering. Except for very small particles,

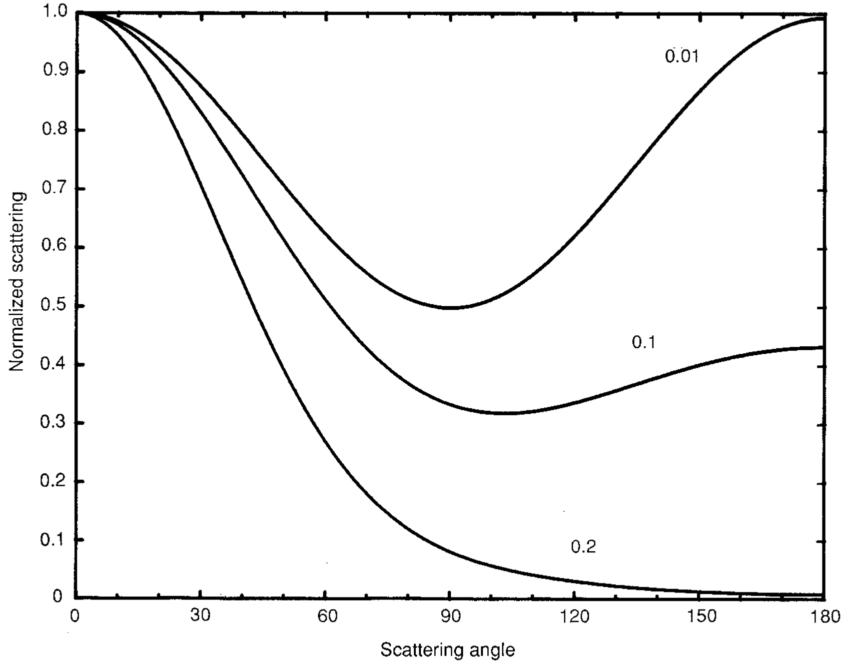

FIGURE 3 Scattering of unpolarized visible light by spheres of radii 0.01, 0.1, and 0.2 μm calculated according to the Rayleigh-Gans approximation.

scattering is peaked in the forward direction; the larger the particle, the sharper the peak. Examples are given in Fig. 3, which shows differential scattering cross sections for unpolarized visible light illuminating spheres of various radii. These curves were obtained using the Rayleigh-Gans approximation,[1,3,5] valid for particles optically similar to the surrounding medium. Forward scattering is much greater than backscattering even for a sphere as small as 0.2 μm.

A simple explanation of forward-backward asymmetry follows from the model of a scatterer as an array of N antennas. If we ignore mutual excitation (the antennas are excited solely by the external source), the total scattered field is the sum of N fields, the phases of which, in general, are different except in the forward direction. Scattering by noninteracting scatterers in this direction—and only in this direction—is in-phase regardless of their separation and the wavelength of the source. Thus as N increases, the scattered irradiance increases more rapidly in the forward direction than in any other direction.

Particles are miniature polarizers and retarders: they scatter differently the orthogonal components into which incident fields can be resolved. Similarly, an optically smooth surface can be both a polarizer and retarder. Just as polarization changes upon reflection are described by decomposing electric fields into components parallel and perpendicular to the plane of incidence, it is convenient to introduce a *scattering plane,* defined by the directions of the incident and scattered waves, for describing scattering by particles.

The incident plane wave is transverse, as is the scattered field at large distances. Thus these fields can be decomposed into two orthogonal components, one parallel, the other perpendicular to the scattering plane. The orthonormal basis vectors are denoted by $\mathbf{e}_{\parallel}$ and $\mathbf{e}_{\perp}$ and form a right-handed triad with the direction of propagation $\mathbf{e}_p$ (of either the incident or scattered waves): $\mathbf{e}_{\perp}\mathbf{x}\mathbf{e}_{\parallel} = \mathbf{e}_p$. Incident and scattered fields are specified relative

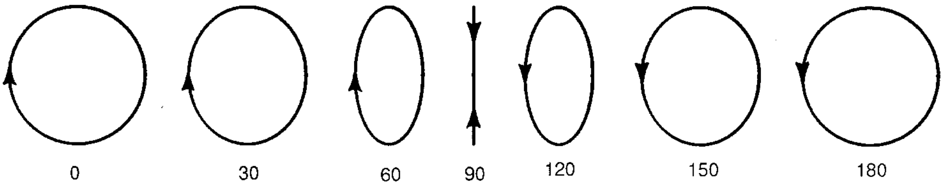

FIGURE 4 Vibration ellipses at various scattering angles for light scattered by a sphere much smaller than the wavelength of the incident right-circularly polarized light.

to different basis vectors. With this decomposition the relation between fields can be written[1,5]

$$\begin{pmatrix} E_{\|s} \\ E_{\perp s} \end{pmatrix} = \frac{\mathbf{e}^{ik(r-z)}}{-ikr} \begin{pmatrix} S_2 & S_3 \\ S_4 & S_1 \end{pmatrix} \begin{pmatrix} E_{\|i} \\ E_{\perp i} \end{pmatrix} \tag{14}$$

where i and s denote incident and scattered, respectively. The elements of this *amplitude scattering matrix* (or Jones matrix) are complex-valued functions of the scattering direction.

If a single particle is illuminated by completely polarized light, the scattered light is also completely polarized but possibly differently from the incident light, and differently in different directions. An example is given in Fig. 4, which shows vibration ellipses of light scattered by a small sphere. The polarization state of the scattered light varies from right-circular (the polarization state of the incident light) in the forward direction, to linear (perpendicular to the scattering plane) at 90°, to left-circular in the backward direction.

Just as unpolarized light can become partially polarized upon specular reflection, scattering of unpolarized light by particles can yield partially polarized light varying in degree and state of polarization in different directions. Unlike specular reflection, however, an ensemble of particles can transform completely polarized incident light into partially polarized scattered light if all the particles are not identical.

Transformations of polarized light upon scattering by particles are described most conveniently by the *scattering matrix* (or Mueller matrix) relating scattered to incident Stokes parameters:[1,5]

$$\begin{pmatrix} I_s \\ Q_s \\ U_s \\ V_s \end{pmatrix} = \frac{1}{k^2r^2} \begin{pmatrix} S_{11} & S_{12} & S_{13} & S_{14} \\ S_{21} & S_{22} & S_{23} & S_{24} \\ S_{31} & S_{32} & S_{33} & S_{34} \\ S_{41} & S_{42} & S_{43} & S_{44} \end{pmatrix} \begin{pmatrix} I_i \\ Q_i \\ U_i \\ V_i \end{pmatrix} \tag{15}$$

The scattering matrix elements S_{ij} for a single particle are functions of the amplitude scattering matrix elements. Only seven of these elements are independent, corresponding to the four amplitudes and three phase differences of the S_j.

The scattering matrix for an ensemble of particles is the sum of matrices for each of them provided they are separated by sufficiently large random distances. Although all 16 matrix elements for an ensemble can be nonzero and different, symmetry reduces the number of matrix elements. For example, the scattering matrix for a rotationally and mirror symmetric ensemble has the form

$$\begin{pmatrix} S_{11} & S_{12} & 0 & 0 \\ S_{12} & S_{22} & 0 & 0 \\ 0 & 0 & S_{33} & S_{34} \\ 0 & 0 & -S_{34} & S_{44} \end{pmatrix} \tag{16}$$

6.5 SCATTERING BY AN ISOTROPIC, HOMOGENEOUS SPHERE: THE ARCHETYPE

An isotropic, homogeneous sphere is the simplest finite particle, the theory of scattering by which is attached to the name of Gustav Mie.[17] So firm is this attachment that in defiance of logic and history every particle under the sun has been dubbed a ‘‘Mie scatterer,’’ and Mie scattering has been promoted from a particular theory of limited applicability to the unearned rank of general scattering process.

Mie was not the first to solve the problem of scattering by an arbitrary sphere.[18] It would be more correct to say that he was the last. He gave his solution in recognizably modern notation and also addressed a real problem: the colors of colloidal gold. For these reasons, his name is attached to the sphere-scattering problem even though he had illustrious predecessors, most notably Lorenz.[19] This is an example in which eponymous recognition has gone to the last discoverer rather than to the first.

Mie scattering is not a physical process; Mie theory is one theory among many. It isn’t even exact because it is based on continuum electromagnetic theory and on illumination by a plane wave infinite in lateral extent.

Scattering by a sphere can be determined using various approximations and methods bearing little resemblance to Mie theory: Fraunhofer theory, geometrical optics, anomalous diffraction, coupled-dipole method, T-matrix method, etc. Thus, is a sphere a Mie scatterer or an anomalous diffraction scatterer or a coupled-dipole scatterer? The possibilities are endless. When a physical process can be described by several different theories, it is inadvisable to attach the name of one of them to it.

There is no distinct boundary between so-called Mie and Rayleigh scatterers. Mie theory includes Rayleigh theory, which is a limiting theory strictly applicable only as the size of the particle shrinks to zero. Even for spheres uncritically labeled ‘‘Rayleigh spheres,’’ there are always deviations between the Rayleigh and Mie theories. By hobbling one’s thinking with a supposed sharp boundary between Rayleigh and Mie scattering, one risks throwing some interesting physics out the window. Whether a particle is a Mie or Rayleigh scatterer is not absolute. A particle may be graduated from Rayleigh to Mie status merely by a change of wavelength of the illumination.

One often encounters statements about Mie scattering by cylinders, spheroids, and other nonspherical particles. Judged historically, these statements are nonsense: Mie never considered any particles other than homogeneous spheres.

Logic would seem to demand that if a particle is a Mie scatterer, then Mie theory can be applied to scattering by it. This fallacious notion has caused and will continue to cause mischief, and is probably the best reason for ceasing to refer to Mie particles or Mie scatterers. Using Mie theory for particles other than spheres is risky, especially for computing scattering toward the backward direction.

More often than not, a better term than Mie or Rayleigh scattering is available. If the scatterers are molecules, molecular scattering is better than Rayleigh scattering (itself an imprecise term):[20] the former term refers to an agent, the latter to a theory. Mie scatterer is just a needlessly aristocratic name for a humble sphere. Wherever Mie scatterer is replaced with sphere, the result is clearer. If qualifications are needed, one can add small or large compared with the wavelength or comparable to the wavelength.

Briefly, the solution to the problem of scattering by an arbitrary homogeneous sphere illuminated by a plane wave can be obtained by expanding the incident, scattered, and internal fields in a series of vector spherical harmonics. The coefficients of these expansion functions are chosen so that the tangential components of the electric and magnetic fields are continuous across the surface of the sphere. Thus this scattering problem is formally identical to reflection and refraction because of interfaces, although the sphere problem is more complicated because the scattered and internal fields are not plane waves.

Observable quantities are expressed in terms of the coefficients a_n and b_n in the expansions of the scattered fields. For example, the cross sections are infinite series:

$$C_{\text{ext}} = \frac{2\pi}{k^2} \sum_{n=1}^{\infty} (2n+1) \operatorname{Re}\{a_n + b_n\} \tag{17}$$

$$C_{\text{sca}} = \frac{2\pi}{k^2} \sum_{n=1}^{\infty} (2n+1)(|a_n|^2 + |b_n|^2) \tag{18}$$

If the permeability of the sphere and its surroundings are the same, the scattering coefficients can be written

$$a_n = \frac{[D_n(mx)/m + n/x]\psi_n(x) - \psi_{n-1}(x)}{[D_n(mx)/m + n/x]\xi_n(x) - \xi_{n-1}(x)} \tag{19}$$

$$b_n = \frac{[mD_n(mx) + n/x]\psi_n(x) - \psi_{n-1}(x)}{[mD_n(mx) + n/x]\xi_n(x) - \xi_{n-1}(x)} \tag{20}$$

ψ_n and ξ_n are Riccati-Bessel functions and the logarithmic derivative

$$D_n(\rho) = \frac{d}{d\rho} \ln \psi_n(\rho) \tag{21}$$

The *size parameter x* is *ka,* where *a* is the radius of the sphere and *k* is the wavenumber of the incident light in the surrounding medium, and *m* is the complex refractive index of the sphere relative to that of this (nonabsorbing) medium. Equations (19) and (20) are one of the many ways of writing the scattering coefficients, some of which are more suited to computations than others.

During the Great Depression mathematicians were put to work computing tables of trigonometric and other functions. The results of their labors now gather dust in libraries. Today, these tables could be generated more accurately in minutes on a pocket calculator. A similar fate has befallen Mie calculations. Before fast computers were inexpensive, tables of scattering functions for limited ranges of size parameter and refractive index were published. Today, these tables could be generated in minutes on a personal computer. The moral is to give algorithms rather than only tables of results, which are mostly useless except as checks for someone developing and testing algorithms.

These days it is not necessary to reinvent the sphere: documented Mie programs are readily available. The first widely circulated program was published as an IBM report by Dave in 1968, although it no longer seems to be available. A Mie program is given in Ref. 5. Reference 6 includes a diskette containing scattering programs for spheres (and other particles). Wiscombe[21,22] suggested techniques for increasing the speed of computations, as did Lentz,[23] whose method makes use of continued fractions. Wang and van de Hulst[24] recently compared various scattering programs.

The primary tasks in Mie calculations are computing the functions in Eqs. (19) and (20) and summing series like Eqs. (17) and (18). Bessel functions are computed by recurrence. The logarithmic derivative, the argument of which can be complex, is usually computed by downward recurrence. $\psi_n(x)$ and $\xi_n(x)$ can be computed by upward recurrence if one does not generate more orders than are needed for convergence, approximately the size parameter *x*. When a program with no logical errors falls ill, it often can be cured by promoting variables from single to double precision.

Cross sections versus radius or wavelength convey physical information; efficiencies versus size parameter convey mathematical information. The size parameter is a variable with less physical content than its components, the whole being less than the sum of its parts. Moreover, cross section versus size parameter (or its inverse) is not equivalent to cross section versus wavelength. Except in the fantasy world of naive modelers, refractive indices vary with wavelength, and the Mie coefficients depend on x and m, wavelength being explicit in the first and implicit in the second.

The complex refractive index is written dozens of different ways, one of which is $n + ik$ (despite the risk of confusing the imaginary part with the wavenumber). The quantities n and k are called *optical constants.* But just as the Lord Privy Seal is neither a lord nor a privy nor a seal, optical constants are neither optical nor constant.

Few quantities in optics are more shrouded in myth and misconception than the complex refractive index. The real part for any medium is often defined as the ratio of the velocity of light c in free space to the phase velocity in the medium. This definition, together with notions that nothing can go faster than c, has engendered the widespread misconception that n must be greater than unity. But n can take on any value, even zero. The phase velocity is not the velocity of any palpable object or of any signal, hence is not subject to speed limits enforced by the special relativity police. The least physically relevant property of a refractive index is that it is a ratio of phase velocities. A refractive index is a response function (or better, is simply related to response functions such as permittivity and permeability): it is a macroscopic manifestation of the microscopic response of matter to a periodic driving force.

When we turn to the imaginary part of the refractive index, we enter a ballroom in which common sense is checked at the door. It has been asserted countless times that an imaginary index of, say, 0.01 corresponds to a weakly absorbing medium (at visible and near-visible wavelengths). Such assertions are best exploded by expressing k in a more physically transparent way. The absorption coefficient α is

$$\alpha = \frac{4\pi k}{\lambda} \tag{22}$$

The inverse of α is the *e-folding distance* (or skin depth), the distance over which the irradiance of light propagating in an unbounded medium decreases by a factor of e. At visible wavelengths, the e-folding distance corresponding to $k = 0.01$ is about 5 μm. A thin sliver of such an allegedly weakly absorbing material would be opaque.

When can a particle (or any object) be said to be strongly absorbing? A necessary condition is that $\alpha d \gg 1$, where d is a characteristic linear dimension of the object. But this condition is not sufficient. As k increases, absorption increases—up to a point. As k approaches infinity, the absorption cross section of a particle or the absorptance of a film approaches zero.

One of the most vexing problems in scattering calculations is finding optical constants dispersed throughout dozens of journals. Palik[25] edited a compilation of optical constants for several solids. The optical constants of liquid water over a broad range were compiled by Hale and Querry;[26] Warren[27] published a similar compilation for ice. For other materials, you are on your own. Good hunting!

For small x and $|m|x$, the extinction and scattering efficiencies of a sphere are approximately

$$Q_{\text{ext}} = 4x \,\text{Im}\left\{\frac{m^2-1}{m^2+2}\right\} \tag{23}$$

$$Q_{\text{sca}} = \frac{8}{3}x^4 \left|\frac{m^2-1}{m^2+2}\right|^2 \tag{24}$$

These equations are the source of a nameless paradox, which is disinterred from time to time, a corpse never allowed eternal peace. If the sphere is nonabsorbing (m real), Eq. (23) yields a vanishing extinction cross section, whereas Eq. (24) yields a nonvanishing scattering cross section. Yet extinction never can be less than scattering. But note that Eq. (23) is only the first term in the expansion of Q_{ext} in powers of x. The first nonvanishing term in the expansion of Q_{sca} is of order x^4. To be consistent, Q_{ext} and Q_{sca} must be expanded to the same order in x. When this is done, the paradox vanishes.

The amplitude-scattering matrix elements for a sphere are

$$S_1 = \sum_n \frac{2n+1}{n(n+1)}(a_n\pi_n + b_n\tau_n) \tag{25}$$

$$S_2 = \sum_n \frac{2n+1}{n(n+1)}(a_n\tau_n + b_n\pi_n) \tag{26}$$

where the angle-dependent functions are

$$\pi_n = \frac{P_n^1}{\sin\theta} \qquad \tau_n = \frac{dP_n^1}{d\theta} \tag{27}$$

and P_n^1 are the associated Legendre functions of the first kind. The off-diagonal elements of the amplitude-scattering matrix vanish, because of which the scattering matrix is block-diagonal and $S_{12} = S_{21}$, $S_{43} = -S_{34}$, $S_{44} = S_{33}$. Thus, when the incident light is polarized parallel (perpendicular) to the scattering plane, so is the scattered light, a consequence of the sphere's symmetry.

6.6 SCATTERING BY REGULAR PARTICLES

The field scattered by any spherically symmetric particle has the same form as that scattered by a homogeneous, isotropic sphere; only the scattering coefficients are different. One such particle is a uniformly coated sphere. Scattering by a sphere with a single layer was first treated by Aden and Kerker.[28] Extending their analysis to multilayered spheres is straightforward.[29]

New computational problems arise in going from uncoated to coated spheres. The scattering coefficients for both contain spherical Bessel functions, which are bounded only if their arguments are real (no absorption). Thus, for strongly absorbing particles, the arguments of Bessel functions can be so large that their values exceed computational bounds. This does not occur for uncoated spheres because the only quantity in the scattering coefficients with complex argument is the logarithmic derivative, a ratio of Bessel functions computed as an entity instead of by combining numerator and denominator, each of which separately can exceed computational bounds. It is not obvious how to write the scattering coefficients for a coated sphere so that only ratios of possibly large quantities are computed explicitly. For this reason the applicability of the coated-sphere program in Ref. 5 is limited. Toon and Ackerman,[30] however, cast the coated-sphere coefficients in such a way that this limitation seems to have been surmounted.

Bessel functions of large complex argument are not the only trap for the unwary. A coated sphere is two spheres. The size parameter for the outer sphere determines the number of terms required for convergence of series. If the inner sphere is much smaller than the outer, the various Bessel functions appropriate to the inner sphere are computed for indices much greater than needed. More indices are not always better. Beyond a certain number, round-off error can accumulate to yield terms that should make ever smaller contributions to sums but may not.

Scattering by spheres and by infinitely long circular cylinders illuminated normally to their axes are in some ways similar. Spherical Bessel functions in the sphere scattering coefficients correspond to cylindrical Bessel functions in the cylinder scattering coefficients. Unlike a sphere, however, an infinitely long cylinder cannot be enclosed in a finite volume. As a consequence, the field scattered by such a cylinder decreases inversely as the square root of distance r instead of inversely as r (for sufficiently large r).

Infinite particles may be mathematically tractable but they are physically unrealizable. In particular, cross sections for infinite cylinders are infinite. But cross sections per unit length of infinite cylinders are finite. Such cross sections may be applied to a finite cylindrical particle by multiplying its length by the cross section per unit length of the corresponding infinite particle. If the aspect ratio (length/diameter) of the finite particle is sufficiently large, what are vaguely called ''end effects'' may be negligible. Because no exact theory for a finite cylinder exists, the aspect ratio at which differences between finite and infinite cylinders become negligible is not known with certainty, although the value 10 is bruited about. Nevertheless, there always will be differences between scattering by finite and infinite particles, which may or may not be of concern depending on the application.

A physical difference between scattering by spheres and by cylinders is that cross sections for cylinders depend on the polarization state of the incident plane wave. But normally incident light illuminating an infinite cylinder and polarized perpendicular (parallel) to the plane defined by the incident wave and the cylinder axis excites only scattered light polarized perpendicular (parallel) to the plane defined by the scattered wave and the cylinder axis. Obliquely incident linearly polarized light can, however, excite scattered light having both copolarized and cross-polarized components.

Obliquely illuminated uncoated cylinders pose no special computational problems. Coated cylinders, however, pose the same kinds of problems as coated spheres and are even more difficult to solve. Toon and Ackerman's[30] algorithm for coated spheres is based on the fact that spherical Bessel functions can be expressed in a finite number of terms. Because cylindrical Bessel functions cannot be so expressed, this algorithm cannot be extended to coated cylinders, for which Bessel functions must be computed separately rather than as ratios and can have values beyond computational bounds. Even if such bounds are not exceeded, problems still can arise.

Although Barabás[31] discussed in detail scattering by coated cylinders, Salzman and Bohren[32] found that his computational scheme is unsuitable when absorption is large. They attempted, with only partial success, to write programs for *arbitrary* coated cylinders. Care must be taken in computing Bessel functions. The often-used Miller algorithm can be inadequate for large, complex arguments.

The simplest nonspherical, finite particle is the spheroid, prolate or oblate. Because the scalar wave equation is separable in spheroidal coordinates, scattering by spheroids can be solved in the same way as for spheres and cylinders. The expansion functions are based on spheroidal rather than spherical or cylindrical wave functions. Asano and Yamamoto[33] were the first to solve in this way the problem of scattering by an arbitrary spheroid. Although Asano[34] subsequently published an extensive set of computations based on this solution, it has not seen widespread use, possibly because of the intractability and exoticness of spheroidal functions.

Computational experience with spheroids and even simpler particles such as spheres and cylinders leads to the inescapable conclusion that hidden barriers lie between a mathematical solution to a scattering problem and an algorithm for reliably and quickly extracting numbers from it.

6.7 COMPUTATIONAL METHODS FOR NONSPHERICAL PARTICLES

The widespread notion that randomly oriented nonspherical particles are somehow equivalent to spheres is symptomatic of a failure to distinguish between the symmetry of an ensemble and that of its members. Considerable effort has been expended in seeking prescriptions for equivalent spheres. This search resembles that for the Holy Grail—and has been as fruitless.

From extensive studies of scattering by nonspherical particles, Mugnai and Wiscombe[35] concluded that ''after examining hundreds of nonspherical results and observing that they all cluster relatively close together, relatively far from the equivolume spheres (except at forward angles), we have come to regard nonspherical particles as normal, and spheres as the most unrepresentative shape possible—almost a singularity.'' This serves as a warning against using Mie theory for particles of all shapes and as a spur to finding methods more faithful to reality. We now turn to some of these methods. Keep in mind that no matter how different they may appear on the surface, they are all linked by the underlying Maxwell equations.

The *T-matrix method* is based on an integral formulation of scattering by an arbitrary particle. It was developed by Waterman, first for a perfect conductor,[36] then for a particle with less restricted properties.[37] It subsequently was applied to scattering problems under the name *extended boundary condition method* (EBCM).[38] Criticism of the T-matrix method was rebutted by Varadan et al.,[39] who cite dozens of papers on this method applied to electromagnetic scattering. Another source of papers and references is the collection edited by Varadan and Varadan.[40] Reference 6 is accompanied by a diskette containing T-matrix programs.

Linearity of the field equations and boundary conditions implies that the coefficients in the spherical harmonic expansion of the field scattered by any particle are linearly related to those of the incident field. The linear transformation connecting these two sets of coefficients is called the T (for transition) matrix.

The T-matrix elements are obtained by numerical integration. Computational difficulties arise for particles with high absorption or large aspect ratios. These limitations of the original T-matrix method have been surmounted somewhat by Iskander et al.,[41] whose extension is dubbed the iterative extended boundary condition method.

Although the T-matrix method is not restricted to axisymmetric particles, it almost exclusively has been applied to spheroids and particles defined by Chebyshev polynomials.[35,42,43]

Despite its virtues, the T-matrix method is not readily grasped in one sitting. Another method, variously called the Purcell-Pennypacker,[44] coupled-dipole,[45] digitized Green's function[46] method and discrete dipole approximation,[47] is mathematically much simpler—the most complicated function entering into it is the exponential—and physically transparent. Although originally derived by heuristic arguments, the coupled-dipole method was put on firmer analytical foundations by Lakhtakia.[48]

In this method, a particle is approximated by a lattice of N dipoles small compared with the wavelength but still large enough to contain many molecules. The dipoles often are, but need not be, identical and isotropic. Each dipole is excited by the incident field and by the fields of all the other dipoles. Thus the field components at each site satisfy a set of $3N$ linear equations. These components can be calculated by iteration[44,49] or by inverting the $3N \times 3N$ coefficient matrix.[45] The coefficient matrix for only one particle orientation need be inverted. This inverse matrix then can be used to calculate scattering for other orientations.[50] A disadvantage of matrix inversion is that the number of dipoles is limited by computer storage.

Arrays of coupled dipoles were considered long before Purcell and Pennypacker entered the scene. More than half a century ago Kirkwood[51] treated a dielectric as an array of molecules, the dipole moment of each of which is determined by the external field and by the fields of all the other molecules. What Purcell and Pennypacker did was to apply the coupled-dipole method to absorption and scattering by optically homogeneous particles. They bridged the gap between discrete arrays and continuous media with the Clausius-Mosotti theory. Because this theory, like every effective-medium theory, is not exact, critics of their method have pronounced it guilty by association. But the Clausius-Mosotti theory is merely the effective-medium theory that Purcell and Pennypacker happened to use. Whatever flaws their method may have, one of them is not that it is forever chained to the ghosts of Clausius and Mosotti. Alleged violations of the optical theorem are easily remedied by using the exact expression for the polarizability of a finite sphere,[52] which in no way changes the structure of the method.

Draine[47] applied this method (under the label *discrete dipole approximation*) to extinction by interstellar grains, obtaining the field components with the conjugate gradient method. An outgrowth of his paper is that by Flatau et al.,[53] who considered scattering by rectangular particles. Goedecke and O'Brien[46] baptized their version of the digitized Green's function method and applied it to scattering of microwave radiation by snowflakes.[54] Varadan et al.[55] applied the method to scattering by particles with anisotropic optical constants. It also has been applied to scattering by helices,[56] by a cylinder on a reflecting surface,[57] and extended to intrinsically optically active particles.[58]

Although Yung's analysis[59] of a large (15,600) array of dipoles representing a sphere suggests that there are no intrinsic limitations to the coupled-dipole method, it is plagued with practical limitations, most notably its inability to treat particles (especially compact ones or ones with large complex refractive indices) much larger than the wavelength of the illumination. Chiapetta,[60] then Singham and Bohren,[61] reformulated the coupled-dipole method, expressing the total field at each dipole as the sum of the incident field and the fields scattered once, twice, and so on by all the other dipoles. Although this formulation is appealing because each term in the scattering-order series has a simple physical interpretation, the series can diverge. The greater the refractive index, the smaller the particle for which the series diverges. For a particle of given volume, fewer terms are needed for convergence the more the particle departs from sphericity. The greater the average separation between dipoles, the weaker the average interaction.

Except for improvements and refinements[52,62,63] that increase accuracy and speed but do not remove barriers imposed by particle size and composition, the coupled-dipole method has not changed much since it first was used by Purcell and Pennypacker. It is not, of course, limited to optically homogeneous particles. It can be applied readily to aggregates of small particles. Indeed, it is best suited to aggregates with low fractal dimension. Berry and Percival[64] considered scattering by fractal aggregates using what they call the *mean-field approximation,* which is essentially the Rayleigh-Gans approximation, in turn a form of the scattering-order formulation of the coupled-dipole method in which the dipoles are excited only by the incident field.

The arbitrary border separating electrical engineering from optics is never more obvious than when it comes to methods for computing scattering. The engineers have theirs, the optical scientists have theirs, and rarely do the twain meet. In the hope of promoting smuggling, even illegal immigration, I must at least mention two methods that fall almost exclusively in the domain of electrical engineering: the method of moments and the finite-difference time-domain technique (FDTD).

Anyone interested in the method of moments must begin with Harrington's book,[65] a focal point from which paths fan out in all directions.

As its name implies, the FDTD technique is applied to what electrical engineers call the *time domain* (as opposed to the *frequency domain,* which most optical scientists inhabit even though they may not know it) and is explicitly labeled a finite-difference method (all methods for particles other than those of simple shape entail discretization in one form or another). Papers by Yee,[66] Holland et al.,[67] Mur,[69] Luebbers et al.,[69] and references cited in them will get you started on the FDTD technique.

When pondering the welter of species and subspecies of methods keep in mind that the differences among them and their ranges of validity are probably smaller than their adherents think or are willing to admit. There is no method that will happily compute scattering of arbitrary waves by particles of arbitrary size and composition in a finite amount of time. Moreover, each method, whatever its merits and demerits, often requires a tedious climb up a learning curve.

CHAPTER 7
SURFACE SCATTERING

E. L. Church*

and

P. Z. Takacs
Brookhaven National Laboratory
Upton, New York

7.1 GLOSSARY

A_0	area
a, b	polarization parameters = $\perp$, $\|$
BRDF	bidirectional reflectance distribution function
BSDF	bidirectional scattering distribution function
f	spatial frequency; $f_x = \xi$, $f_y = \eta$
G	power spectral density function including the specular contribution
I	intensity in power per steradian
P	generalized pupil function
R	Fresnel intensity reflection coefficient
S_1	one-dimensional or profile power spectral density
S_2	two-dimensional or area power spectral density
θ, φ	angles
σ_{ba}	bistatic radar cross section
Φ_{ba}	polarization factor

7.2 INTRODUCTION

The theory of wave scattering by imperfect surfaces has been highly developed in the fields of radiophysics, acoustics, and optics. It is the subject of a number of books,[1–3] book sections,[4–9] and review articles,[10–16] and its practical application to scattering from optical

* Work performed in part while the Author was with the U.S. Army Armament Research, Development and Engineering Center, Picatinny, N.J.

surfaces has been discussed in the readable and informative texts of Bennett[17] and Stover.[18] Bennett has also published a selection of reprints from the extensive literature in the related areas of surface finish and its measurement.[19]

The purpose of this article is to provide a frame of reference for interpreting the existing literature and understanding more recent developments in the description, characterization, and specification of scattering from optical-quality surfaces.

Discussions of related subjects can be found in the articles on ''Measurement of Scatter,'' ''Control of Stray Light,'' ''X-Ray Optics,'' and ''Diffraction'' elsewhere in this *Handbook.*

7.3 NOTATION

The most important quantity in the discussion of surface scattering is the bidirectional reflectance distribution function (BRDF), which is defined precisely in Stover's article on ''Measurement of Scatter.'' The BRDF is a multidimensional function that describes the angular and polarization dependence of the intensity of light reflected and scattered from a surface, and is related to the better-known angular-resolved or differential scattered intensity $dI/d\Omega$ and the bistatic radar cross section σ_{ba}, according to

$$\mathrm{BRDF}_{ba}(\theta_i, \theta_s, \varphi_s) = \frac{1}{\cos\theta_s} \cdot \frac{1}{I_i}\left(\frac{dI_s}{d\Omega}\right)_{ba} = \frac{\sigma_{ba}}{4\pi A_0 \cos\theta_i \cos\theta_s} \tag{1}$$

Here I_i is the incident intensity (power per steradian), I_s is the far-field reflected and scattered intensity, A_0 is the illuminated surface area, and the subscripts a and b denote the states of linear polarization of the incident and scattered radiation (note the right-to-left ordering). When the electric vector is perpendicular (or parallel) to the plane defined by the propagation direction and the surface normal, $a, b = s = \perp$ (or $p = \|$) in optics, and TE (or TM) in radiophysics. Polarization aficionados will note that the quantities defined in Eq. (1) are the square magnitudes of the components of the 2×2 Jones scattering matrix, and correspond to the upper-left quadrant of the 4×4 Stokes scattering matrix.[20]

Acoustic (scalar) scattering is described in terms of the analogous acoustic cross section, but without the polarization notation. Instead, there are two extreme forms of the acoustic boundary conditions, which correspond to the scattering of $\perp$- and $\|$-polarized electromagnetic radiation from a perfectly reflecting (i.e., infinitely conducting) surface. The first is called a ''soft'' surface, which uses the Dirichlet boundary condition, and the second is a ''hard'' surface, which uses the Neumann boundary condition.

As explained later, the angular distribution of the scattered intensity is essentially a Fourier spectrogram of the surface errors, so that it is convenient to discuss scattering in the frequency domain, that is, in terms of the spatial frequency vector **f** lying in the surface plane. The components of this vector are related to the scattering angles by

$$\mathbf{f} = \begin{pmatrix} f_x \\ f_y \end{pmatrix} = \frac{1}{\lambda}\begin{pmatrix} \sin\theta_s \cos\varphi_s - \sin\theta_i \\ \sin\theta_s \sin\varphi_s \end{pmatrix} \tag{2}$$

which can be viewed as a generalization of the grating equation for first-order diffraction from a grating with the spatial wavelength $d = 1/f$. f_x and f_y are frequently denoted by ξ and η in the Fourier-optics literature.

7.4 SCATTERING THEORY

Surface scattering arises from any deviation from the ideal interface that upsets the delicate interference effects required for rectilinear propagation. In principle, relating the BRDF to specific scattering structures is a straightforward application of Maxwell's equations but, more often than not, approximations are necessary to get practically useful results. The best known of these approximations are the physical-optics (Kirchhoff) and the perturbation (Rayleigh-Rice) theories, which despite their advanced age are still subjects of lively investigation.[21]

In the important case of small-angle scattering from weakly scattering surfaces, however, the predictions of all such theories are the same since in those limits the scattering is determined by simple linear-momentum considerations. For the present purposes we consider the most elementary scattering theory that captures that physics—the first-order Born approximation. This approximation has the added advantages that *it includes the effects of the measurement system and surface effects on an equal footing, and can be readily generalized to include both topographic and nontopographic scattering mechanisms.*

In general, scattering problems require the solution of an integral equation that relates the incident and scattered fields. The first-order Born approximation is the first term in an iterative solution of that equation, obtained by setting the total field in the integrand equal to the incident field.[3–5,9] The key quantity in the first-order Born approximation for the BRDF is the square magnitude of an integral containing three factors—an incident plane wave, a scattered plane wave, and an interaction term that couples them—integrated over the illuminated area of the surface. In particular

$$\mathrm{BRDF}_{ba} = \frac{1}{\lambda^2}\Phi_{ba}(\varphi_s)R_a(\theta_i)G(\mathbf{f}) \tag{3}$$

where

$$G(\mathbf{f}) = \frac{1}{A_0}\left|\int_{A_0} d\mathbf{r}\, e^{i2\pi\mathbf{f}\cdot\mathbf{r}}\, P(\mathbf{r})\right|^2 \tag{4}$$

and $\mathbf{r}$ is the position vector in the surface plane. Note that the single exponential factor appearing here, which causes the integral to appear in the form of a Fourier transform, is the product of the input and scattered plane waves, and P is the interaction that couples them. The remaining factors in Eq. (3) also have a simple physical interpretation: Φ_{ba} is a polarization factor which equals $\cos^2 \varphi_s$ when $a = b$ and $\sin^2 \varphi_s$ when $a \neq b$, and R_a is the Fresnel intensity reflection coefficient of the smooth surface.

The interaction, P can be factored into system and surface terms

$$P(\mathbf{r}) = P_{\mathrm{syst}}(\mathbf{r}) \cdot P_{\mathrm{surf}}(\mathbf{r}) \tag{5}$$

where P_{syst} is the pupil function of the measuring system and P_{surf} accounts for surface imperfections. It is convenient to write $P_{\mathrm{surf}} = 1 + p(\mathbf{r})$, where the 1 represents the ideal surface and p is the "perturbation" that describes deviations from a perfectly smooth surface.

For a perfect surface, $p = 0$, and the BRDF given by Eqs. (3) to (5) is just the response function of the measuring system—a sharp spike in the specular direction whose shape and width are determined by the system pupil function. In the case of an imperfect surface, $p \neq 0$, Eqs. (3) to (5) predict a modification of shape and intensity of this specular core, plus scattering out of the core into larger angles. In the following discussion we concentrate on the scattering distribution and return to core effects under "Finish Specification." To make the distinction clear we call the scattering part of the BRDF the bidirectional scattering distribution function, or BSDF.

In general, $p(\mathbf{r})$, the perturbation responsible for scattering, has an irregular or random dependence on surface position, which leads to a scattered intensity distribution in the form of a highly irregular speckle pattern. In general, we are not interested in the fine-scale structure of that pattern, but only its average or smoothed value as a function of scattering angle. In order to relate individual scattering measurements to surface statistics, the locally smoothed values of the scattered intensity are taken to equal the average scattering pattern of an ensemble of statistically equivalent surfaces measured under the same conditions.

That average takes the form

$$\langle \mathrm{BSDF}_{ba} \rangle = \frac{1}{\lambda^2} \Phi_{ba}(\varphi_s) R_a(\theta_i) S_p(\mathbf{f}) \tag{6}$$

where $\langle\ \rangle$ denotes the ensemble average and

$$S_p(\mathbf{f}) = \lim_{A_0 \to \infty} \left\langle \frac{1}{A_0} \left| \int_{A_0} d\mathbf{r}\, e^{i2\pi\mathbf{f}\cdot\mathbf{r}} p(\mathbf{r}) \right|^2 \right\rangle \tag{7}$$

is the two-dimensional power spectral density (PSD) of the perturbation p. The power spectrum is the most important factor in the expression for the BSDF since it is a purely surface quantity and contains all of the information about the surface responsible for scattering.

In the case of polished surfaces the power spectrum of the surface errors is generally a smooth and broad function of spatial frequency, and the smoothed value of the BSDF is independent of the system pupil function. On the other hand, if the surface roughness contains periodic components, such as tool marks in precision-machined surfaces, the BSDF will contain sharp diffraction lines. The positions and intensities of those lines are related to the feed rates and amplitudes of the tool marks, while their widths are determined by the system pupil function.[22–24]

If the surface roughness is spatially isotropic, as is usually assumed for randomly polished surfaces, the PSD depends only on the magnitude of the surface spatial frequency and is independent of its direction in the surface plane. This means that the BSDF depends only on the magnitude of $\mathbf{f}$ in Eq. (2), so that aside from angular-limit (band-limit) effects, all of the information about the surface spectrum can be obtained from scattering measurements made in the plane of incidence ($\varphi_s = 0$).

There are two other cases where scanning in the plane of incidence is sufficient: first, when the surface is "one-dimensional"—i.e., gratinglike—with its grooves oriented perpendicularly to the plane of incidence, and second, when an arbitrary surface is illuminated at an extreme glancing angle of incidence and the scattered intensity is measured by a slit detector perpendicular to the plane of incidence. In both of these cases the Born formalism described above leads to the one-dimensional form for the BSDF:

$$\langle \mathrm{BSDF}_{ba} \rangle = \frac{1}{\lambda} \delta_{b,a} R_a(\theta_i) S_p(f_x) \tag{8}$$

This expression differs from the two-dimension form in Eq. (6) in two ways: it is proportional to $1/\lambda$ rather than $1/\lambda^2$ and involves the one-dimensional or profile PSD instead of the two-dimensional or area PSD.[24] The definition of the one-dimensional power spectrum and its connection with the two-dimensional form are given later, under "Profile Measurements."

There is a final feature of the Born-approximation expression of the BSDF that is worth noting. In the plane of incidence both the one- and two-dimensional forms of the BSDF, although different, are functions of the quantity

$$|\lambda f_x| = |\sin \theta_s - \sin \theta_i| \tag{9}$$

rather than θ_i and θ_s individually. This is sometimes written as $\beta - \beta_0$ and the reduced dependency is described as "shift invariance."[25] The Born formalism, however, shows that it is a manifestation of the grating equation or, more fundamentally, linear momentum conservation in first-order scattering.

7.5 SURFACE MODELS

Surface models introduce new features into the BSDF which can be used to identify specific scattering mechanisms and to determine values of their characteristic physical parameters. One of the nice features of the Born approximation is that it permits a variety of scattering mechanisms to be discussed in a common language. Three such scattering mechanisms are discussed below.

Topographic Scattering

Surface roughness is the principal source of scattering from most optical surfaces at visible wavelengths. It comes from the phase fluctuations impressed on the reflected wavefront by the surface height fluctuations Z:

$$P_{\text{surf}}(\mathbf{r}) = e^{i(4\pi/\lambda)\cos\theta_i \cdot Z(\mathbf{r})} \approx 1 + i\frac{4\pi}{\lambda}\cos\theta_i \cdot Z(\mathbf{r}) \tag{10}$$

Optical-quality surfaces are usually "smooth" in the sense that the exponent above is so small that the two-term expansion on the right is sufficient for describing the scattering outside the specular core. The second term on the right is then p_z, the perturbation responsible for topographic scattering. In that case Eqs. (6) and (7) give

$$\langle \text{BSDF}_{ba} \rangle_z = \frac{16\pi^2}{\lambda^4}\cos^2\theta_i \Phi_{ba}(\varphi_s) R_a(\theta_i) S_z(\mathbf{f}) \tag{11}$$

where the factor S_z is the two-dimensional PSD of the height fluctuations, Z. More refined scalar and vector scattering theories give similar results in the smooth-surface limit. For example, the widely used first-order Rayleigh-Rice vector perturbation theory[4,26] gives

$$\langle \text{BSDF}_{ss} \rangle_z = \frac{16\pi^2}{\lambda^4}\cos\theta_i \cos\theta_s \cos^2\varphi_s \sqrt{R_s(\theta_i)R_s(\theta_s)}\, S_z(\mathbf{f}) \tag{12}$$

for s to s (i.e., $\perp$ to $\perp$) scatter. The simplicity of this expression has earned it the name of "the golden rule" of smooth-surface scattering. The corresponding expressions for *p-s, s-p,* and *p-p* scattering involve more complicated polarization-reflectivity factors and are given in the literature.[4,18,23,24]

In the case of rougher surfaces, higher terms in the expansion of the exponential in Eq. (10) must be taken into account. The resulting expression for the BSDF involves a more complicated dependence on the PSD of the height fluctuations, as well as a dependence on their height distribution function, which is irrelevant in the smooth-surface limit.[1–7]

Material Scattering

A perfectly smooth surface ($Z = 0$) may still scatter because of fluctuations in the composition or density of the surface material. For the lack of a better term we call this *material scattering.* The simplest way of describing such effects is to write the Fresnel-amplitude reflection coefficient of the surface in the form

$$P_{\text{surf}}(\mathbf{r}) = 1 + [\zeta_a(\mathbf{r}) - \bar{\zeta}_a]/\bar{\zeta}_a \tag{13}$$

where $\bar{\zeta}_a$ is the average reflection coefficient. The unity on the right corresponds to a perfect surface and the second term represents the fluctuations about that average, and is the perturbation, p_m, responsible for scattering. The corresponding BSDF is then

$$\langle \text{BSDF}_{ba} \rangle_m = \frac{1}{\lambda^2} \Phi_{ba}(\varphi_s) R_a(\theta_i) S_m(\mathbf{f}) \tag{14}$$

where S_m is the PSD of p_m given by Eqs. (7) and (13). This PSD can, in principle, be related to specific models of the material inhomogeneities, such as the magnitudes and spatial distribution of variations in composition.

Elson, Bennett, and Stover have recently appplied this model to the study of nontopographic scatter from composite beryllium mirrors.[27] A more fundamental source of material scattering from such mirrors is the fact that beryllium metal is optically anisotropic, and the randomly oriented crystallites in the surface lead to significant nontopographic scattering even for pure materials.[28]

If the fluctuations in material properties that are responsible for scattering are distributed throughout the volume of the material, the expression for the BSDF involves the three-dimensional PSD of those fluctuations rather than the two-dimensional form appearing in surface scattering. However, in the limit where the skin depth of the reflecting material is less than the characteristic size of the inhomogeneities—that is, the inhomogeneities can be considered to be columnar—the three-dimensional formalism reduces to the two-dimensional form in Eq. (14).[29–31]

Defect Scattering

The surface models considered above take the perturbations responsible for scattering to be distributed broadly and continuously over the surface. An alternative is to have them localized at isolated regions of the surface, such as pits or bumps in the topographic case and patches of different reflectivity in the case of material scattering.

As an illustration, consider a sparse distribution of identical pits or bumps. In that case the surface height deviations can be written

$$Z(\mathbf{r}) = \sum_j Z_d^{(j)}(\mathbf{r} - \mathbf{r}_j) \tag{15}$$

where $\mathbf{r}_j$ is the location of the jth defect and $Z_d^{(j)}$ is its topographic shape. If the defects are randomly distributed,

$$\langle \mathrm{BSDF}_{ba} \rangle_d = \frac{1}{\lambda^2} \Phi_{ba}(\varphi_s) R_a(\theta_i) S_d(\mathbf{f}) \tag{16}$$

where S_d is the PSD of the collection of defects.[24] For a collection of cylindrical pits or protrusions, for example,

$$S_d(\mathbf{f}) = \frac{1}{A_0} \sum_j \left[2\pi r_j^2 \cdot \frac{J_1(2\pi f r_j)}{\pi f r_j} \cdot \sin\left(\frac{2\pi}{\lambda} h_j \cos\theta_i\right)\right]^2 \tag{17}$$

where r_j and h_j are the radius and height of the jth defect, and the sum is taken over all defects within the illuminated surface area, A_0. This result is instructive but would be quantitative unrealistic for large values of h_j because of the omission of shadowing and other effects in this elementary calculation.

A number of exact calculations of the scattering from particular defects and structures can be found in the literature which may be more useful in modeling real "scratch-and-dig" defects in surfaces than the analysis given above.[4,32–35] Another useful calculation is that for the scattering of dust on smooth surfaces by Videen, Wolfe, and Bickel.[36–37]

The measured BSDFs of real surfaces may involve contributions from one or more scattering mechanisms, such as those discussed above. The next two sections discuss methods of identifying the dominant mechanisms involved through their different characteristics, such as their different dependencies on the radiation wavelength.

7.6 WAVELENGTH SCALING

All first-order expressions for the BSDF appear as the product of factors, each corresponding to a different feature of the scattering process. Equation (12), for example, involves an inverse power of the radiation wavelength, obliquity factors, a reflectivity factor, and finally, the power spectral density of the perturbation responsible for scattering.

The wavelength factor comes from two sources: an inherent factor of $1/\lambda^2$ from the dimensionality of the problem [$1/\lambda$ in the one-dimensional case, Eq. (8)], and an additional factor of $1/\lambda^2$ for topographic scatter since the radiation "sees" the height fluctuations in terms of its wavelength.[31] This additional factor means that, although the topographic component may dominate scattering at visible wavelengths, its contribution to the total BSDF can be overwhelmed by nontopographic or "anomalous" scattering mechanisms at infrared wavelengths.[38]

The reflectivity factor in the BSDF depends on the radiation wavelength through the index of refraction or permittivity of the surface material, although the reflection coefficient of highly reflective mirrors may be effectively constant over a wide range of wavelengths.

The final factor in the BSDF, the PSD, depends on the radiation wavelength principally through its argument, the spatial frequency, although its magnitude can also involve inherent wavelength dependencies. In the case of topographic scattering, the PSD is a purely geometric quantity, independent of the radiation wavelength, while the PSD of material fluctuations can depend on the wavelength.

The radiation-wavelength dependence of the argument of the power spectrum comes from purely geometric considerations. According to Eq. (2), the spatial frequency corresponding to a given scattering direction is inversely proportional to the radiation wavelength. This predictable dependence can be eliminated in data analysis by comparing BSDF measurements made at different radiation wavelengths as a function of spatial frequency rather than scattering angle.

Recent results indicate that mirrors made of some materials, such as molybdenum and silicon, behave as purely topographic scatterers from visible to 10-micron radiation wavelengths, while others show significant nontopographic contributions.[38–40]

If different scattering mechanisms are present, and they are statistically independent, their BSDFs add. If they are not independent, there may be important interference effects which have an intermediate wavelength dependence.[31,41]

7.7 PROFILE MEASUREMENTS

The models described above relate the PSD of surface imperfections to more fundamental physical quantities that are known a priori or can be measured independently. Surface topography, for example, can be measured directly using optical or mechanical profiling techniques, which raises the question of how to use profile data to determine the two-dimensional PSD appearing in Eq. (12). That is, how can BSDFs be predicted from profile measurements?

Algorithms for estimating two-dimensional spectra from two-dimensional arrays of profile data are readily available.[42] The usual procedure, though, is to use the PSDs estimated from profiles taken by "one-dimensional" profiling instruments, or profiles stripped from rectangular arrays of "two-dimensional" measurements. In either case, one gets estimates of the *one-dimensional power spectral density* of the surface:

$$S_z(f_x) = \lim_{L\to\infty} \left\langle \frac{2}{L} \left| \int_{-L/2}^{+L/2} dx e^{i2\pi f_x x} Z(x) \right|^2 \right\rangle \tag{18}$$

which contains information over the range of surface frequencies

$$\frac{1}{L} < f_x < \frac{N}{2L} \tag{19}$$

where L is the profile length and N is the number of data points in the profile. The dynamic range of such measurements—the ratio of the highest to lowest frequency included—is then $N/2$, which can be 1000 or more in practice. In principle, the estimation of power spectra from limited data sets is straightforward, but it involves some subtleties and must be done with care.[42–45] Procedures for doing this are presently being codified in an ASTM standard.[46]

It is important to recognize, though, that the profile spectrum is not just a special form of the area spectrum, but is related to it in a more complicated way than might have been supposed. In particular, they are connected by the integral transform

$$S_1(f_x) = 2 \int_{-\infty}^{+\infty} df_y\, S_2(f_x, f_y) \tag{20}$$

where $f_x > 0$. This accounts for their different units—for example, $S_1(f_x)$ for topographic errors is usually expressed in units of micrometers to the third power, while $S_2(f_x, f_y)$ is in micrometers to the fourth power.[24,45] (We have added subscripts 1 and 2 in Eqs. (20) and (21) to emphasize the distinction between one- and two-dimensional spectra.

In general, Eq. (20) cannot be solved to give $S = S_2$ (the quantity that appears in the expression for the BSDF) in terms of S_1 determined from profile measurements. However, in the special case of an isotropically rough surface, it can, and S_2 can be written as a different but related integral transform of S_1, namely:[24,45]

$$S_2(\mathbf{f}) = -\frac{1}{2\pi}\int_f^\infty \frac{df_x}{\sqrt{f_x^2 - f^2}} \cdot \frac{d}{df_x} S_1(f_x) \tag{21}$$

Unfortunately, the integral on the right cannot be evaluated directly from measured (estimated) profile spectra since real data sets involve strong speckle fluctuations and do not include the high-frequency information needed to extend the upper limit of the integration to infinity. The usual way of handling these difficulties is fit the measured profile spectrum to a physically reasonable analytic model before evaluating Eq. (21). This does three things: it smooths the fluctuations, adds a priori physical information required to extrapolate the data outside the measurement bandwidth, and condenses the data into a few finish parameters.[45]

A useful model for this purpose is the *ABC* or K-correlation model,

$$S_1(f_x) = A[1 + (Bf_x)^2]^{-C/2} \tag{22}$$

where *A, B,* and *C* are the adjustable model parameters. *A* is the value of the profile spectrum in the low-frequency limit, $B/2\pi$ is a "correlation length" which determines the location of the transition between the low- and high-frequency behavior, and *C* is the exponent of the power-law fall-off at high frequencies. The corresponding two-dimensional form of the *ABC* spectrum, determined from the above transformations, is

$$S_2(\mathbf{f}) = A'[1 + (Bf)^2]^{-(C+1)/2} \tag{23}$$

where $A' = AB\Gamma((C+1)/2)/(2\sqrt{\pi}\,\Gamma(C/2))$ for $C > 0$.[40,45]

The *ABC* model is useful since it contains a minimal set of physical parameters, is mathematically tractable, and reduces to a number of more familiar forms as special cases. For example, $C = 2$ gives a lorentzian spectrum, and large *B* gives the fractal-like forms:

$$S_1(f_x) = K_n f_x^{-n} \tag{24}$$

and

$$S_2(\mathbf{f}) = \frac{\Gamma((n+1)/2)}{2\sqrt{\pi}\,\Gamma(n/2)} \cdot K_n f^{-(n+1)} \tag{25}$$

Equation (25) corresponds to an inverse-power-law form for the BSDF. Isolated examples of such scattering distributions have been reported for a number of years[24,25,47] but their ubiquity and importance is only now being recognized.[48]

Equations (22) to (25) provide a mechanism for comparing profile and BSDF measurements of a given surface, and this—along with wavelength scaling—offers another way of distinguishing topographic and nontopographic scattering mechanisms in real surfaces. Such comparisons have been reported in several recent papers.[27,40,–49]

A related procedure, that does not involve scattering as such, is to make mechanical and optical profile measurements of a given surface and to compare spectra deduced from them over a common frequency range. Differences could come from the fact that mechanical measurements are sensitive to topographic effects, while optical measurements are sensitive to material effects as well. Preliminary comparisons of this type indicate that machined silicon is essentially a pure topographic scatterer at HeNe wavelengths.[50,51]

7.8 FINISH PARAMETERS

Optical finish measurements are frequently reported in terms of one or more classical topographic finish parameters—the rms (root mean square) surface roughness σ, the rms profile slope μ, and the surface correlation length l. These are appealing parameters since they are "obvious" measures of quality and numerical values can be estimated directly from raw profile data using simple, intuitive algebraic expressions (estimators).

On the other hand, they suffer from the fact that their values can depend significantly on the measuring instrument used, and do not necessarily represent intrinsic properties of the surfaces being measured. In the early days, when there were only one or two instruments that could measure optical surface finish at all, and measurements were used mainly for comparative purposes, instrumental effects were not an important concern. But nowadays, when many different measurement techniques are available and there is a need for a more quantitative understanding of the measured data, these instrumental effects must be recognized and understood.

The royal road to understanding the effects of the measurement process lies in the frequency domain, which has already appeared naturally in the discussion of surface scattering. For example, it is easy to see that for linear measurement systems the measured value of the mean-square profile roughness and slope are given by weighted integrals or moments of the profile PSD:

$$\begin{pmatrix} \sigma \\ \mu \end{pmatrix}^2_{\text{meas}} = \int_0^\infty df_x\, S_1(f_x) T(f_x) \begin{pmatrix} 1 \\ 2\pi f_x \end{pmatrix}^2 \tag{26}$$

The factor $T(f_x)$ in the integrand is the square magnitude of the transfer function of the particular measurement process involved, and accounts for the fact that real measurements are sensitive to only a limited range of surface spatial frequencies. In contrast, the intrinsic values of these parameters are defined by Eq. (26) where $T(f_x) = 1$.

In the case of mechanical profile measurements $T(f_x)$ is usually taken to be a unit rectangle; that is, a constant equal to unity within the measurement bandpass and zero outside. In the case of optical profile measurements it is usually taken to be a triangle function that falls from unity at zero frequency to zero at the incoherent cutoff of the optical system involved.[43,44,51,52] Although Eq. (26) applies to profile measurements, it is readily generalized to two-dimensional measurement processes,[44,53] where the area in the frequency plane defined by the nonvanishing transfer function is called the *frequency footprint* of the measurement process.[53]

The literature also describes topographic finish in terms of the "correlation length," a length parameter characterizing its transverse properties. Unfortunately, though, most of the values in the literature have been determined without taking the possibly large effects of the measurement bandwidth into account, and must be interpreted with considerable care.[43,48,54]

The standards literature does not yet completely address the issue of measurement bandwidths. The 1985 version of ANSI/ASME B46, which is principally directed towards mechanical surfaces, lists low-frequency limits but not high-frequency ones, although the updated version will.[55] On the other hand, ASTM F1408, for the total integrated scatter (TIS) method for measuring the effective rms surface roughness[56] specifies wavelength and angular parameters that translate to a measurement bandwidth of

$$0.07 < f < 1.48\ \mu\text{m}^{-1} \tag{27}$$

It is important to note that these limits correspond to a dynamic range of only 21.5, which is much less than that of many current profiling instruments. This means that the effective roughness value of a given surface determined by conventional TIS techniques can be significantly smaller than that calculated from profile measurements.[53,57] Noll and Glenn, for example, have reported TIS roughness values that are less than Talystep roughnesses by a factor of 3 or more.[58]

The most striking example of bandwidth effects occurs for fractal surfaces, that is, surfaces with inverse-power-law spectra. Such surfaces do not have finite intrinsic values of the roughness, slope, or correlation length, although they do have *finite measured values* of these quantities, since the low- and high-frequency divergences are cut off by the finite measurement band-pass.[24,48,59–61]

In the light of this, it is more realistic to use the classical topographic finish parameters measured under standardized conditions for descriptive and comparative purposes only, and to use the parameters of the power spectrum for a more comprehensive and precise description—for example, A, B, and C in the ABC model and n and K_n in the fractal model.

The advantages of the power-spectrum description come from the fact that the PSD is directly related to the BSDF, it is an intrinsic surface property and can be used to calculate conventional finish parameters from Eq. (26).[38,40,49]

7.9 FINISH SPECIFICATION

Imperfect surface finish is undesirable since it degrades the performance of an optical system. This raises the question of how to specify surface finish in terms of performance requirements. Although this subject is outside the scope of this article, it is useful to indicate how the ideas discussed above are involved.

The simplest performance requirement is that the distribution of the scattered light intensity is less than some prescribed function of the scattering angle away from the specular direction. This can be translated directly into limitations on error spectra using Eqs. (12) (14) and (16). This method—using an inverse-power-law spectrum—was proposed a number of years ago for x-ray mirrors.[47] and has recently been adopted in an international (ISO) standard for the designation of optical surface finish.[62]

A variant of this is the requirement that the total integrated intensity scattered out of the image core be less than some fraction of the total reflected intensity. In the case of topographic errors this appears in the form of the famous Strehl ratio:

$$\frac{\text{Core intensity, } Z \neq 0}{\text{Core intensity, } Z = 0} \approx e^{-(4\pi\sigma\cos\theta_i/\lambda)^2} \tag{28}$$

where σ is the effective rms roughness of the surface evaluated by integrating the two-dimensional power spectrum of the equivalent surface roughness using the two-dimensional analog of Eq. (26), where the frequency limits of $T(\mathbf{f})$ are determined from the angular limits through the grating equation, Eq. (2). The extreme values of these angles are determined by the core size in one limit, and scattering parallel to the surface plane in the other.[57]

The integrated scattering intensity is important since it represents a loss of the core intensity. In the case of imaging optics, the effects of surface errors on the detailed distribution of the core intensity are also of interest: for example, its on-axis image intensity, the image width, and its spatial-frequency distribution. Expressions for these effects follow from precisely the same Born-approximation result, Eqs. (3) to (5), that to this point we have used only to examine the properties of the scattered radiation, that is, the BSDF.

One interesting result of this analysis is the fact that the effects on imaging are automatically finite for surfaces with fractal surface errors, even though fractal power spectra diverge at long surface spatial wavelengths. This is because the finite size of the pupil function makes the imaging effects insensitive to spatial wavelengths longer than the size of the illuminated area of the mirror. The interested reader is referred to the literature for details of these and related issues.[59–61]

QUANTUM OPTICS

CHAPTER 8

OPTICAL SPECTROSCOPY AND SPECTROSCOPIC LINESHAPES

Brian Henderson

University of Strathclyde
Glasgow, United Kingdom

8.1 GLOSSARY

A_{ba}	Einstein coefficient for spontaneous emission
a_0	Bohr radius
B_{if}	the Einstein coefficient between initial state, $\|i\rangle$, and final state, $\|f\rangle$
E_{DC}	Dirac Coulomb term
E_{hf}	hyperfine energy
E_n	eigenvalues of quantum state, n
$E(t)$	electric field at time t
$E(\omega)$	electric field at frequency, ω
e	charge on the electron
ED	electric dipole term
EQ	electric quadrupole term
$\langle f\| \mathbf{V}' \|i\rangle$	matrix element of perturbation, V'
g_a	degeneracy of ground level
g_b	degeneracy of excited level
g_N	gyromagnetic ratio of nucleus
H_{so}	spin-orbit interaction hamiltonian
$\hbar$	Planck's constant
I	nuclear spin
$I(t)$	the emission intensity at time t
$\mathbf{j}$	total angular momentum vector given by $\mathbf{j} = 1 \pm \frac{1}{2}$
l_i	orbital state
M_N	mass of nucleus N
MD	magnetic dipole term

m	mass of the electron
$n_\omega(T)$	equilibrium number of photons in a blackbody cavity radiator at angular frequency, ω, and temperature, T
QED	quantum electrodynamics
R_∞	Rydberg constant for an infinitely heavy nucleus
$R_{nl}^{(r)}$	radial wavefunction
s	spin quantum number with the value $\frac{1}{2}$
s_i	electron spin
T	absolute temperature
W_{ab}	transition rate in absorption transition between states $\|a\rangle$ and $\|b\rangle$
W_{ba}	transition rate in emission transition from state $\|b\rangle$ to state $\|a\rangle$
Z	charge on the nucleus
$\alpha = e^2/4\pi\varepsilon_0\hbar c$	fine structure constant
ε_0	permittivity of free space
μ_B	Bohr magneton
$\rho(\omega)$	energy density at frequency, ω
$\zeta(r)$	spin-orbit parameter
τ_R	radiative lifetime
ω	angular velocity
$\Delta\omega$	natural linewidth of the transition
$\Delta\omega_D$	Doppler width of transition
ω_k	mode, k, with angular frequency, ω

Spectroscopic measurements have, throughout the century, played a key role in the development of quantum theory. This article will present a simple description of the quantum basis of spectroscopic phenomena, as a prelude to a discussion of the application of spectroscopic principles in atomic, molecular, and solid-state physics. A brief survey will be presented of the multielectron energy-level structure in the three phases of matter and of the selection rules which determine the observation of optical spectra. Examples will be given of the fine-structure, hyperfine-structure, and spin-orbit splittings in the spectra of atoms, molecules, and solids. Solid-state phenomena to be considered will include color center, transition metal, and rare earth ion spectra.

The intrinsic or homogeneous lineshapes of spectra are determined by lifetime effects. Other dephasing processes, including rotational and vibrational effects, lead to splitting and broadening of spectra. There are also sources of inhomogeneous broadening associated with Doppler effects in atomic and molecular spectra and crystal field disorder in solids. Methods of recovering the homogeneous lineshape include sub-Doppler laser spectroscopy of atoms, optical hole burning, and fluorescence line narrowing.

Finally, the relationship between linewidth and lifetime are discussed and the effects of time-decay processes outlined. The consequences of measurements in the picosecond and subpicosecond regime will be described. Examples of vibrational relaxation in molecular and solid-state spectroscopy will be reviewed.

8.2 INTRODUCTORY COMMENTS

Color has been used to enhance the human environment since the earliest civilizations. Cave artists produced spectacular colorations by mixing natural pigments. These same pigments, burned into the surfaces of clays to produce color variations in pottery, were also used to tint glass. The explanation of the coloration process in solids followed from Newton's observation that white light contains all the colors of the rainbow,[1] the observed color of a solid being complementary to that absorbed from white light by the solid. Newton measured the wavelength variation of the refractive index of solids, which is responsible for dispersion, and his corpuscular theory of light explained the laws of reflection and refraction.[1] The detailed interpretation of polarization, diffraction, and interference followed from the recognition that light is composed of transverse waves, the directions of which were related to the direction of the electric field in Maxwell's electromagnetic theory:[2,3] the electronic constituents of matter are set into transverse oscillation relative to the propagating light beam. Subsequently, Einstein introduced the photon in explaining the photoelectric effect.[4] Thus the operating principles of optical components in spectrometers, such as light sources, mirrors, lenses, prisms, polarizers, gratings, and detectors, have been with us for a long time.

Many significant early developments in quantum physics led from optical spectroscopic studies of complex atoms. After Bohr's theory of hydrogen,[5] the quantum basis of atomic processes developed apace. One of Schrödinger's first applications of wave mechanics was in calculations of atomic energy levels and the strengths of spectroscopic transitions.[6] Schrödinger also demonstrated the formal equivalence of wave mechanics and Heisenberg's matrix mechanics. Extensions of spectroscopy from atomic physics to molecular physics and solid-state physics more or less coincided with the early applications of quantum mechanics in these areas.

A survey of the whole of spectroscopy, encompassing atoms, molecules, and solids, is not the present intent. Rather it is hoped that by choice of a few critical examples the more general principles linking optical spectroscopy and the structure of matter can be demonstrated. The field is now vast: Originally the exclusive domain of physicists and chemists, optical spectroscopy is now practiced by a variety of biophysicists and biochemists, geophysicists, molecular biologists, and medical and pharmaceutical chemists with applications to proteins and membranes, gemstones, immunoassay, DNA sequencing, and environmental monitoring.

8.3 THEORETICAL PRELIMINARIES

The outstanding success of the Bohr theory was the derivation of the energy-level spectrum for hydrogenic atoms:

$$E_n = -\frac{mZ^2e^4}{2(4\pi\varepsilon_0)^2n^2\hbar^2} = -\frac{Z^2hc}{n^2}R_\infty \tag{1}$$

Here the principal quantum number n is integral; $h = 2\pi\hbar$ is Planck's constant; Z is the charge on the nucleus, m and e are, respectively, the mass and charge on the electron; and ε_0 is the permittivity of free space. The Rydberg constant for an infinitely heavy nucleus, R_∞, is regarded as a fundamental atomic constant with approximate value 10,973,731 m^{-1}. Equation (1) is exactly the relationship that follows from the boundary conditions required to obtain physically realistic solutions for Schrödinger's time-independent equation for one-electron atoms. However, the Schrödinger equation did not account for the *fine structure* in the spectra of atoms nor for the splittings of spectral lines in magnetic or electric fields.

In 1927 Dirac developed a relativistic wave equation,[7] which introduced an additional angular momentum for the spinning electron of magnitude $s^*\hbar$, where $s^* = \sqrt{s(s+1)}$ and the spin quantum number s has the value $s = \frac{1}{2}$. The orbital and spin angular momenta are coupled together to form a total angular momentum vector $\mathbf{j}$, given by $\mathbf{j} = 1 \pm \frac{1}{2}$. In the hydrogenic ground state $|nl\rangle = |10\rangle$, this spin-orbit coupling yields a value of $\mathbf{j} = \frac{1}{2}$ only, giving the $1S_{1/2}$ level. In the first excited state, for which $n = 2$ the $l = 0$, $\mathbf{j} = \frac{1}{2}$ is represented by $2S_{1/2}$, while $l = 1$ leads to $\mathbf{j} = \frac{3}{2}$ $(2P_{3/2})$ and $\mathbf{j} = \frac{1}{2}(2P_{1/2})$ levels, these two levels being separated by the fine structure interval.[8] The Dirac form of the Coulomb energy, expressed as an expansion in powers of $Z \times$ the fine structure constant, $\alpha = (e^2/4\pi\varepsilon_0\hbar c)$, is then

$$E_{DC} = -\frac{Z^2}{n^2} R_\infty hc\left[1 + \frac{(Z\alpha)^2}{n}\left(\frac{1}{\mathbf{j} + \frac{1}{2}} - \frac{3}{4n}\right) + \mathrm{O}((Z\alpha)^4)\right] \tag{2}$$

The second term in the bracket in Eq. (2) is the spin-orbit correction to the energies which scales as $(Z^4\alpha^2)/n^3$. In the case of hydrogenic atoms this relativistic coupling removes the $nP_{1/2} - nP_{3/2}$ and $nD_{3/2} - nD_{5/2}$ degeneracy, but does not split the $nS_{1/2}$ level away from the $nP_{1/2}$ level. A further relativistic correction to Eq. (1) involves replacing the electronic mass in R_∞ by the reduced mass of the electron $\mu = mM/(M + m)$, which introduces a further shift of order $(m/M)_N(1 - (Z\alpha/2n)^2)E_{DC}$. Here M_N is the mass of the nucleus.

There are two further energy-level shifts.[9] The so-called quantum electrodynamic (QED) shifts include contributions due to finite nuclear size, relativistic recoil, and radiative corrections, collectively described as the Lamb shift, as well as terms due to electron self-energy and vacuum polarization. The Lamb shift raises the degeneracy of the $nS_{1/2} - nP_{1/2}$ levels. Overall, the QED shift scales as $\alpha(Z\alpha)^4/n^3$.[10] The interaction of the electronic and nuclear magnetic moments gives rise to hyperfine structure in spectra. The hyperfine contribution to the electronic energies for a nucleus of mass M_N, nuclear spin I, and gyromagnetic ratio g_N, is given by

$$E_{hf} = \alpha^2\left(\frac{Z^3}{n^3}\right)\left(\frac{g_N m}{M_N}\right) hcR_\infty \frac{F(F-1) - I(I+1) - j(j+1)}{j(j+2)(2l+1)} \tag{3}$$

where $\mathbf{j} = \mathbf{l} + \mathbf{s}$ is the total electronic angular momentum and $\mathbf{F} = \mathbf{I} + \mathbf{j}$ is the total atomic angular momentum. E_{hf} scales as $Z^3\alpha^2/n^3$ and is larger for S-states than for higher-orbit angular momentum states. More generally, all the correction terms scale as some power of Z/n, demonstrating that the shifts are greatest for $n = 1$ and larger nuclear charge. Experiments on atomic hydrogen are particularly important, since they give direct tests of relativistic quantum mechanics and QED.

8.4 RATES OF SPECTROSCOPIC TRANSITION

The rates of transitions may be determined using time-dependent perturbation theory. Accordingly, it is necessary to consider perturbations which mix stationary states of the atom. The perturbations are real and oscillatory in time with angular velocity, ω, and have the form

$$H_1 = V \exp(-i\omega t) + V^* \exp(\omega t) \tag{4}$$

where V is a function only of the spatial coordinates of the atom. In the presence of such a time dependent perturbation, the Schrödinger equation

$$(H_0 + H_1)\Psi = i\hbar \frac{\delta\Psi}{\delta t} \tag{5}$$

has eigenstates

$$\Psi = \sum_n c_n(t)\, |nlm\rangle \exp(-iE_n t/\hbar) \tag{6}$$

which are linear combinations of the n stationary solutions of the time independent

Schrödinger equation, which have the eigenvalues, E_n. The time-dependent coefficients, $c_m(t)$, indicate the extent of mixing between the stationary state wavefunctions, $|nlm\rangle$. The value of $|c_j(t)|^2$, the probability that the electronic system, initially in state i will be in a final state f after time, t, is given by

$$|c_f(t)|^2 = 4\left|\frac{V_{fi}}{\hbar}\right|^2 \frac{\sin^2 \frac{1}{2}(\omega_{fi} - \omega)t}{(\omega_{fi} - \omega)^2} \tag{7}$$

for an absorption process in which the final state f is higher in energy than the initial state, i. This expression defines the Bohr frequency condition,

$$\hbar\omega = E_f - E_i \tag{8}$$

and $\omega_{fi} = (E_f - E_i)/\hbar$. Obviously, $|c_f(t)|^2$ has a maximum value when $\omega_{fi} = \omega$, showing that the probability of an absorption transition is a maximum when $E_f - E_i = \hbar\omega$. The emission process comes from the $V^* \exp(\omega t)$ term in Eq. (4): the signs in the numerator and denominator of Eq. (7) are then positive rather than negative. For the probability to be significant then requires that $\omega_{fi} + \omega = 0$, so that the final state, f, is lower in energy than the initial state. If the radiation field has a density of oscillatory modes $u(\omega)$ per unit frequency range, then Eq. (7) must be integrated over the frequency distribution. The transition rate is then

$$W_{fi} = \frac{2\pi}{\hbar^2} |V_{fi}^{\omega}|^2 u(\omega_{fi}) \tag{9}$$

in which the V_{fi}^{ω} indicates that only a narrow band of modes close to $\omega = \omega_{fi}$ has been taken into account in the integration. This equation, which gives the probability of a transition from $|i\rangle \rightarrow |f\rangle$ per unit time, is known as Fermi's Golden Rule.

In Eq. (9) $V_{fi} = \langle f|\, V\, |i\rangle$ and $V_{fi}^* = \langle f|\, \mathbf{V}^*\, |i\rangle$ determine the transition probabilities for absorption and emission between the initial, i, and final states, f. In fact $|V_{fi}^{\omega}|$ and $|V_{if}^{\omega^*}|$ are identical and the transition probabilities for absorption and emission are equal. For the kth mode with angular frequency ω_k the perturbation takes the form

$$V_k^{\omega} \cong \sum_i \left(er_i \cdot E_k^0 + \frac{e}{2m}(l_i + 2s_i) \cdot B_k^0 + \tfrac{1}{2} er_i \cdot r_i \cdot kE_k^0 \right) \tag{10}$$

The first term in Eq. (10) is the electric dipole (ED) term. The second and third terms are the magnetic dipole (MD) and electric quadrupole terms (EQ), respectively. The relative strengths of these three terms are in the ratio $(ea_0)^2 : (\mu_B/c)^2 : ea_0^2/\lambda^2$ where a_0 and μ_B are the Bohr radius and Bohr magneton, respectively. These ratios are then approximately $1:10^{-5}:10^{-7}$. Since the electromagnetic energy per unit volume contained in each mode, including both senses of polarization, is given by $2\varepsilon_0\kappa\, |E_k^0|^2$, the energy density, $\rho(\omega)$, per unit volume per unit angular frequency is just $4\varepsilon_0\kappa\, |E_k^0|^2\, u_k(\omega)$. Hence, from Eq. (9) and using only the first term Eq. (10) the electric dipole transition rate is determined as

$$W_{if} = \frac{\pi}{2\varepsilon_0\kappa\hbar^2} \sum_{\mathbf{k}} \left| \langle f| \sum_i er_i \cdot \hat{\varepsilon}_k\, |i\rangle \right|^2 \rho(\omega) \tag{11}$$

where the summations are over the numbers of electrons, i, and polarization vectors, $\mathbf{k}$. For randomly polarized radiation Eq. (11) becomes

$$W_{if} = \frac{2\pi}{6\varepsilon_0\kappa\hbar^2} \left| \langle f| \sum_i er_i\, |i\rangle \right|^2 \rho(\omega) \tag{12}$$

If the radiation has all the $\mathbf{E_k}$ vectors pointing along the z-direction then only this mode is taken into account and

$$W_{if} = \frac{\pi}{2\varepsilon_0 \kappa \hbar^2} \left| \langle f| \sum_i ez_i \, |i\rangle \right|^2 \rho(\omega) \tag{13}$$

These relationships Eqs. (12) and (13) are used subsequently in discussing experimental techniques for measuring optical absorption and luminescence spectra. They result in the selection rules that govern both polarized and unpolarized optical transitions.

For the most part the succeeding discussion is concerned with radiative transitions between the ground level, a, and an excited level, b. These levels have degeneracies g_a and g_b with individual ground and excited states labeled by $|a_n\rangle$ and $|b_m\rangle$ respectively. The probability of exciting a transition from state $|a_n\rangle$ to state $|b_m\rangle$ is the same as that for a stimulated transition from $|b_m\rangle$ to $|a_n\rangle$. The transition rates in absorption, W_{ab}, and in emission, W_{ba}, are related through

$$g_a W_{ab} = g_b W_{ba} \tag{14}$$

assuming the same energy density for the radiation field in absorption and emission. Since the stimulated transition rate is defined by

$$W_{ab} = B_{ab}\rho(\omega) \tag{15}$$

the Einstein coefficient, B_{ab}, for stimulated absorption is directly related to the squared matrix element $|\langle b_m| \sum_i |er_i \, |a_n\rangle|^2$. Furthermore, the full emission rate is given by

$$W_{ba} = A_{ba}[1 + n_\omega(T)] \tag{16}$$

where $n_\omega(T)$ is the equilibrium number of photons in a blackbody cavity radiator at angular frequency, ω, and temperature, T. The first term in Eq. (16) (i.e., A_{ba}) is the purely spontaneous emission rate, related to the stimulated emission rate by

$$A_{ba} = 2B_{ba}u_k(\omega)\hbar\omega_k \tag{17}$$

Equation (17) shows that the spontaneous transition probability is numerically equal to the probability of a transition stimulated by one photon in each electromagnetic mode, **k**. Similarly the stimulated absorption rate is given by

$$W_{ab} = B_{ab}\rho(\omega) = \frac{g_b}{g_a} A_{ba} n_\omega(T) \tag{18}$$

These quantum mechanical relationships show how the experimental transition rates, for both polarized and unpolarized radiation, are determined by the mixing of the states by the perturbing oscillatory electric field. Since the radiative lifetime, τ_R, is the reciprocal of the Einstein A coefficient for spontaneous emission (i.e., $\tau_R = (A_{ba})^{-1}$) we see the relationship between luminescence decaytime and the selection rules via the matrix element $|\langle b_m| \sum_i er_i \, |a_n\rangle|$.

8.5 LINESHAPES OF SPECTRAL TRANSITIONS

Consider the excitation of optical transitions between two nondegenerate levels $|a\rangle$ and $|b\rangle$. The instantaneous populations of the upper level at some time t after the atomic system has been excited with a very short pulse of radiation of energy $\hbar\omega_{ab}$ is given by

$$N_b(t) = N_b(0) \exp{(-A_{ba}t)} \tag{19}$$

where A_{ba} is the spontaneous emission rate of photons from level $|b\rangle$ to level $|a\rangle$. Since the energy radiated per second $I(t) = A_{ba}N_b(t)\hbar\omega_{ab}$, the emission intensity at time t and frequency ω_{ba} is given by $I(t) = I(0)\exp(-t/\tau_R)$, where the radiative decaytime, τ_R, is defined as the reciprocal of the *spontaneous decay rate,* i.e., $\tau_R = (1/A_{ba})$. The expectation value of the time that the electron spends in the excited state, $\langle t\rangle$, is calculated from

$$\langle t\rangle = \frac{1}{N_b(0)}\int_{-\infty}^{+\infty} N_b(t)\,dt = (A_{ba})^{-1} = \tau_R \tag{20}$$

This is just the average time, or *lifetime,* of the electron in the excited state. In consequence, this simple argument identifies the radiative decaytime with the lifetime of the electron in the excited state. Typically for an allowed electric dipole transition $\tau_R \sim 10^{-8}$ s.

The radiation from a collection of atoms emitting radiation at frequency ω_{ba} at time $t > 0$ has an associated electric field at some nearby point given by

$$E(t) = E_0 \exp(i\omega_{ba}t)\exp(-t/2\tau_R) \tag{21}$$

(i.e., the electric field oscillates at the central frequency of the transition on the atom). The distribution of frequencies in $E(t)$ is obtained by Fourier analyzing $E(t)$ into its frequency spectrum, from which

$$E(\omega) = \frac{E_0}{\sqrt{(\omega_{ab} - \omega)^2 + (2\tau_R)^{-2}}}\exp(i\phi(\omega)) \tag{22}$$

where $\phi(\omega)$ is a constant phase factor. Since $I(t) \simeq E(t)^2$ we obtain the intensity distribution of frequencies given by

$$I(\omega) = \frac{I_0}{(\omega_{ab} - \omega)^2 + (2\tau_R)^{-2}} \tag{23}$$

This classical argument shows that the distribution of frequencies in the transition has a *lorentzian* shape with full width at half maximum (FWHM), $\Delta\omega$, given by

$$\Delta\omega = \frac{1}{\tau_R} = A_{ba} \tag{24}$$

An identical lineshape is derived from wave mechanics using time dependent perturbation theory. This relationship between the *natural linewidth* of the transition, $\Delta\omega$, and the radiative decaytime, τ_R, is related to the uncertainty principle. The time available to measure the energy of the excited state is just $\langle t\rangle$; the width in energy of the transition is $\Delta E = \hbar\Delta\omega$. Hence $\Delta E\langle\tau\rangle = \hbar\Delta\omega\tau_R = \hbar$ follows from Eq. (24). For $\tau_R \cong 10^{-8}$ s the energy width $\Delta E/c \simeq 5 \times 10^{-2}\,\text{m}^{-1}$. Hence the natural linewidths of a transition in the visible spectrum is $\Delta\lambda \simeq 2 \times 10^{-3}$ nm.

The broadening associated with the excited state lifetime is referred to as *natural* or *homogeneous* broadening. There are other processes which modulate the energy levels of the atom thereby contributing to the overall decay rate, τ^{-1}. It is this overall decay rate, $\tau^{-1} > \tau_R^{-1}$, which determines the width of the transition. Examples of such additional processes include lattice vibrations in crystals and the vibrations/rotations of molecules. In gas-phase spectroscopy, random motion of atoms or molecules leads to inhomogeneous broadening via the Doppler effect. This leads to a gaussian spectral profile of FWHM given by

$$\Delta\omega_D = \frac{4\pi}{c}\left(\frac{2kT}{M}\ln 2\right)^{1/2}\omega_{ba} \tag{25}$$

showing that the Doppler width varies as the square root of temperature and is smaller in heavier atoms. In solids distortions of the crystal field by defects or growth faults lead to strain which is manifested as inhomogeneous broadening of spectra. The resulting lineshape is also a gaussian. The great power of laser spectroscopy is that spectroscopists recover the true homogeneous width of a transition against the background of quite massive inhomogeneous broadening.

8.6 SPECTROSCOPY OF 1-ELECTRON ATOMS

Figure 1*a* shows the energy level structure of atomic hydrogen for transitions between $n = 3$ and $n = 2$ states, i.e., the Balmer α transition. Electric dipole transitions are indicated by vertical lines. The relative strengths of the various lines are indicated by the lengths of the vertical lines in Fig. 1*b*. Also shown in Fig. 1*b* is a conventional spectrum obtained using a discharge tube containing deuterium atoms cooled to $T = 50\,\mathrm{K}$. This experimental arrangement reduces the Doppler width of the Balmer α transition at

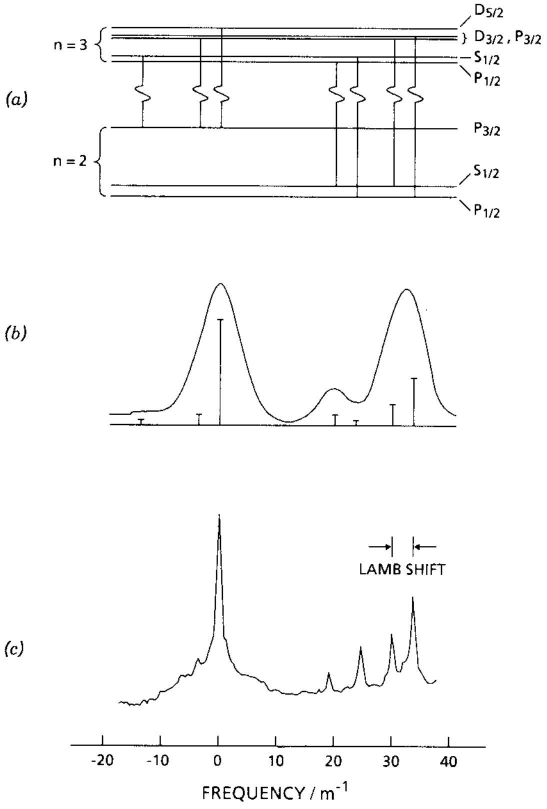

FIGURE 1 (*a*) The structure of the $n = 3$ and $n = 2$ levels of hydrogen showing the Balmer α-transitions. (*b*) A low resolution discharge spectrum of deuterium cooled to 50 K. (*c*) A Doppler-free spectrum of the Balmer α-spectrum of hydrogen. *(After Hänsch et al.*[12]*)*

656 nm to 1.7 GHz. Nevertheless, only three transitions $2P_{3/2} \rightarrow 3D_{5/2}$, $2S_{1/2} \rightarrow 3P_{1/2}$, and $2P_{1/2} \rightarrow 3D_{3/2}$ are resolved.[11] However, sub-Doppler resolution is possible using laser saturation spectroscopy.[12] Figure 1*c* shows the Doppler free Balmer α spectrum to comprise of comparatively strong lines due to $2P_{3/2} \rightarrow 3D_{5/2}$, $2S_{1/2} \rightarrow 3P_{1/2}$, $2S_{1/2} \rightarrow 3P_{3/2}$, and $2P_{1/2} \rightarrow 3D_{3/2}$ transitions, as well as a very weak $2P_{3/2} \rightarrow 3D_{3/2}$ transition. Also evident is a cross-over resonance between the two transitions involving a common lower level $2S_{1/2}$, which is midway between the $2S_{1/2} \rightarrow 3P_{1/2}$, $3P_{3/2}$ transitions. The splitting between $2P_{3/2}$, $2P_{1/2} \rightarrow 3D_{3/2}$ transitions measures the spin-orbit splitting in the n = 2 state, which from Eq. (2) is about 36.52 m^{-1}. The Lamb shift is measured from the splitting between $2S_{1/2} \rightarrow 3P_{3/2}$ and $2P_{1/2} \rightarrow 3D_{3/2}$ lines to be 3.53 m^{-1}, which compares well with the original microwave measurement (3.537 m^{-1}).[13] Subsequently, Hänsch et al.[14] made an interferometric comparison of a Balmer α-line with the 632.8 nm line from He-Ne locked to a component of $^{129}I_2$, thereby deriving a value of R_∞ of 10973731.43(10) m^{-1}, at that time an order of magnitude improvement in accuracy on previous values. Neither the $2S_{1/2}$ nor $2P_{1/2}$ hfs was resolved in this experiment, both splittings being less than the system resolution of *ca* 0.05 m^{-1}. This probably followed from the use of pulsed dye lasers where the laser linewidth exceeds by factors of ten the linewidth available from single-frequency CW dye lasers. Subsequent measurements using CW dye lasers standardized against I_2-stabilized He-Ne lasers gave further improvements in the value of R_∞.[15,16] Also using the Balmer α-transition Stacey et al[17] have studied the isotope shifts between spectra from hydrogen, deuterium, and tritium. The spectrum shown in Fig. 2 reveals the $2S_{1/2}$ hyperfine splitting on the $2S_{1/2} \rightarrow P_{3/2}$ and $2S_{1/2} \rightarrow 3D_{3/2}$ transitions. These measurements yield isotope shifts of 124259.1(1.6) MHz and 41342.7(1.6) MHz for *H-D* and *D-T* respectively, which accord well with theoretical values.

The literature on H-atom spectroscopy is vast, no doubt fueled by the unique relationship between experimental innovation and fundamental tests of relativistic quantum mechanics and QED. This article is not a comprehensive survey. However, it would be seriously remiss of the author to omit mention of three other categories of experimentation. The first experimental arrangement uses crossed atomic and laser beams: a well-collimated beam of atoms propagates perpendicular to a laser beam which, after traversing the atomic beam, is reflected to propagate through the atomic beam again in the opposite direction. The interaction between the counterpropagating beams and the atoms in the atomic beam is signaled by a change in the beam flux. The atomic beam replaces

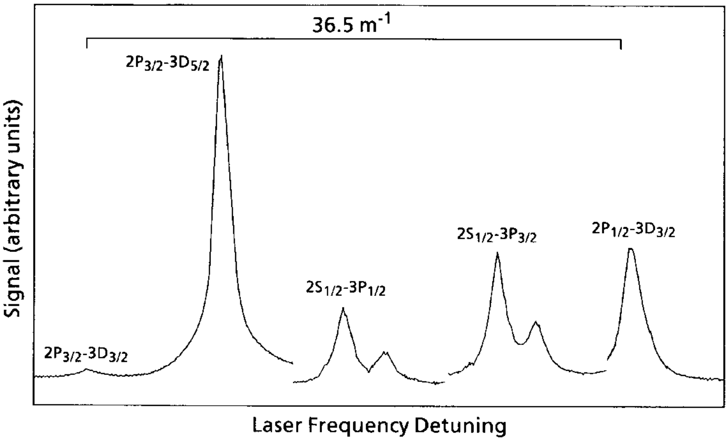

FIGURE 2 Showing hyperfine structure splittings of the $2S_{1/2} \rightarrow 3P_{3/2}$, $3D_{3/2}$ transition in hydrogen. *(After Stacey.[17])*

the discharge unit used in conventional atomic spectroscopy, thereby reducing errors due to the electric fields in discharges. This experiment is the optical analogue of the Lamb-Retherford radio-frequency experiment[13] and has been much used by workers at Yale University.[18] They reported a value of $R_\infty = 10973731.573(3)\ \text{m}^{-1}$ in experiments on the Balmer β ($n = 2$ to $n = 4$) transition.

There have been several other studies of the Balmer β transition, which has a narrower natural linewidth than the Balmer-α transition. However, because it is weaker than the Balmer α transition, Wieman and Hänsch used a polarization scheme to enhance the sensitivity of the saturation absorption scheme.[19] Finally, the metastable $2S_{1/2}$ level may decay spontaneously to the $1S_{1/2}$ ground state with the emission of two photons with energies that sum to the energy separation between $1S_{1/2}$ and $2S_{1/2}$. Such a process has a radiative decaytime of 0.14 s, giving a natural linewidth for the $2S_{1/2} \rightarrow 1S_{1/2}$ transition of order 1 Hz! The probability of a two-photon absorption transition is quite low. However, as with laser absorption saturation spectroscopy, two photon absorption experiments are made feasible by Doppler-free resolution. Wieman and Hänsch[20] used an amplified CW laser beam at 243 nm to excite a two-photon absorption transition, which they detected by observing the Lyman α emission at 121 nm. In addition, part of the laser beam was split off and used to measure simultaneously the Balmer β spectrum. The coupled experiment permitted a direct measurement of the ground-state Lamb shift of 8161(29) MHz. Recently Ferguson and his colleagues have developed standard cells using $^{130}\text{Te}_2$ lines for studies of the Balmer β and $1S_{1/2} \rightarrow 2S_{1/2}$ transitions.[10,21]

8.7 MULTIELECTRON ATOMS

In order to calculate the energy level spectrum of a multielectron atom we require a suitable hamiltonian describing the interaction of all the electrons with the nucleus and with each other. A convenient starting point is the simplified Dirac equation for a one-electron atom, viz.,

$$H = H_0 + H_{so} \tag{26}$$

where H_0 is the simplified hamiltonian for the electron in the field of a nucleus of charge Ze at rest, i.e.,

$$H_0 = \frac{p^2}{2m} - \frac{Ze^2}{4\pi\varepsilon_0 r} \tag{27}$$

and $H_{so} = -\zeta(r)l \cdot s$ is the spin-orbit hamiltonian. Wavefunctions which satisfy Eq. (27) are

$$\psi_{nlm_l}(r) = R_{nl}^{(r)} Y_l^m(\theta\phi) \tag{28}$$

where the labels n, l, and m are quantum numbers which characterize the eigenstates. The eigenvalues, given in Eq. (1), depend only on the principal quantum number, n, which takes positive integral values. The quantum number, l, characterizing the orbital angular momentum also takes integral values, $l = 0, 1, 2, 3, \ldots, (n - 1)$, whereas m_1 measures the z-component of the orbital angular momentum. There are $21 + 1$ integral values of l given by $m = l, (l - 1), (l - 2), \ldots, -(l - 1), -l$, and for a given value of n there are several different orbital states with identical energy. H_{so}, among other interactions, raises this degeneracy.

It is convenient to represent the orbital wavefunction, ψ_{nlm} by the ket $|nlm\rangle$. Including spin angular momentum we represent a *spin orbital* by $|nlsmm_s\rangle$ or more simply by $|nlmm_s\rangle$. Recalling the brief discussion of the coupled representation, whereby $j = l + s$, an equally valid representation is $|nljm_j\rangle$. Indeed the new basis states $|nljm_j\rangle$ are just linear combinations of the $|nlmm_s\rangle$ basis states.[8] Each wavefunction has a definite parity. The parity of wavefunctions is important in determining the selection rules of spectra. The inversion operator P_i, defined by $P_i f(r) = f(-r)$ for any function of r, gives the following result

$$P_i \, |nlm\rangle = (-1)^l \, | \, nlm\rangle \tag{29}$$

Hence, for even values of l the wavefunctions are said to have even parity since they do not change sign under inversion of coordinates. For l odd the wavefunctions have odd parity. The strength of an optical transition is determined by a matrix element $\langle\psi_b| \, \mu \, |\psi_a\rangle$, where the integration is taken over the volume of the atom. In the electric dipole approximation $\mu = -er$ so that the matrix element is zero except that the wavefunction ψ_a and ψ_b have opposite parity. This defines the Laporte selection rule which states that the parity of a state must change from odd to even (or vice versa) in an electric dipole transition.

The hamiltonian for multielectron aotms is a sum over all N electrons of one-electron operators [see Eq. (1)] plus an electron-electron Coulomb repulsion between electrons i and j separated by a distance r_{ij}. Hence we may write this as

$$H = \sum_i \left(\frac{P_i^2}{2m} - \frac{Ze^2}{4\pi\varepsilon_0 r_i} + \zeta(r_i) l_i \cdot s_i \right) + \sum_{i \neq j} \frac{e^2}{4\pi\varepsilon_0 r_{ij}} \tag{30}$$

The computational complexity militates in favor of an approximate solution because the spin-orbit and electron-electron interactions are not spherically symmetric. In consequence, the first stage of the approximation is to Eq. (30) in the form

$$H = \sum_i \frac{p_i^2}{2m} + V_i'(r_i) + \zeta(r_i) l_i \cdot s_i. \tag{31}$$

where $V_i'(r_i)$ is a spherically symmetric one-electron operator which represents the potential energy of the ith electron in the field of the nucleus and all the electrons. The first two terms in this sum constitute the orbital hamiltonian, H_0, a sum of one-electron hydrogen-like hamiltonians (Eq. (27)), but with a more complicated radial potential energy function, $V'(r)$. The radial and angular parts of each one electron hamiltonian are separable and we write orbital functions

$$R_{nl}'(r_i) Y_l^m(\theta, \phi) = |nlm\rangle \tag{32}$$

However, $R_{nl}'(r_i)$ is the solution of the radial equation involving the central potential, $V'(r_i)$, which is characterized by the quantum numbers n and l. In consequence, the energy of the one electron state also depends on both n and l. The complete spin orbital is characterized by four quantum numbers including spin (i.e., $u = |nlmm_s\rangle$) and the many electron eigenstate of H_0 is a product of one electron states

$$U = \prod_i |nlmm_s\rangle_i \tag{33}$$

The energy E_u of this product state is

$$E_u = \sum_i E_{n_i l_i} \tag{34}$$

which depends on the set of $n_i l_i$ values. However, since E_u does not depend on m_l and m_s these eigenstates have a large degeneracy.

Experimentally the complete wavefunctions of electrons are antisymmetric under the exchange of orbital and spin coordinates of any two electrons. The product wavefunction, Eq. (33), does not conform to the requirement of interchange symmetry. Slater solved this problem by organizing the spin orbitals into an antisymmetric N-electron wavefunction in determinantal form.[22] The application of the Hartree-Fock variational approach to determine the central field potential consistent with the best Slater wavefunctions is described in detail by Tinkham.[23] There are many different sets of energy eigenfunctions that can be chosen; the net result is that the eigenstates of H_0 can be classified by a set of quantum numbers LSM_LM_S for each (n_il_i) electron configuration, where $L = \sum_i l_i$ and $S = \sum_i s_i$. That the eigenfunctions must be antisymmetric restricts the number of possible L and S values for any given configuration. Since $J = L + S$ is also a solution of H_0, we can represent the eigenstates of the configuration by the ket $|LSM_LM_S\rangle$ or alternatively by $|LSJM_J\rangle$ where the eigenstates of the latter are linear combinations of the former.

There is a particular significance to the requirement of antisymmetric wavefunctions in the Slater determinantal representation. A determinant in which any two rows or columns are identical has the value of zero. In the present context, if two one electron states are identical, then two columns of the Slater determinant are identical, and the wavefunction is identically zero. This is a statement of the Pauli Exclusion Principle: no two electrons in an atom can occupy identical states (i.e. can have the same four quantum numbers). The Slater wavefunctions indicate those one-electron states which are occupied by electrons. To see how this works consider two equivalent electrons in p-states on an atom. For $n = n'$ for both electrons, the l-values may be combined vectorially to give $L = 2$, 1, and 0. Similarly, the two electron spins, $s = \frac{1}{2}$, may be combined to give $S = 1$ or 0. The antisymmetric requirement on the total wavefunction means that the symmetric orbitals D $(L = 2)$ and S $(L = 0)$ states can only be combined with the antisymmetric spin singlet, $S = 0$. The resulting spin orbitals are represented by ^1D and ^1S. In contrast the antisymmetric P state must be combined with the spin triplet, which is a symmetric function, yielding the antisymmetric spin orbital, ^3P. However, for two inequivalent p-electrons in an excited state of the atom both spin singlet and spin triplet states are possible for the S, P, and D orbital states.

8.8 OPTICAL SPECTRA AND THE OUTER ELECTRONIC STRUCTURE

Optical spectroscopy probes those electronic transitions associated with a small number of electrons outside the closed shells of electrons. This gives further simplification to the computational problem since the multielectron hamiltonian

$$H = \sum_i \frac{p_i^2}{2m} + V'(r_i) + \zeta(r_i) l_i \cdot s_i + \sum_{i>j} \left(\frac{e^2}{4\pi\varepsilon_0 r_i} \right) \tag{35}$$

is summed only over the outer electrons where each of these electrons moves in the central field of the nucleus and the inner closed-shell electrons, $V'(r_i)$. Neglecting the smallest term due to the spin-orbit interaction, the hamiltonian in Eq. (35) takes the form $H_0 + H'$, where H_0 is a sum of one-electron hamiltonian with the radial potential functions $V'(r_i)$ and H' is the energy of the Coulomb interaction between the small number of outer electrons. The corrections to the one electron energies are then the diagonal matrix elements $\langle n_il_im_im_{si}| H' |n_il_im_im_{si}\rangle$, expressed either in terms of Racah parameters, A, B, C, or Slater parameters, F_0, F_2, $F_4 \ldots$.[24] Transition metal ion energy levels are normally described in terms of the Racah parameters and rare earth ion energy levels in terms of the Slater functions. The effect of H' is to split each configuration (n_il_i) into a number of LS terms for each of which there are $(2L + 1)$ $(2S + 1)$ distinct energy eigenstates. We represent the energy eigenstates by the kets $|(n, l)LSJM_j\rangle$, which are defined as linear combinations of the $|(n_il_i)LSM_LM_S\rangle$ states.

Returning briefly to the $(np)^2$ configuration (characteristic of the Group 4 elements, C, Si, Ge, etc. of the Periodic Table) it is noted that the diagonal matrix elements evaluated in terms of Slater parameters are given by $E(^1D) = F_0 + F_2$, $E(^1S) = F_0 + 10F_2$ and $E(^3P) = F_0 - 5F_2$. For the different atoms it is the relative values of F_0 and F_2 which change through the series $(2p)^2$, $(3p)^2$, $(4p)^2$, etc. Note that it is the term with maximum multiplicity, ^3P, which is lowest in energy in conformity with Hund's rule. A similar situation arises for the $(np)^4$ configuration of, for example, atomic O, S, and Se which might equally and validly be considered as deriving from two holes in the $(np)^2$ configuration. The general conclusion from this type of analysis is that the energy level structures of atoms in the same period of the Periodic Table are identical, with the principal differences being the precise energies of the eigenstates. This is evident in Fig. 3, the term scheme for atomic Li, which has the outer electron configuration $(2S)^1$; this may be looked on as a pseudo-one-electron atom. There is general spectroscopic similarity with atomic hydrogen, although the $(ns)^1 - (np)^1$ splittings are much larger than in hydrogen. The $3S_{1/2} \leftrightarrow 2S_{1/2}$ transition is forbidden in Li just as the $2S_{1/2} \leftrightarrow 1S_{1/2}$ transition is in hydrogen. However, it is unlikely to be observed as a two-photon process in emission because the $3S_{1/2} \rightarrow 2P_{3/2,1/2}$ and $2P_{3/2,1/2} \rightarrow 2S_{1/2}$ transitions provide a much more effective pathway to the ground state.

The comparison between Li and Na is much more complete as Figs. 3 and 4 show: assuming as a common zero energy the ground state, the binding energies are $E(2S_{1/2}, \text{Li}) = 43{,}300\,\text{cm}^{-1}$ and $E(3S_{1/2}, \text{Na}) = 41{,}900\,\text{cm}^{-1}$. The energies of the corresponding higher lying nS, nP, and nD levels on Li are quite similar to those of the $(n+1)S$, $(n+1)P$, and $(n+1)D$ levels on Na. This similarity in the energy level structure is reflected in the general pattern of spectral lines, although the observed wavelengths are a little different. For example, the familiar D-lines in the emission spectrum of Na occur at $\lambda \simeq 589.9$ nm whereas the corresponding transition in Li occur at 670.8 nm.

Examination of the term schemes for a large number of elements reveal striking similarities between elements in the same group of the Periodic Table, due to this structure being determined by the number of electrons outside the closed shell structure. These term diagrams also reveal a very large number of energy levels giving rise to line spectra in the ultraviolet, visible, and infrared regions of the spectrum. The term diagrams are not very accurate. Tables of accurate energy levels determined from line spectra have been compiled by C. E. Moore[25] for most neutral atoms and for a number of ionization states of the elements. This comprehensive tabulation reports energy levels to a very large principal quantum number ($n \cong 10$, 11).

The term diagram of the neutral Tl atom, $(6p)^1$ configuration (see Fig. 5) shows two interesting features in comparison with those for alkali metals (see Figs. 3 and 4). In the $(6p)^1$ state the spin-orbit splitting into $6P_{1/2}$ and $6P_{3/2}$ levels amounts to almost $8000\,\text{cm}^{-1}$ whereas the spin-orbit splitting between the $3P_{1/2}$ and $3P_{3/2}$ levels of Na is only $17\,\text{cm}^{-1}$. This reflects the (Z^4/n^3) dependence of the spin-orbit coupling constant. Furthermore, when Tl is in the $7S_{1/2}$ state it can decay radiatively via transitions to either $6P_{3/2}$ or $6P_{1/2}$, each with a distinct transition probability. The relative probability of these transitions is known as the branching ratio for this mode of decay. Other examples of branching are apparent in Fig. 5: the branching ratios are intrinsic properties of the excited state.

8.9 SPECTRA OF TRI-POSITIVE RARE EARTH IONS

The rare earth elements follow lanthanum (Z = 57) in the Periodic Table from cerium (Z = 58), which has the outer electron configuration $4f^15d^16s^2$ to ytterbium (Z = 70) with electron configurations $4f^{13}5d^16s^2$. In the triply charged state in ionic crystals all $5d$ and $6s$

Yb^{3+}	13	$^2F_{7/2}$

electrons are used in ionic bonding and the many energy levels of these R.E.$^{3+}$ ions are due to the partially filled $4f$ shell. The number of electrons in the $4f$ shell for each trivalent ion and the ground state configuration is indicated in Table 1. The energy levels of the unfilled $4f^n$ shells spread out over some 40,000 cm^{-1} giving rise to numerous radiative transitions with energies in the visible region. A remarkable feature of the $4f^n$ electrons is that they are shielded by the outer $5s$ and $5d$ shells of electrons, with the result that $4f$ electrons are not strongly affected by interactions with neighboring ions in crystals. In consequence, the energy levels of the $4f$ electrons in crystals are essentially the free ion levels characterized by quantum numbers L, S, and J. As with the free ions the R.E.$^{3+}$ ions in crystals have very sharp energy levels which give rise to very sharp line spectra. The crystal field interaction does split the R.E.$^{3+}$ ion levels, but this splitting is very much smaller than the splittings between the free ion levels. Hence for rare earth ions in different crystals the gross features of the optical spectra are unchanged.

As discussed in Section 8.6 the eigenstates of the $4f$ electrons are calculated using the central field approximation from which each $4f$ electron state is characterized by the ket $|n = 4,\ l = 3m_l m_s\rangle$. The effect of the Coulomb repulsion between electrons, $H' = \sum_i e^2/4\pi\varepsilon_0 r_{ij}$, is to split the energy levels of the $4f^n$ configuration into different LS terms, with wavefunctions characterized by kets $|LSM_LM_S\rangle$. The magnitudes of the electrostatic interaction for each LS-level are expressed as sums of Slater electron-electron integrals F_k, with $k = 0$, 2, 4, and 6 for $4f$ electrons. Since F_0 contributes equally to all LS states of the same $4f^n$ configuration, this term can be neglected. Generally, these Slater integrals are regarded as adjustable parameters with magnitudes determined by fitting to the measured line spectra. The values of the F_k integrals for $4f^n$ ions in many crystals vary by only about 2 percent from those obtained for free ions; they also vary slightly depending on the nature of the surrounding ions. The next largest term in the hamiltonian, after H', is spin-orbit coupling. If the spin-orbit coupling energy is much smaller than the energy separation in the LS term then the spin-orbit interaction can be written as $\zeta L \cdot S$ and the wavefunctions are characterized by $|LSJM_J\rangle$. The additional energy of the J-multiples are given by the Landé interval formula

$$E_J = \frac{\zeta}{2}[J(J+1) - L(L+1) - S(S+1)] \tag{36}$$

from which it is evident that the separation between adjacent levels is given by $J\zeta$ where J

refers to the upper J value. However, deviations from this Landé interval rule do occur because of mixing of different LS-terms when spin-orbit coupling and electron-electron interaction are of similar magnitudes. Clear examples of this are obtained from the spectra of $Pr^{3+}(4f^2)$ and $Tm^{3+}(4f^{12})$.

As representative of the type of spectra observed from R.E.$^{3+}$ ions in ionic crystals we consider just one example: $Nd^{3+}(4f^3)$ in $Y_3Al_3O_{12}$(YAG). The Nd^{3+}-YAG material is important as the gain medium in a successful commercial laser. Nd^{3+} has a multitude of levels many of which give rise to sharp line emission spectra. A partial energy level structure is shown in Fig. 6. The low temperature emission is from the $^4F_{3/2}$ level to all the ^4I_J levels of the Nd^{3+} ion. The spectra in Fig. 6 also show the splittings of the ^4I_J levels by the crystal field, corresponding to the energy level splitting patterns given in the upper

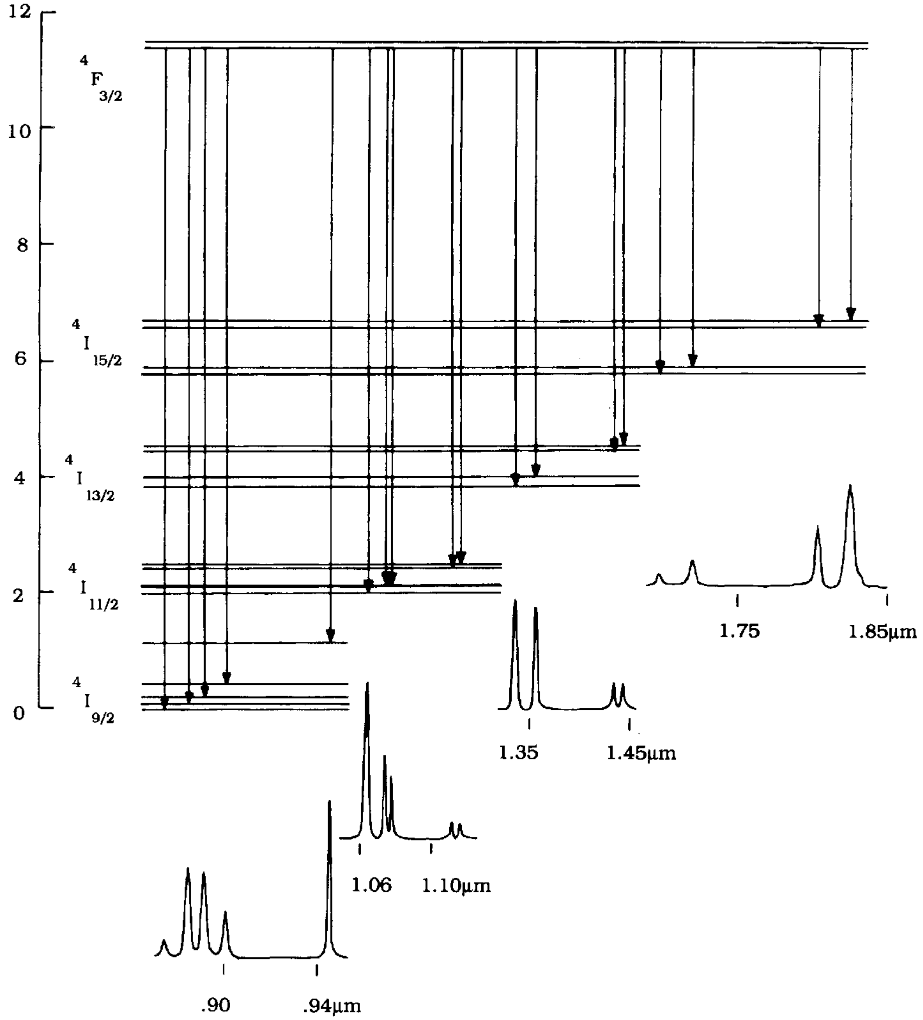

FIGURE 6 The low temperature photoluminescence spectrum from the $^4F_{3/2}$ level of Nd^{3+} in $Y_3Al_5O_{12}$ and the corresponding energy level structure. *(After Henderson and Imbusch.*[8]*)*

portion of Fig. 6. Depending upon crystal quality these lines can be quite narrow with half-widths of order a few gigahertz. Nevertheless the low-temperature width in the crystal is determined by the distribution of internal strains and hence the lines are inhomogeneously broadened. The natural linewidth of rare earth ion spectra is of the order of a few megahertz. By using optical hole burning (OHB), which is similar to the saturated absorption spectroscopy discussed earlier for atomic hydrogen, it is possible to eliminate the inhomogeneous broadening and recover the homogeneous lineshape of the spectrum. In principle, the natural width is determined by lifetime processes of which there are more numerous sources in crystals than in atomic vapors. Indeed the width may be determined by random modulation of the optical lineshape by photons and by both nuclear and electronic spins of neighboring ions. The two most general techniques for determining the homogeneous widths of optical transitions in solids are optical holeburning (OHB) and fluorescence line narrow (FLN). Examples of these techniques are discussed elsewhere in this treatise.

8.10 VIBRATIONAL AND ROTATIONAL SPECTRA OF MOLECULES

A consultation of any one of the Tables of data in Moore's compilation[25] shows that the energy level schemes of most atoms are complex. This is confirmed by the associated atomic spectra. Considerable interpretive simplication is afforded by the construction of term diagrams (e.g., Figs. 3–5), on which a very large number of lines may be associated with a much smaller number of terms, each term corresponding to an energy level of the atom. The observed spectral lines are due to transitions between pairs of terms (not all pairs) which occur subject to an appropriate selection rule. The spectra of even simple molecules measured with low dispersion show characteristic band spectra which are even more complicated than the most complex atomic spectra. These band spectra, when studied at higher spectral resolution, are observed to consist of an enormous number of closely spaced lines. At first acquaintance, such band spectra appear to be so complex as to defy interpretation. Order can be brought to the riot of spectral components by constructing term schemes for molecules involving electronic, vibrational, and rotational energy terms, which enable the molecular spectroscopist to account for each and every line.

Molecular physics was a research topic to which quantum mechanics was applied from the very earliest times. Heitler and London developed the valence band theory of covalency in the H_2-molecule in 1927.[26] The theory shows that with both electrons in 1s states there are two solutions to the hamiltonian

$$E_{\pm} = 2E(1\mathrm{H}) + \frac{K \pm \Im}{1 \pm \mathcal{S}} \tag{37}$$

where $E(1\mathrm{H})$ is the energy of an electron in the ground state of atomic hydrogen, K is the Coulomb interaction due to the mutual actions of charges distributed over each atom, $\Im$ is the exchange energy, and $\mathcal{S}$ is the overlap integral. The exchange energy is a purely quantum mechanical term, representing the frequency with which the deformation of the wavefunctions by their mutual interaction oscillates from one atom to another. The positive sign refers to the symmetric combination of orbital wavefunctions for the two hydrogen atoms. Since the overall wavefunction must be antisymmetric, the combined spin states must be antisymmetric (i.e., the spin singlet $S = 0$; this state is labeled $^1\Sigma_g$. The evaluation of the integrals in Eq. (37) as a function of internuclear separation leads to Fig. 7

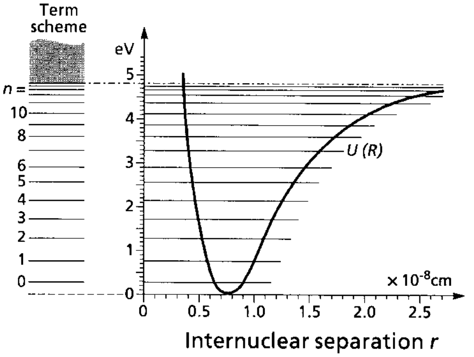

FIGURE 7 The internuclear potential, $V(R - R_0)$, in the ground state $^1\Sigma_g$ of the hydrogen molecule.

for the spin singlet state. This $^1\Sigma_g$ ground state has a potential energy minimum of about 4.8 eV (experimentally) with the nuclei separated by 0.75 nm, relative to the total energy of the two hydrogen atoms at infinity. The theoretical value of the binding energy on the valence band model is only 3.5 eV.[26] The negative sign in Eq. (37) guarantees that in the state characterized by the antisymmetric combination of orbital states and $S = 1$, i.e. $^3\Sigma_u$, the energy is monotonically ascending, corresponding to repulsion between the two hydrogen atoms for all values of R. In such a state the molecule dissociates.

The energy versus internuclear separation curve in Fig. 7 represents the effective potential well, in which the protons oscillate about their mean positions. This is the potential used in the Born-Oppenheimer treatment of the molecular vibrations in the spectra of diatomic molecules.[27] The potential function may be written as a Taylor expansion

$$V(R - R_0) = V_0 + (R - R_0)\left(\frac{dV}{d(R - R_0)}\right)_0 + \frac{(R - R_0)^2}{2}\left(\frac{d^2V}{d(R - R_0)^2}\right)_0$$
$$+ \frac{(R - R_0)^3}{6}\left(\frac{d^3V}{d(R - R_0)^3}\right)_0$$

where the subscript 0 refers to values of the differentials at $R = R_0$ and higher terms have been ignored. For a molecule in stable equilibrium the potential energy is a minimum and the force at $R = R_0$ must be zero. In consequence, the potential energy function may be written as

$$V(R - R_0) = \tfrac{1}{2}(R - R_0)^2\left(\frac{d^2V}{d(R - R_0)^2}\right)_0 + \tfrac{1}{6}(R - R_0)^3\left(\frac{d^3V}{d(R - R_0)^3}\right)_0 \qquad (38)$$

after setting $V_0 = 0$.

The excited states of H_2 are constructed on the assumption that only one electron is excited in the transition: the appropriate configurations may be written as $(1s, 2s)$, $(1s, 2p)$, $(1s, 3s)$, etc. The electronic states of the molecule are then suitable combinations of the atomic states and categorized according to the total orbital angular momentum determined by vector addition of individual electronic orbital momenta. These orbital angular momentum states are designated as Σ, Π, Λ, etc. when the total angular momentum quantum number is 0, 1, 2, etc. Thus the electronic state in Fig. 7 is described as the $^1\Sigma_g$

(ground state) and the lowest lying excited state as ${}^3\Sigma_\mathrm{u}$, where the subscripts g and u indicate even (gerade) and odd (ungerade) parity of the orbital states, respectively. The first excitation states associated with the (1*s*, 2*s*) molecular configuration, designated as ${}^1\Sigma_\mathrm{g}$ and ${}^3\Sigma_\mathrm{u}$, have energies

$$E_{\pm} = E(1\mathrm{H}) + E(2\mathrm{H}) + \frac{K \pm \Im}{1 \pm \mathcal{S}} \tag{39}$$

Because the charge distributions are different in the atomic 1*s* and 2*s* states, the values of K and $\Im$ are also different in the (1*s*, 2*s*) configuration relative to the ground configuration. Obviously, as the orbital degeneracy of the molecular configuration increases so does the number of molecular levels resulting from the configuration. For example, there are six molecular levels associated with (1*s*, *np*) configuration, ten associated with (1*s*, *nd*), and so on. Roughly speaking, half of these levels will have a potential minimum in a graph of electronic potential energy versus internuclear separation (e.g., Fig. 7), and are associated with "bonding" orbitals of the molecule. In the other levels the force between the constituent atoms is repulsive for all values of the internuclear separation. In such orbitals the molecules will tend to dissociate.

The potential energy curve for a molecular bonding orbital (e.g., Fig. 7) is of the form given by Eq. (38). In the lowest order approximation this relation defines a potential well which is harmonic in the displacements from the equilibrium value. Of course, not all values of the potential energy, $V(R - R_0)$, are permitted: the vibrational energy of the molecule is quantized, the quantum number n having integral values from n = 0 to infinity. The energy levels are equally spaced with separations $h\nu_v$. The second term is an anharmonic term which distorts the parabolic shape relative to the harmonic oscillator. There are two important differences between the quantized harmonic and anharmonic oscillators. First, where there is an infinite number of levels in the former, there is only a finite number of vibrational states for an anharmonic molecule. Second, the levels are not equally spaced in the anharmonic oscillator, except close to the potential minimum. For this reason the anharmonic oscillator will behave like a harmonic oscillator for relatively small values of the vibrational quantum number. It is normal to assume harmonic vibrations in the Born-Oppenheimer approximation.[27]

Molecular spectra fall into three categories, according as they occur in the far infrared (20–100 μm), near infrared (800–2000 nm), or visible/near ultraviolet (750–150 nm) region. Spectra excited by radiation in the infrared region are associated with changes in the rotational energy of the molecule. Spectra in the near-infrared region correspond to simultaneous changes in the rotational and vibrational energy of the molecule. Finally, the visible and ultraviolet spectra signal simultaneous changes in the rotational, vibrational, and electronic energies of the molecule. The latter category has the greatest potential complexity since in interpreting such visible/ultraviolet spectra we must, in principle, solve the molecular hamiltonian containing terms which represent electronic, vibrational, and rotational energies.

If we simplify the molecular problem somewhat we may represent the stationary states of a molecule by a linear sum of three energy terms: an electronic term determined by a quantum number n, a vibrational term determined by a quantum number, v, and a rotational term determined by a quantum number, r. The band spectra emitted by molecules are then characterized by three different kinds of excitations: electronic, vibrational, and rotational with frequencies in the ratio $\nu_{el} : \nu_v : \nu_r = 1 : \sqrt{m/M} : m/M$, where m is the electronic mass and M is the reduced molecular mass. In an optical transition the electronic configuration (*nl*) changes, and generally we expect the vibrational/rotational state to change also. In consequence, for a particular electronic transition, we expect splittings into a number of vibrational components, each of which is split into a number of rotational components. Using the rough ratio rule given previously, and assuming the Rydberg to be a characteristic electronic transition, we find spectral splittings of 500 cm^{-1}

and 60 cm^{-1} to characterize the vibrational and rotational components, respectively. Since the quantized energy levels of the harmonic oscillator and rigid rotor are given by

$$E_v = (n + \tfrac{1}{2)}h\nu_v \tag{40}$$

$$E_r = r(r+1)h\nu_r \tag{41}$$

where $\nu_v = (1/2\pi)\sqrt{k/M}$ and $\nu_r = \hbar/4\pi I$, in which k is the "spring" constant, M is the reduced molecular mass, and $I = Ml^2$ is the moment of inertia for a dumbbell shaped molecule of length l, and applying to the usual selection rules for electronic ($\Delta l = \pm 1$, with $\Delta j = 0, \pm 1$), vibrational ($\Delta v = \pm 1, \pm 2, \ldots$), and rotational ($\Delta r = 0, \pm 1$) transitions, we expect transitions at the following frequencies

$$\nu = \nu_0 + (n'' - n')/\nu_v + (r''(r''+1) - r'(r'+1))\nu_r \tag{42}$$

where the superscript primes and double primes refer to final and initial states. For simplicity we have assumed that the vibrational spring constants and rotational moments of inertia are unchanged in the transitions. The number of potential transition frequencies is obviously very large and the spectrum consists of very many closely spaced lines. Of course, the vibrational/rotational structure may be studied directly in microwave spectroscopy.[28] An early account of the interpretation of such spectra was given by Ruark and Urey.[29] For many years such complex spectra were recorded photographically; as we discuss in later sections, Fourier transform spectroscopy records these spectra electronically and in their finest detail. Subsequent detailed accounts of the energy levels of molecular species and their understanding via spectroscopic measurements have been given by Slater, Hertzberg and others.[30–32]

An example of the complexities of band spectra, for a simple diatomic molecule, is given in Fig. 8, in this case for the photographically recorded β-bands ($2\Pi \rightarrow 3\Sigma$) of the nitric oxide molecule. Under low dispersion band spectra are observed (see Fig. 8*a*) which break down into line spectra under very high resolution (see Fig. 8*b*). This band system is emitted in transitions having common initial and final electronic states, with all the electronic states corresponding to a multiplet in atomic spectra. The electronic energy difference determines the general spectral range in which the bands are observed. However, the positions of the individual bands are determined by the changes in the vibrational quantum numbers. The spectra in Fig. 8 are emission spectra: the bands identified in Fig. 8*a* by (n', n'') are so-called *progressions* in which the transition starts on particular vibrational levels ($n' = 0$) of the upper electronic state and ends on a series of

FIGURE 8 Characteristic band spectra of the diatomic NO molecule under conditions of (*a*) low resolution and (*b*) high resolution. *(After Ruark and Urey.*[29]*)*

different vibrational levels (n'') of the lower electronic level. Such n' progressions measure the vibrational energy level differences in the lower electronic levels. Specifically identified in Fig. 8*a* are band progressions $n' = 0 \rightarrow n'' = 4, 5, 6, 7 \ldots$ and $n' = 1 \rightarrow n'' = 10, 11, 12 \ldots$. Also evident, but not identified in Fig. 8*a,* are *sequences* of lines in which the difference in vibrational quantum number $n' - n''$ is a constant. For example, either side of the $(0, 4)$ band can be seen $\Delta n = -4$ and -3 sequences, respectively.

The $(0, 7)$ band is shown under much higher spectral resolution in Fig. 8*b,* revealing a plethora of closely spaced lines associated with the rotational structure. For transitions in which the vibrational quantum number changes by some multiple of unity, i.e., $\Delta n = 1, 2, 3$, etc., the rotational quantum number changes by $\Delta r = 0$ and ± 1. The three branches of the rotational spectrum have the following positions (measured in cm^{-1}):

$$R = A + 2B(r + 1) \qquad \text{for } \Delta r = -1 \text{ and } r = 0, 1, 2 \ldots \tag{43a}$$

$$Q = A + Cr \qquad \text{for } \Delta r = 0 \text{ and } r = 0, 1, 2 \ldots \tag{43b}$$

$$P = A - 2Br \qquad \text{for } \Delta r = +1 \text{ and } r = 1, 2, 3 \ldots \tag{43c}$$

where in each case r refers to the rotational quantum number in the final electronic-vibrational state, $A = \bar{v}_e + \bar{v}_v$, and $B = \hbar/4\pi cI$. In consequence, if $C = 0$, the Q-branch consists of a single line at $Q(r) = v_e + v_v$, and the P- and R-branches shift linearly to lower and higher wavenumbers, respectively, relative to the Q-branch for increasing values of r. The spectra in Fig. 8 show that for the NO molecule $C \neq 0$ so that the lines in the P- and R-branches are shifted by $\pm 2B$ relative to the Q-branch lines. The particular Q-branches are defined by $l' = l'' = r + \frac{1}{2}$ with r being either 0 or 1, i.e., $l' = l'' = \frac{1}{2}$ or $\frac{3}{2}$. The $C \neq 0$ implies that the Eqs. (41) and (43) are inaccurate and additional rotational energy terms must be included even for vibrational states close to the bottom of the potential well (i.e., small n-values). Roughly the rotational term in Eq. (43) must be multiplied by $1 - (2\hbar^2(r + 1)^2/4\pi^2 I^2)$, which has the further consequence that the separations of lines in the P- and R- branches corresponding to particular values of r increase with increasing r. A detailed analysis of Fig. 8*b* shows this to be the case.

8.11 LINESHAPES IN SOLID STATE SPECTROSCOPY

There are many modes of vibration of a crystal to which the optical center is sensitive. We will concentrate on one only, the breathing mode in which the ionic environment pulsates about the center. The variable for the lattice state, the so-called configurational coordinate, is labeled as Q. For the single mode of vibration the system oscillates about its equilibrium value Q_0^a in the ground state and Q_0^b in the excited state. The ground and excited state configurational coordinate curves are assumed to have identical harmonic shapes, and hence vibrational frequencies for the two states. This is illustrated in Fig. 9. In the Born-Oppenheimer approximation the optical center-plus-lattice system is represented in the electronic ground state by the product function[27]

$$\Phi_a(r_i, Q) = \Psi_a(r_i, Q_0^a)\chi_a(Q) \tag{44}$$

and in the electronic excited state by

$$\Phi_b(r_i, Q) = \Psi_b(r_i, Q_0^b)\chi_b(Q) \tag{45}$$

The first term in the product is the electronic wavefunction, which varies with the electronic positional coordinate r_i, and hence is an eigenstate of $H_0 = \sum_i(p_i^2/2m) + V'(r_i)$, and is determined at the equilibrium separation Q_0^a. The second term in the product wave function is $\chi_a(Q)$, which is a function of the configurational coordinate Q. The entire ionic potential energy in state a is then given by

$$E^a(Q) = E_0^a + V_a(Q) \tag{46}$$

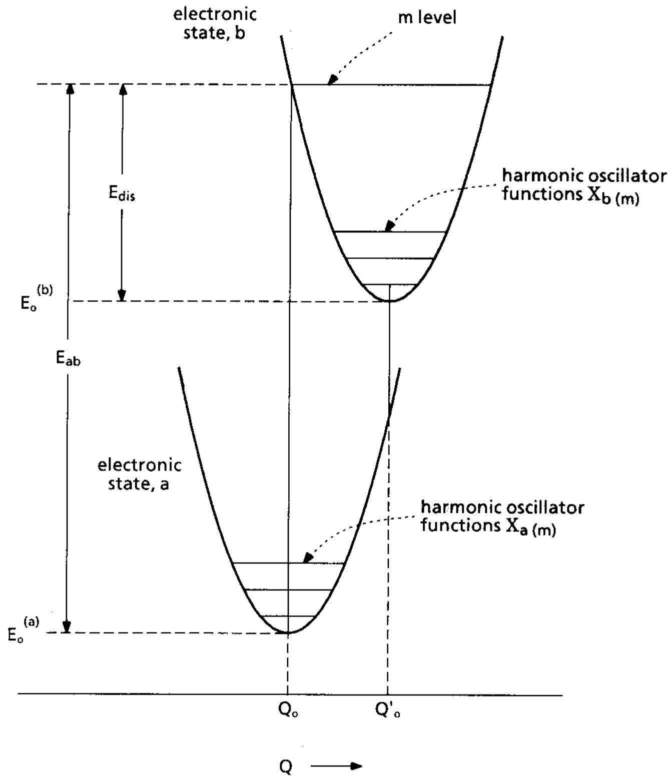

FIGURE 9 A configurational coordinate diagram showing the interionic potential in the harmonic approximation for electronic states $|a\rangle$ and $|b\rangle$. *(After Henderson and Imbusch.[8])*

The $E^a(Q)$ in Fig. 9 is an harmonic potential function. This is an approximation to the potential used in Eq. (38) and illustrated in Fig. 7. A similar expression obtains for $E^b(Q)$. This representation of the Born-Oppenheimer approximation is often referred to as the *configurational coordinate model.*[38]

Treating the electronic energy of the ground state E_0^a as the zero of energy, we write the ionic potential energy in the ground state as

$$E^a(Q) = \tfrac{1}{2}M\omega^2(Q - Q_0^a)^2 \qquad (47)$$

and in the excited state as

$$E_0^b(Q) = E_{ab} + \tfrac{1}{2}M\omega^2(Q - Q_0^a)^2 - (2S)^{1/2}\hbar\omega\left(\frac{M\omega}{\hbar}\right)^{1/2}(Q - Q_0^a) \qquad (48)$$

where E_{ab} is essentially the peak energy in an absorption transition between states $|a\rangle$ and $|b\rangle$ with the lattice at the coordinate, Q_0^a, where the Huang-Rhys parameter S is defined as

$$S = \frac{E_{\mathrm{dis}}}{\hbar\omega} = \frac{1}{2}\frac{M\omega^2}{\hbar\omega}(Q_0^b - Q_0^a)^2 \qquad (49)$$

If the vertical line from $Q = Q_0^a$ in Fig. 9 intersects the upper configurational coordinate curve at the vibrational level n' then

$$E_{\text{dis}} = S\hbar\omega = (n' + \tfrac{1}{2})\hbar\omega \tag{50}$$

The shapes of absorption and emission spectra are found to depend strongly on the difference in electron-lattice coupling between the states, essentially characterized by $(Q_0^b - Q_0^a)$ and by E_{dis}.

The radiative transition rate between the states $|a, n'\rangle \rightarrow |b,n''\rangle$ where n' and n'' are vibrational quantum numbers is given by,[8]

$$W(a, n' - b, n'') = |\langle\psi_b(r_i, Q_0^a)\chi_b(n'')|\ \mu\ |\psi_a(r_i, Q_0^a)\chi_a(n')\rangle|^2 \tag{51}$$

which can be written as

$$W(a, n' - b, n'') = W_{ab}\ |\langle\chi_b(n'')\ |\ \chi_a(n')\rangle|^2 \tag{52}$$

where W_{ab} is the purely electronic transition rate. The shape function of the transition is determined by the square of the vibrational overlap integrals, which are generally not zero. The absorption bandshape at $T = 0$ K where only the $n' = 0$ vibrational level is occupied, is

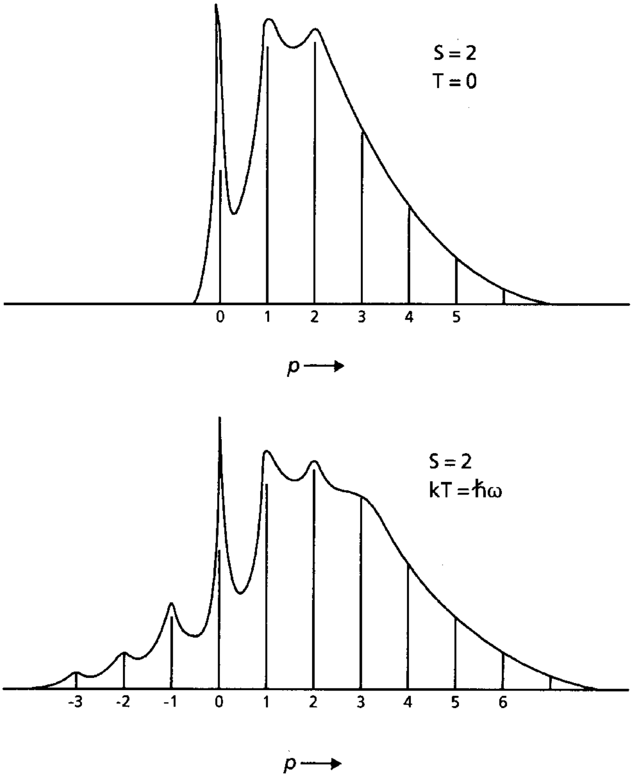

FIGURE 10 Showing the zero-phonon line and the Stokes shifted sideband on one side of the zero-phonon line at $T = 0$. When the temperature is raised the anti-Stokes sidebands appear on the other side of the zero-phonon line. *(After Henderson and Imbusch.[8])*

then given by

$$I_{ab}(E) = I_0\Sigma_{n''}\frac{S^{n''}\exp(-S)}{n''!}\,\delta(E_0 + n''\hbar\omega - E) \tag{53}$$

where $E_0 = E_{b0} - E_{a0}$ is the energy of the transition between the zero vibrational levels of electronic states a and b. This is usually referred to as the *zero-phonon transition,* since $\Sigma_{n''}S^{n''}\exp(-S)/n''! = 1$, I_0 is the total intensity of the transition, which is independent of S. The intensity of the zero phonon transition I_{00} is given by

$$I_{00} = I_0\exp(-S) \tag{54}$$

so that if $S = 0$ all the intensity is contained in the zero-phonon transition. On the other hand, when S is large, the value of I_{00} tends to zero and the intensity is concentrated in the *vibrational sidebands.* The single configurational coordinate model is relevant to the case of electron-vibrational structure in the spectra of molecules and the intensities so calculated fit observations rather well.

The net effect of this analysis is given in Fig. 10, which represents the absorption case when $S = 2$. At $T = 0$ we see a strong zero-phonon line, even stronger phonon-assisted transitions at $n'' = 1$ and 2, and then decreasing intensity in the phonon sidebands at $n'' = 3$, 4, 5, etc. These individual transitions are represented by the vertical lines in this predicted

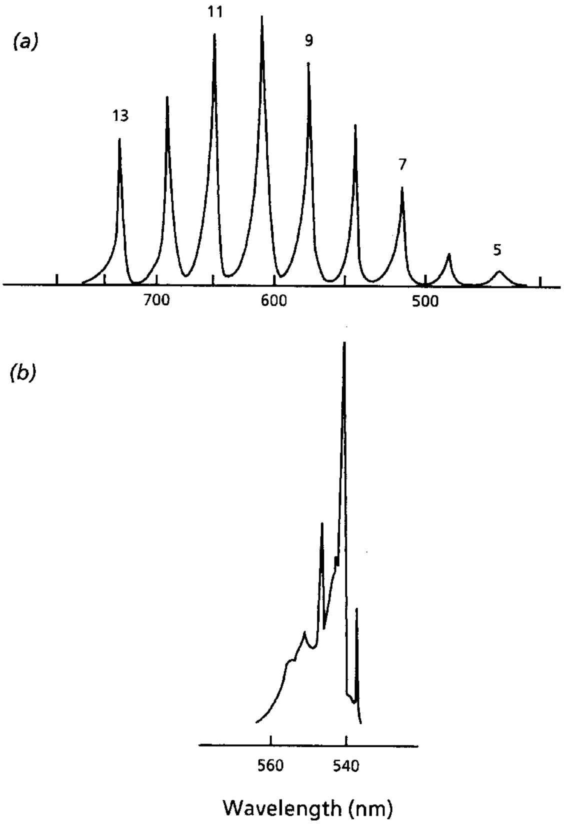

FIGURE 11 Photoluminescence spectrum of O_2^- in KBr at 77 K. *(After Rebane and Rebane.[33])*

spectrum. The envelope of these sidebands, given the solid line, represents the effects of adding a finite width, $n''\hbar\omega$, to each sideband feature. The effect is to smear out the structure, especially at larger phonon numbers. Also in Fig. 10 we show the effect of temperature on the sideband shape in absorption, which is to reveal structure at lower energies than that of the zero-phonon line. Although the lineshape changes, the total intensity is independent of temperature, whereas the zero-phonon line intensity is given by

$$I_{00} = I_0 \exp\left(- S \coth\left(\frac{\hbar\omega}{2kT}\right)\right) \tag{55}$$

which decreases with increasing temperature. For small values of $S \ll 1$, the phonon sideband intensity increases according to $I_0 S \coth(\hbar\omega/2kT)$. These effects are shown in Fig. 10 also.

Three examples of the optical bandshapes in solid state spectra are considered. Figure 11 shows the luminescence spectrum of the molecular ion O_2^- in KBr measured at 77 K.[33] The O_2^- ion emits in the visible range from 400–750 nm, and the spectrum shown corresponds to the vibrational sidebands corresponding to $n'' = 5$ up to 13. The optical center is strongly coupled, $S = 10$, to the internal vibrational mode of the O_2^- ion with energy $\hbar\omega \simeq 1000\,\text{cm}^{-1}$. However, as the detail of the $n'' = 8$ electronic vibrational transition is shown at $T = 4.2$ K, there is also weak coupling $S \simeq 1$ to the phonon spectrum of the KBr, where the maximum vibrational frequency is only about $200\,\text{cm}^{-1}$.

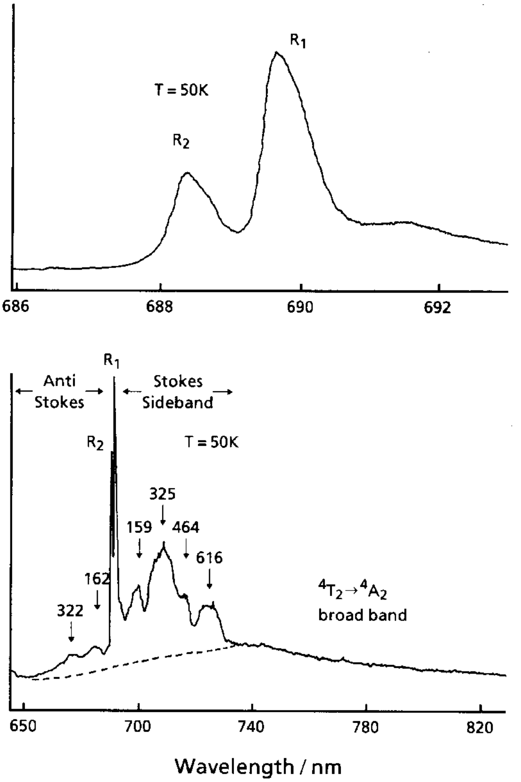

FIGURE 12 The photoluminescence spectrum of Cr^{3+} ions in $Y_3Ga_5O_{12}$.

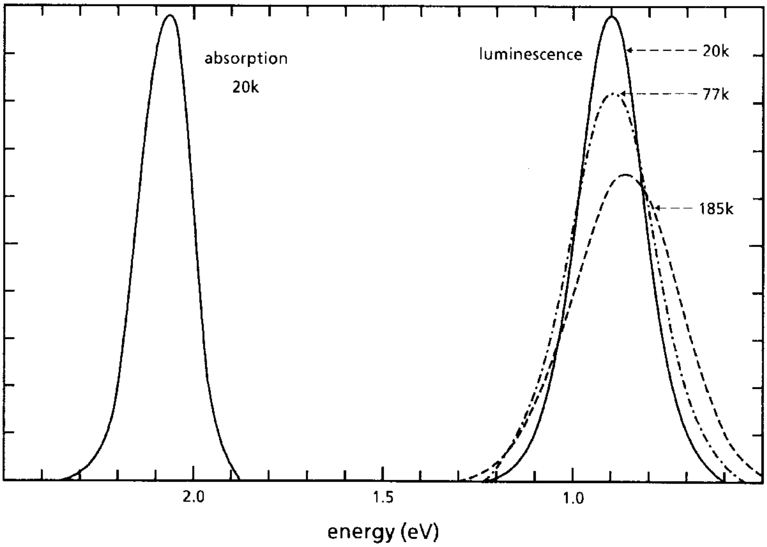

FIGURE 13 Optical absorption and photoluminescence of F-centers in KBr. *(After Gebhardt and Kuhnert.[37])*

The Cr^{3+} ion occupies a central position in the folklore of solid state spectroscopy. In yttrium gallium garnet, $Y_3Ga_5O_{12}$, the Cr^{3+} ion occupies a Ga^{3+} ion site at the center of six octahedrally-disposed O^{2-} ions. The crystal field at this site is intermediate in strength[8] so that the ^2E and $^4T_2$ states are mixed by the combined effects of spin-orbit coupling and zero-point vibrations. The emission then is a composite spectrum of $^2E \rightarrow {}^4A_2$ transition and $^4T_2 \rightarrow {}^4A_2$ transition, with a common radiative lifetime.[34] As Fig. 12 shows, the composite spectrum shows a mélange of the R-line and its vibronic sideband, $^2E \rightarrow {}^4A_2$ transition with $S \sim 0.3$, and the broadband $^4T_2 \rightarrow {}^4A_2$ transition for which $S \sim 6$.[35] Understanding this particular bandshape is complex.[34–36]

The final example, in Fig. 13, shows the absorption and emission spectra of F-centers in KBr.[37] This is a strongly coupled system with $S \simeq 30$. Extension of the configurational coordinate model to the luminescence spectrum shows that the absorption and emission sidebands are mirror images of each other in the zero-phonon line. With S small (less than 6) there is structure in absorption and emission. However for S large, there is no structure, at least when a spectrum of vibrational modes interacts with the electronic states. The F-center represents strong coupling to a band of vibrational frequencies rather than to a single breathing mode of vibration. The effect of this is to broaden the spectrum to look like the envelope encompassing the spectrum of sharp sidebands shown in Fig. 10. In this case the zero-phonon line position is midway between the peaks in the absorption and emission bands of the F-center in KBr. Note also that as the temperature is raised the bands broaden and the peak shifts to longer wavelengths.

9.1 GLOSSARY

$\underline{\mathbf{A}}$	vector field
$\underline{\mathbf{B}}$	magnetic induction
c	speed of light
$\underline{\mathbf{D}}$	displacement field
d_{M}	penetration depth in a metal
d_{TIR}	evanescent field depth for total internal reflection
$\underline{\mathbf{E}}$	electric field
$\mathscr{E}_{\mathrm{g}}$	band gap energy
$\underline{\mathbf{E}}_{\mathrm{loc}}$	local electric field
$-e$	electronic charge
e_{i}^{σ}	components of unit vectors of incident polarization
e_{s}^{ρ}	components of unit vectors of scattered polarization
f_{j}	oscillator strength
$\underline{\mathbf{G}}$	reciprocal lattice vector
$\mathbf{H}$	hamiltonian
$\underline{\mathbf{H}}$	magnetic field
I	irradiance
$\underline{\underline{\mathbf{I}}}$	unit tensor
$\underline{\mathbf{J}}_{\mathrm{c}}$	conduction current density
$\underline{\underline{\mathbf{K}}}$	dielectric constant or relative permittivity

$\underline{\mathbf{k}}$	electron wave vector
$\underline{\mathbf{M}}$	induced magnetization
m	electron mass
m^*	effective electron mass
$\mathbf{N}$	charge density
N_{L}	refractive index for left circularly polarized light
N_{R}	refractive index for right circularly polarized light
n	real part of refractive index
$\mathbf{P}$	Kane momentum matrix element
$\underline{\mathbf{P}}$	induced dipole moment per unit volume
$\mathbf{P_D}$	dielectric amplitude reflection polarization ratio
$\mathbf{P}_{\mathrm{j'j}}$	momentum matrix elements
$\mathbf{P}_{\mathrm{M}}$	metallic amplitude reflection polarization ratio
$P_{\mathbf{p}\sigma,\mathbf{ij}}$	elasto-optic coefficients
$\mathbf{p}$	electron momentum
$\tilde{\mathbf{q}}$	complex photon wave vector
$\hat{\mathbf{q}}$	unit photon wave vector
R	reflectance
$\mathbf{R}_{ex}$	exciton Rydberg
$\mathbf{R}_{\sigma,\mathrm{p}}$	Raman scattering coefficient
r_p	field reflection amplitude for p-polarization
r_s	field reflection amplitude for s-polarization
$\underline{\mathbf{S}}$	Poynting vector
$\mathbf{s_{ij}}$	components of lattice strain
$\mathbf{S_R}$	Raman scattering efficiency
$\mathbf{s_j}$	phonon oscillator strength
$\mathbf{T}$	transmittance
$\mathbf{t_p}$	field transmission amplitude for p-polarization
$\mathbf{t_s}$	field transmission amplitude for s-polarization
$\mathbf{V}$	volume of unit cell
$\mathbf{V}(\underline{r})$	periodic lattice potential
$\mathbf{v}$	phase velocity
$\mathbf{W}(\omega)$	transition rate
$\mathbf{Z}$	number of electrons per atom
α	absorption coefficient
β	two-photon absorption coefficient
Γ	damping constant
Δ_{D}	dielectric reflection polarization phase difference
Δ_{M}	metallic reflection polarization phase difference
Δ_s	specific rotary power

Δ_{so}	spin-orbit energy splitting
δ	energy walk-off angle
$\underline{\underline{\varepsilon}}$	electrical permittivity
$\tilde{\varepsilon}$	complex permittivity
$\varepsilon(\infty)$	high frequency permittivity
$\varepsilon(0)$	static permittivity
ε_1	real part of permittivity
ε_2	imaginary part of permittivity
ε_0	electrical permittivity of vacuum
$\tilde{\eta}$	complex refractive index
$\bar{\theta}$	principal angle for metallic reflection
θ_{OA}	angle between optic axis and principal axis
θ_{B}	Brewster's angle
θ_{c}	total internal reflection critical angle
θ_{TIR}	phase change for total internal reflection
κ	imaginary part of refractive index
$\underline{\underline{\mu}}$	magnetic permeability
μ_0	magnetic permeability of vacuum
ξ	Hooke's Law constant
$\hat{\boldsymbol{\xi}}$	unit polarization vector
ρ_{f}	free charge density
ρ_{p}	band or polarization charge density
ρ_{p}	real field amplitude for p-polarization
ρ_{s}	real field amplitude for s-polarization
ρ_{t}	total charge density
$\tilde{\sigma}$	complex conductivity
$\underline{\underline{\sigma}}$	electrical conductivity
σ_1	real part of conductivity
σ_2	imaginary part of conductivity
τ	scattering or relaxation time
ϕ	scalar field
$\phi_{i'}$	ground state wave function
$\tilde{\chi}$	complex susceptibility
χ'	real part of susceptibility
χ''	imaginary part of susceptibility
$\underline{\underline{\chi}}_{\mathrm{e}}$	electrical susceptibility
$\underline{\underline{\chi}}_{\mathrm{m}}$	magnetic susceptibility
$\psi_{\underline{\mathbf{k}}}$	Bloch solution wave function
ω	photon frequency
ω_{j}	resonant oscillation frequency
ω_{LO}	longitudinal optical phonon frequency

ω_{p}	plasma frequency
ω_{s}	surface plasmon frequency
ω_{TO}	transverse optical phonon frequency

9.2 INTRODUCTION

This chapter describes the fundamental interactions of light with solids. The discussion is restricted to *intrinsic* optical properties. *Extrinsic* optical properties of solids are described in Chap. 8 "Optical Spectroscopy and Spectroscopic Lineshapes." Basic formulas, definitions, and concepts are listed for reference and as a foundation for subsequent chapters of this volume of the *Handbook*. More detailed accounts of specific optical properties and particular types of solid are given in later chapters, i.e., Chap. 42 "Optical Properties of Films and Coatings," and in Vol. II, Chaps. 23 "Crystals and Glasses," 35 "Metals," 36 "Semiconductors," and 13 "Electro-Optic Modulators." The reader is referred to the many texts which provide more elaborate discussions of the optical properties of solids.[1–12]

Electrical measurements distinguish three general types of solids by their conductivities, i.e., dielectrics, semiconductors, and metals. Optically, these three groups are characterized by different fundamental band gap energies, $\mathscr{E}_{\mathrm{g}}$. Although the boundaries are not sharply defined, an approximate distinction is given by, metals $\mathscr{E}_{\mathrm{g}} \leq 0$, semiconductors, $0 < \mathscr{E}_{\mathrm{g}} < 3\,\mathrm{eV}$, and dielectrics, $\mathscr{E}_{\mathrm{g}} > 3\,\mathrm{eV}$. Solids may be found in single crystal, polycrystalline, and amorphous forms. Rudimentary theories of the optical properties of condensed matter are based on light interactions with perfect crystal lattices characterized by extended (nonlocal) electronic and vibrational energy states. These eigenstates are determined by the periodicity and symmetry of the lattice and the form of the Coulomb potential which arises from the interatomic bonding.

The principal absorption bands in condensed matter occur at photon energies corresponding to the frequencies of the lattice vibrations (phonons) in the infrared, and electronic transitions in the near infrared, visible, or ultraviolet. A quantum mechanical approach is generally required to describe electronic interactions, but classical models often suffice for lattice vibrations. Although the mechanical properties of solids can vary enormously between single crystal and polycrystalline forms, the *fundamental* optical properties are similar, even if the crystallite size is smaller than a wavelength, since the optical interaction is microscopic. However, electronic energy levels and hence optical properties are fundamentally altered when one or more dimensions of a solid are reduced to the scale of the deBroglie wavelength of the electrons. Modern crystal growth techniques allow fabrication of atomic precision epitaxial layers of different solid materials. Ultrathin layers, with dimensions comparable with or smaller than the deBroglie wavelength of an electron, may form quantum wells, quantum wires, and quantum dots in which electronic energy levels are quantized. Amorphous solids have random atomic or molecular orientation on the distance scale of several nearest neighbors, but generally have well-defined bonding and local atomic order which determine the overall optical response.

9.3 PROPAGATION OF LIGHT IN SOLIDS

Dielectrics and semiconductors provide transparent spectral regions at radiation frequencies between the phonon vibration bands and the fundamental (electronic) absorption edge. Maxwell's equations successfully describe the propagation, reflection, refraction, and scattering of harmonic electromagnetic waves.

Maxwell's Equations

Four equations relate the macroscopically averaged electric field **E** and magnetic induction **B** to the total charge density, ρ_t (sum of the bound or polarization charge, ρ_p, and the free charge, ρ_f), the conduction current density, $\mathbf{J}_c$, the induced dipole moment per unit volume, **P**, and the induced magnetization of the medium, **M** (expressed in SI units):

$$\nabla \cdot \mathbf{E} = \frac{\rho_t}{\varepsilon_0} \tag{1}$$

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \tag{2}$$

$$\nabla \cdot \mathbf{B} = 0 \tag{3}$$

$$\nabla \times \mathbf{B} = \mu_0\left(\varepsilon_0 \frac{\partial \mathbf{E}}{\partial t} + \frac{\partial \mathbf{P}}{\partial t} + \mathbf{J}_c + \nabla \times \mathbf{M}\right) \tag{4}$$

where $\varepsilon_0 = 8.854 \times 10^{-12}$ F/m is the permittivity of vacuum, $\mu_0 = 4\pi \times 10^{-7}\, H/m$ is the permeability of vacuum and c the speed of light in vacuum, $c = 1/\sqrt{\varepsilon_0 \mu_0}$. By defining a displacement field, **D**, and magnetic field, **H**, to account for the response of a medium

$$\mathbf{D} = \mathbf{P} + \varepsilon_0 \mathbf{E} \tag{5}$$

$$\mathbf{H} = \frac{\mathbf{B}}{\mu_0} - \mathbf{M} \tag{6}$$

and using the relation between polarization and bound charge density,

$$-\nabla \cdot \mathbf{P} = \rho_p \tag{7}$$

Equations (1) and (4) may also be written in the form

$$\nabla \cdot \mathbf{D} = \rho_f \tag{8}$$

and

$$\nabla \times \mathbf{H} = \frac{\partial \mathbf{D}}{\partial t} + \mathbf{J}_c \tag{9}$$

Vector **A** and scalar ϕ fields may be defined by

$$\mathbf{B} = \nabla \times \mathbf{A} \tag{10}$$

$$\mathbf{E} = -\nabla \phi - \frac{\partial \mathbf{A}}{\partial t} \tag{11}$$

A convenient choice of gauge for the optical properties of solids is the Coulomb (or transverse) gauge

$$\nabla \cdot \mathbf{A} = 0 \tag{12}$$

which ensures that the vector potential **A** is transverse for plane electromagnetic waves while the scalar potential represents any longitudinal current and satisfies Poisson's equation

$$\nabla^2 \phi = -\frac{\rho_t}{\varepsilon_0} \tag{13}$$

Three constitutive relations describe the response of conduction and bound electrons to the electric and magnetic fields:

$$\mathbf{J}_c = \underline{\underline{\sigma}}\mathbf{E} \tag{14}$$

$$\mathbf{D} = \mathbf{P} + \varepsilon_0\mathbf{E} = \underline{\underline{\varepsilon}}\mathbf{E} \tag{15}$$

$$\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M}) = \underline{\underline{\mu}}\mathbf{H} \tag{16}$$

Here $\underline{\underline{\sigma}}$ is the electrical conductivity, $\underline{\underline{\varepsilon}}$ is the electrical permittivity, and $\underline{\underline{\mu}}$ is the magnetic permeability of the medium and are in general tensor quantities which may depend on field strengths. An alternative relation often used to define a dielectric constant (or relative permittivity), $\underline{\underline{\mathbf{K}}}$, is given by $\mathbf{D} = \varepsilon_0\underline{\underline{\mathbf{K}}}\mathbf{E}$. In isotropic media using the approximation of linear responses to electric and magnetic fields, σ, ε, and μ are constant scalar quantities.

Electronic, $\underline{\underline{\chi}}_e$, and magnetic, $\underline{\underline{\chi}}_m$, susceptibilities may be defined to relate the induced dipole moment, $\mathbf{P}$, and magnetism, $\mathbf{M}$ to the field strengths, $\mathbf{E}$ and $\mathbf{H}$:

$$\mathbf{P} = \varepsilon_0\underline{\underline{\chi}}_e\mathbf{E} \tag{17}$$

$$\mathbf{M} = \varepsilon_0\underline{\underline{\chi}}_m\mathbf{H} \tag{18}$$

Thus,

$$\underline{\underline{\varepsilon}} = \varepsilon_0(\underline{\underline{\mathbf{I}}} + \underline{\underline{\chi}}_e) \tag{19}$$

and

$$\underline{\underline{\mu}} = \mu_0(\underline{\underline{\mathbf{I}}} + \underline{\underline{\chi}}_m) \tag{20}$$

where $\underline{\underline{\mathbf{I}}}$ is the unit tensor.

Wave Equations and Optical Constants

The general wave equation derived from Maxwell's equations is

$$\nabla^2\mathbf{E} - \nabla(\nabla \cdot \mathbf{E}) - \varepsilon_0\mu_0\frac{\partial^2\mathbf{E}}{\partial t^2} = \mu_0\left(\frac{\partial^2\mathbf{P}}{\partial t^2} + \frac{\partial\mathbf{J}_c}{\partial t} + \nabla \times \frac{\partial\mathbf{M}}{\partial t}\right) \tag{21}$$

For dielectric (nonconducting) solids

$$\nabla^2\mathbf{E} = \mu\varepsilon\frac{\partial^2\mathbf{E}}{\partial t^2} \tag{22}$$

The harmonic plane wave solution of the wave equation for monochromatic light at frequency, ω,

$$\mathbf{E} = \tfrac{1}{2}\mathbf{E}_0 \exp i(\mathbf{q} \cdot \mathbf{r} - \omega t) + \text{c.c.} \tag{23}$$

in homogeneous ($\nabla\varepsilon = 0$), isotropic ($\nabla \cdot \mathbf{E} = 0$, $\mathbf{q} \cdot \mathbf{E} = 0$), nonmagnetic ($\mathbf{M} = 0$) solids results in a complex wave vector, $\tilde{\mathbf{q}}$,

$$\tilde{\mathbf{q}} = \frac{\omega}{c}\sqrt{\frac{\varepsilon}{\varepsilon_0} + i\frac{\sigma}{\varepsilon_0\omega}} \tag{24}$$

A complex refractive index, $\tilde{\eta}$, may be defined by

$$\tilde{\mathbf{q}} = \frac{\omega}{c}\tilde{\eta}\hat{\mathbf{q}} \tag{25}$$

where $\hat{\mathbf{q}}$ is a unit vector and

$$\tilde{\eta} = n + i\kappa \tag{26}$$

Introducing complex notation for the permittivity, $\tilde{\varepsilon} = \varepsilon_1 + i\varepsilon_2$, conductivity, $\tilde{\sigma} = \sigma_1 + i\sigma_2$, and susceptibility, $\tilde{\chi}_e = \chi_e' + i\chi_e''$, we may relate

$$\varepsilon_1 = \varepsilon = \varepsilon_0(1 + \chi_e') = \varepsilon_0(n^2 - \kappa^2) = -\frac{\sigma_2}{\omega} \tag{27}$$

and

$$\varepsilon_2 = \varepsilon_0\chi_e'' = 2\varepsilon_0 n\kappa = \frac{\sigma}{\omega} = \frac{\sigma_1}{\omega} \tag{28}$$

Alternatively,

$$n = \left[\frac{1}{2\varepsilon_0}\left(\sqrt{\varepsilon_1^2 + \varepsilon_2^2} + \varepsilon_1\right)\right]^{1/2} \tag{29}$$

$$\kappa = \left[\frac{1}{2\varepsilon_0}\left(\sqrt{\varepsilon_1^2 + \varepsilon_2^2} - \varepsilon_1\right)\right]^{1/2} \tag{30}$$

The field will be modified locally by induced dipoles. If there is no free charge, ρ_f, the local field, $\mathbf{E}_{loc}$, may be related to the external field, $\mathbf{E}_i$, in isotropic solids using the Clausius-Mossotti equation which leads to the relation

$$\mathbf{E}_{loc} = \frac{n^2 + 2}{3}\mathbf{E}_i \tag{31}$$

Energy Flow

The direction and rate of flow of electromagnetic energy is described by the Poynting vector

$$\mathbf{S} = \frac{1}{\mu_0}\mathbf{E} \times \mathbf{H} \tag{32}$$

The average power per unit area (irradiance, I), W/m^2, carried by a uniform plane wave is given by the time averaged magnitude of the Poynting vector

$$I = \langle \mathbf{S} \rangle = \frac{cn\,|\mathbf{E}_0|^2}{2} \tag{33}$$

The plane wave field in Eq. (23) may be rewritten for absorbing media using Eqs. (25) and (26).

$$\mathbf{E}(\mathbf{r}, t) = \tfrac{1}{2}\mathbf{E}_0(\mathbf{q}, \omega)\exp\left(-\frac{\omega}{c}\kappa\hat{\mathbf{q}}\cdot\mathbf{r}\right)\exp\left[i\left(\frac{\omega}{c}n\hat{\mathbf{q}}\cdot\mathbf{r} - \omega t\right)\right] + \text{c.c.} \tag{34}$$

The decay of the propagating wave is characterized by the extinction coefficient, κ. The attenuation of the wave may also be described by Beer's law

$$I = I_0\exp(-\alpha z) \tag{35}$$

where α is the absorption coefficient describing the attenuation of the irradiance, I, with distance, z. Thus,

$$\alpha = \frac{2\omega\kappa}{c} = \frac{4\pi\kappa}{\lambda} = \frac{\sigma_1}{\varepsilon_0 cn} = \frac{\varepsilon_2\omega}{\varepsilon_0 cn} = \frac{\chi_e''\omega}{cn} \tag{36}$$

The power absorbed per unit volume is given by

$$P_{\text{abs}} = \alpha I = \frac{\omega\chi_e''}{2}|\mathbf{E}_0|^2 \tag{37}$$

The second exponential in Eq. (34) is oscillatory and represents the phase velocity of the wave, $v = c/n$.

Anisotropic Crystals

Only amorphous solids and crystals possessing cubic symmetry are optically isotropic. In general, the speed of propagation of an electromagnetic wave in a crystal depends both on the direction of propagation and on the polarization of the light wave. The linear electronic susceptibility and dielectric constant may be represented by tensors with components of $\underline{\underline{\chi}}_e$ given by

$$P_i = \varepsilon_0 \chi_{ij} E_j \tag{38}$$

where i and j refer to coordinate axes. In an anisotropic crystal, $\mathbf{D} \perp \mathbf{B} \perp \mathbf{q}$ and $\mathbf{E} \perp \mathbf{H} \perp \mathbf{S}$, but **E** is not necessarily parallel to **D** and the direction of energy flow **S** is not necessarily in the same direction as the propagation direction **q**.

From energy arguments it can be shown that the susceptibility tensor is symmetric and it therefore follows that there always exists a set of coordinate axes which diagonalize the tensor. This coordinate system defines the principal axes. The number of nonzero elements for the susceptibility (or dielectric constant) is thus reduced to a maximum of three (for any crystal system at a given wavelength). Thus, the dielectric tensor defined by the direction of the electric field vector with respect to the principal axes has the form

$$\begin{bmatrix} \varepsilon_1 & 0 & 0 \\ 0 & \varepsilon_2 & 0 \\ 0 & 0 & \varepsilon_3 \end{bmatrix}$$

The principal indices of refraction are

$$n_i = \sqrt{1 + \chi_{ij}} = \sqrt{\varepsilon_i} \tag{39}$$

with the **E**-vector polarized along any principal axis, i.e. $\mathbf{E} \parallel \mathbf{D}$. This case is designated as an ordinary or **o**-ray in which the phase velocity is independent of propagation direction. An extraordinary or **e**-ray occurs when both **E** and **q** lie in a plane containing two principal axes with different n. An *optic axis* is defined by any propagation direction in which the phase velocity of the wave is independent of polarization.

Crystalline solids fall into three classes: (1) optically isotropic, (2) uniaxial, or (3) biaxial (see Table 1). All choices of orthogonal axes are principal axes and $\varepsilon_1 = \varepsilon_2 = \varepsilon_3$ in *isotropic* solids. For a *uniaxial* crystal, $\varepsilon_1 = \varepsilon_2 \neq \varepsilon_3$, a single optic axis exists for propagation in direction **3**. In this case, the ordinary refractive index, $n_0 = n_1 = n_2$, is independent of the direction of polarization in the **1-2** plane. Any two orthogonal directions in this plane can be chosen as principal axes. For any other propagation direction, the polarization can be divided into an **o**-ray component in the **1-2** plane and a perpendicular **e**-ray component

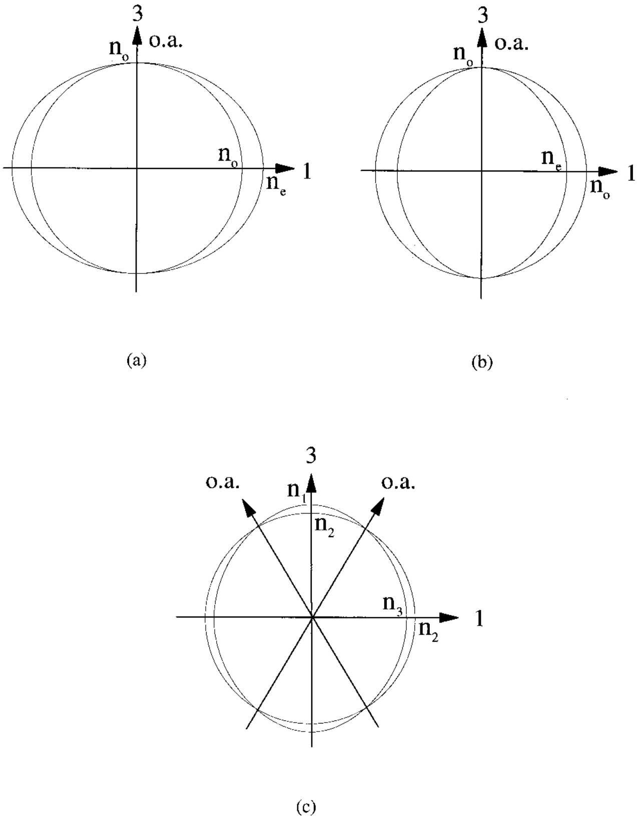

FIGURE 1 Illustration of directional dependence of refractive indices and optic axes in: (*a*) a uniaxial, positive birefringent crystal; (*b*) a uniaxial, negative birefringent crystal; and (*c*) a biaxial crystal.

(see Fig. 1). The dependence of the **e**-ray refractive index with propagation direction is given by the ellipsoid

$$n_j(\theta_i) = \frac{n_i n_j}{(n_i^2 \cos^2 \theta_i + n_j^2 \sin^2 \theta_i)^{1/2}} \tag{40}$$

where θ_i is defined with respect to optic axis, $i = 3$, and $j = 1$ or 2. $\theta_i = 90°$ gives the refractive index $n_e = n_3$ when the light is polarized along axis **3**. The difference between n_0 and n_e is the birefringence. Figure 1*a* illustrates the case of positive birefringence, $n_e > n_0$, and Fig. 1*b* negative birefringence, $n_e < n_0$. The energy walk-off angle, δ (the angle between **S** and **q** or **D** and **E**), is given by

$$\tan \delta = \frac{n^2(\theta)}{2} \left[\frac{1}{n_3^2} - \frac{1}{n_1^2} \right] \sin 2\theta \tag{41}$$

In *biaxial* crystals, diagonalization of the dielectric tensor results in three independent coefficients, $\varepsilon_1 \neq \varepsilon_2 \neq \varepsilon_3 \neq \varepsilon_1$. For orthorhombic crystals, a single set of orthogonal principal axes is fixed for all wavelengths. However, in monoclinic structures only one principal axis is fixed. The direction of the other two axes rotate in the plane perpendicular to the fixed axis as the wavelength changes (retaining orthogonality). In triclinic crystals there are no fixed axes and orientation of the set of three principal axes varies with wavelength. Equation (40) provides the **e**-ray refractive index within planes containing two principal axes. Biaxial crystals possess two optic axes. Defining principal axes such that $n_1 > n_2 > n_3$, then both optic axes lie in the **1**-**3** plane, at an angle θ_{OA} from axis **1**, as illustrated in Fig. 1*c,* where

$$\sin \theta_{\mathrm{OA}} = \pm \frac{n_1}{n_2} \sqrt{\frac{n_2^2 - n_3^2}{n_1^2 - n_3^2}} \tag{42}$$

Crystals with certain point group symmetries (see Table 1) also exhibit optical activity, i.e., the ability to rotate the plane of linearly polarized light. An origin for this phenomenon is the weak magnetic interaction $\nabla \times \mathbf{M}$ [see Eq. (21)], when it applies in a direction perpendicular to **P** (i.e., **M** ∥ **P**). The specific rotary power Δ_s (angle of rotation of linearly polarized light per unit length) is given by

$$\Delta_s = \frac{\pi}{\lambda}(n_{\mathrm{L}} - n_{\mathrm{R}}) \tag{43}$$

where n_{L} and n_{R} are refractive indices for left and right circular polarization. Optical activity is often masked by birefringence, however, polarization rotation can be observed in optically active materials when the propagation is along the optic axis or when the birefringence is coincidentally zero in other directions. In the case of propagation along the optic axis of an optically active uniaxial crystal such as quartz, the susceptibility tensor may be written

$$\begin{bmatrix} \chi_{11} & i\chi_{12} & 0 \\ -i\chi_{12} & \chi_{11} & 0 \\ 0 & 0 & \chi_{33} \end{bmatrix}$$

and the rotary power is proportional to the imaginary part of the magnetic susceptibility, $\chi_m'' = \chi_{12}$:

$$\Delta_s = \frac{\pi\chi_{12}}{n\lambda} \tag{44}$$

Crystals can exist in left- or right-handed versions. Other crystal symmetries, e.g., $\bar{4}2\mathrm{m}$, can be optically active for propagation along the **2** and **3** axes, but rotation of the polarization is normally masked by the typically larger birefringence, except at accidental degeneracies.

Interfaces

Applying boundary conditions at a plane interface between two media with different indices of refraction leads to the laws of reflection and refraction. Snell's law applies to all **o**-rays and relates the angle of incidence, θ_{A} in medium A, and the angle of refraction, θ_{B} in medium B, to the respective ordinary refractive indices n_{A} and n_{B}:

$$n_{\mathrm{A}} \sin \theta_{\mathrm{A}} = n_{\mathrm{B}} \sin \theta_{\mathrm{B}} \tag{45}$$

Extraordinary rays do not satisfy Snell's law. The propagation direction for the **e**-ray can be found graphically by equating the projections of the propagation vectors in the two media along the boundary plane. Double refraction of unpolarized light occurs in anisotropic crystals.

The field amplitude ratios of reflected and transmitted rays to the incident ray (r and t) in isotropic solids (and **o**-rays in anisotropic crystals) are given by the Fresnel relations.

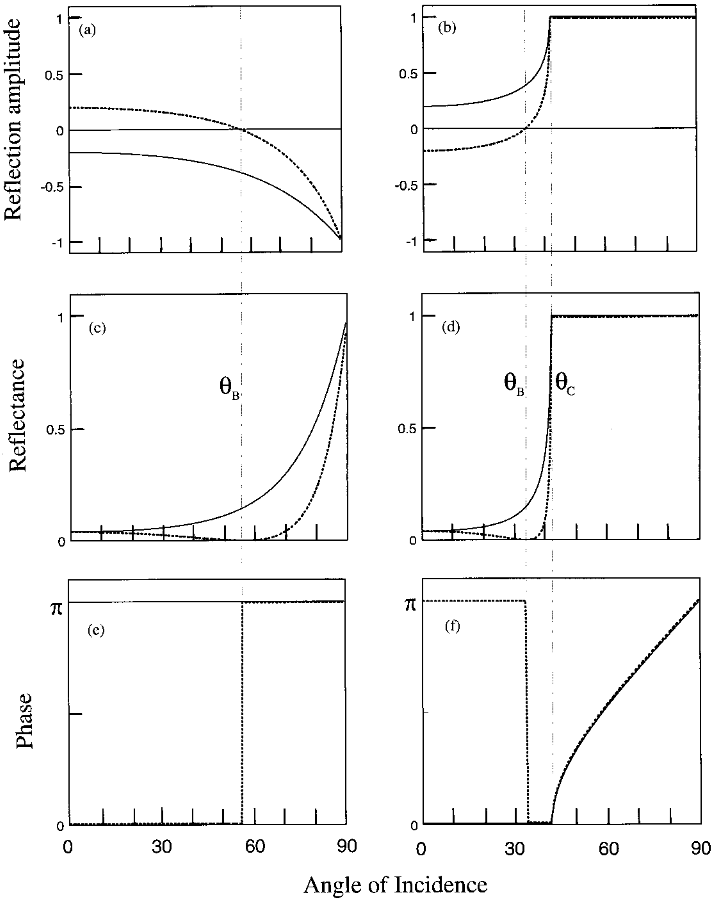

FIGURE 2 The electric field reflection amplitudes (a, b), energy reflectance (c, d), and phase change (e, f) for s- (solid lines) and p- (dashed lines) polarized light for external (a, c, e) and internal (b, d, f) reflection in the case $n_A = 1$, $n_B = 1.5$. θ_B is the polarizing or Brewster's angle and θ_c is the critical angle for total internal reflection.[2]

For s- (σ or TE) polarization (**E**-vector perpendicular to the plane of incidence) (see Fig. 2a) and p- (π or TM) polarization (**E**-vector parallel to the plane of incidence) (see Fig. 2b):

$$r_s = \frac{E_{rs}}{E_{is}} = \frac{n_A \cos\theta_A - \sqrt{n_B^2 - n_A^2 \sin^2\theta_A}}{n_A \cos\theta_A + \sqrt{n_B^2 - n_A^2 \sin^2\theta_A}} \tag{46}$$

$$r_p = \frac{E_{rp}}{E_{ip}} = \frac{n_B^2 \cos\theta_A - n_A\sqrt{n_B^2 - n_A^2 \sin^2\theta_A}}{n_B^2 \cos\theta_A + n_A\sqrt{n_B^2 - n_A^2 \sin^2\theta_A}} \tag{47}$$

$$t_s = \frac{E_{ts}}{E_{is}} = \frac{2n_A \cos\theta_A}{n_S \cos\theta_A + \sqrt{n_B^2 - n_A^2 \sin^2\theta_A}} \tag{48}$$

$$t_p = \frac{E_{tp}}{E_{ip}} = \frac{2n_A n_B \cos\theta_A}{n_B^2 \cos\theta_A + n_A\sqrt{n_B^2 - n_A^2 \sin^2\theta_A}} \tag{49}$$

At normal incidence, the energy reflectance, R (see Figs 2c and d), and transmittance, T, are

$$R = \left|\frac{E_r}{E_i}\right|^2 = \left|\frac{n_B - n_A}{n_B + n_A}\right|^2 \tag{50}$$

$$T = \left|\frac{E_t}{E_i}\right|^2 = \frac{4n_A^2}{|n_A + n_B|^2} \tag{51}$$

The p-polarized reflectivity (see Eq. (47)] goes to zero at Brewster's angle under the condition

$$\theta_B = \tan^{-1}\left(\frac{n_A}{n_B}\right) \tag{52}$$

If $n_A > n_B$, total internal reflection (TIR) occurs when the angle of incidence exceeds a critical angle:

$$\theta_c = \sin^{-1}\left(\frac{n_A}{n_B}\right) \tag{53}$$

This critical angle may be different for s- and p-polarizations in anisotropic crystals. Under conditions of TIR, the evanescent wave amplitude drops to e^{-1} in a distance

$$d_{TIR} = \frac{c}{\omega}(n_A^2 \sin^2\theta_A - n_B^2)^{-1/2} \tag{54}$$

The phase changes on reflection for external and internal reflection from an interface with $n_A = 1.5$, $n_B = 1$ are plotted in Figs. 2e and f. Except under TIR conditions, the phase change is either 0 or π. The complex values predicted by Eqs. (46) and (47) for angles of incidence greater than the critical angle for TIR imply phase changes in the reflected light which are neither 0 nor π. The phase of the reflected light changes by π at Brewster's angle in p-polarization. The ratio of s to p reflectance, P_D, is shown in Fig. 3a and the phase difference, $\Delta_D = \phi_p - \phi_s$, in Fig. 3$b$. Under conditions of TIR, the phase change on reflection, ϕ_{TIR}, is given by

$$\tan\frac{\phi_{TIR}}{2} = \frac{\sqrt{\sin^2\theta_A - \sin^2\theta_c}}{\cos\theta_A} \tag{55}$$

9.4 DISPERSION RELATIONS

For most purposes, a classical approach is found to provide a sufficient description of dispersion of the refractive index within the transmission window of insulators, and for optical interactions with lattice vibrations and free electrons. However the details of interband transitions in semiconductors and insulators and the effect of d-levels in transition metals require a quantum model of dispersion close to these resonances.

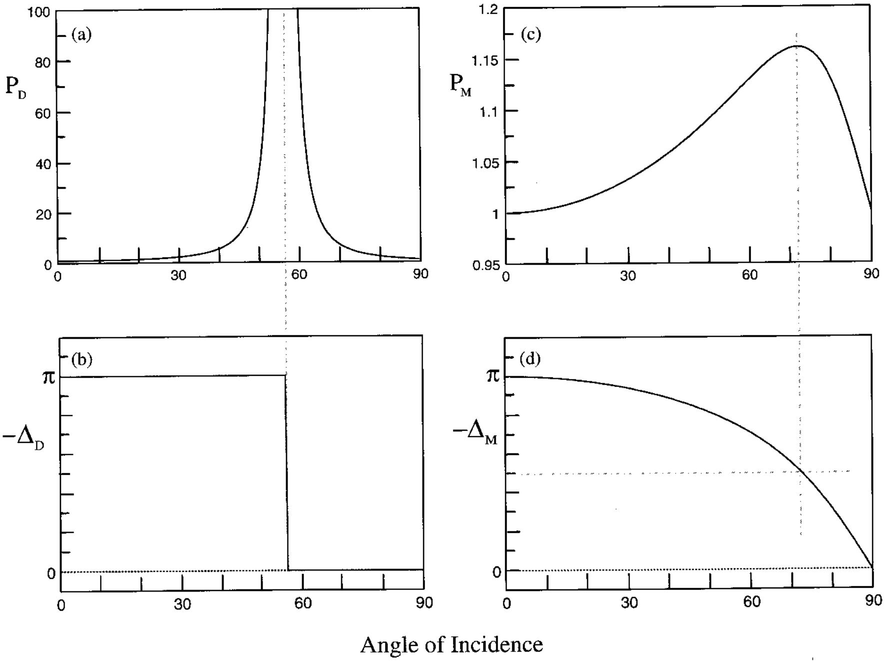

FIGURE 3 Typical polarization ratios, P, (a, c) and phase differences, Δ, (b, d) for s- and p-polarizations at dielectric, D, and metallic, M, surfaces.[1]

Classical Model

The Lorentz model for dispersion of the optical constants of solids assumes an optical interaction via the polarization produced by a set of damped harmonic oscillators. The polarization **P** induced by a displacement **r** of bound electrons of density N and charge $-e$ is

$$\mathbf{P} = -Ne\mathbf{r} \tag{56}$$

Assuming the electrons to be elastically bound (Hooke's law) with a force constant, ξ,

$$-e\mathbf{E}_{\text{loc}} = \xi\mathbf{r} \tag{57}$$

the differential equation of motion is

$$m\frac{d^2\mathbf{r}}{dt^2} + m\Gamma\frac{d\mathbf{r}}{dt} + \xi\mathbf{r} = -e\mathbf{E}_{\text{loc}} \tag{58}$$

where m is the electron mass and Γ is a damping constant. Here the lattice is assumed to have infinite mass and the magnetic interaction has been neglected. Solving the equation of motion for fields of frequency ω gives a relation for the complex refractive index and dielectric constant:

$$\tilde{\eta}^2 = \frac{\tilde{\varepsilon}}{\varepsilon_0} = 1 + \frac{Ne^2}{m\varepsilon_0}\sum_{\text{j}} \frac{f_{\text{j}}}{(\omega_{\text{j}}^2 - \omega^2 - i\Gamma_{\text{j}}\omega)} \tag{59}$$

We have given the more general result for a number of resonant frequencies

$$\omega_{\mathrm{j}} = \sqrt{\frac{\xi_{\mathrm{j}}}{m}} \tag{60}$$

where the f_{j} represent the fraction of electrons which contribute to each oscillator with force constant ξ_{j}. f_{j} represent oscillator strengths.

A useful semi-empirical relation for refractive index in the transparency region of a crystal known as the Sellmeier formula follows directly from Eq. (59) under the assumption that, far from resonances, the damping constant terms $\Gamma_{\mathrm{j}}\omega$ are negligible compared to $(\omega_{\mathrm{j}}^2 - \omega^2)$:

$$n^2 = 1 + \sum_{\mathrm{j}} \frac{A_{\mathrm{j}}\lambda^2}{\lambda^2 - \lambda_{\mathrm{j}}^2} \tag{61}$$

Sum Rules

The definition of oscillator strength results in the sum rule for electronic interactions

$$\sum_{\mathrm{j}} f_{\mathrm{j}} = Z \tag{62}$$

where Z is the number of electrons per atom. The periodicity of the lattice in solids (see Sec. 9.7) leads to the modification of this sum rule to

$$\sum_{\mathrm{m}} \mathrm{f}_{\mathrm{mn}} = \frac{m}{\hbar^2}\frac{\partial^2 \mathscr{E}_n}{\partial k^2} - 1 = \frac{m}{m_n^*} - 1 \tag{63}$$

where m_n^* is an effective mass (see "Energy Band Structures" in Sec. 9.7).

Another sum rule for solids equivalent to Eq. (62) relates the imaginary part of the permittivity or dielectric constant and the plasma frequency, ω_{p},

$$\int_0^\infty \omega\varepsilon_2(\omega)\, d\omega = \tfrac{1}{2}\pi\omega_{\mathrm{p}}^2 \tag{64}$$

where $\omega_{\mathrm{p}}^2 = \mathrm{N}e^2/\varepsilon_0\mathrm{m}$ (see "Drude Model" in Sec. 9.6).

Dispersion relations are integral formulas which relate refractive properties to the absorptive process. Kramers-Kronig relations are commonly used dispersion integrals based on the condition of causality which may be related to sum rules. These relations can be expressed in alternative forms. For instance, the reflectivity of a solid is often measured at normal incidence and dispersion relations used to determine the optical properties. Writing the complex reflectivity amplitude as

$$\tilde{r}(\omega) = r_{\mathrm{r}}(\omega)e^{i\theta(\omega)} \tag{65}$$

the phase shift, θ, can be determined by integrating the experimental measurement of the real amplitude, r_{r},

$$\theta(\omega) = -\frac{2\omega}{\pi}\mathscr{P}\int_0^\infty \frac{\ln r_{\mathrm{r}}(\omega')}{\omega'^2 - \omega^2}\, d\omega' \tag{66}$$

and the optical constants determined from the complex Fresnel relation,

$$r_{\mathrm{r}}(\omega)e^{\mathrm{i}\theta} = \frac{(n - 1 + i\kappa)}{(n + 1 + i\kappa)} \tag{67}$$

Sum rules following from the Kramers-Kronig relations relate the refractive index $n(\omega)$ at a given frequency, ω, to the absorption coefficient, $\alpha(\omega')$, integrated over all frequencies, ω', according to

$$n(\omega) - 1 = \frac{c}{\omega}\mathcal{P}\int_0^\infty \frac{\alpha(\omega')\,d\omega'}{\omega'^2 - \omega^2} \tag{68}$$

Similarly, the real and imaginary parts of the dielectric constant, ε' and ε'', may be related via the integral relations,

$$\varepsilon_1(\omega) - 1 = \frac{2}{\pi}\mathcal{P}\int_0^\infty \frac{\omega'\varepsilon_2(\omega')}{\omega'^2 - \omega^2}d\omega' \tag{69}$$

$$\varepsilon_2(\omega) = -\frac{2\omega}{\pi}\mathcal{P}\int_0^\infty \frac{\varepsilon_1(\omega') - 1}{\omega'^2 - \omega^2}d\omega' \tag{70}$$

9.5 LATTICE INTERACTIONS

The adiabatic approximation is the normal starting point for a consideration of the coupling of light with lattice vibrations, i.e., it is assumed that the response of the outer shell electrons of the atoms to an electric field is much faster than the response of the core together with its inner electron shells. Further, the harmonic approximation assumes, that for small displacements, the restoring force on the ions will be proportional to the displacement. The solution of the equations of motion for the atoms within a solid under these conditions give normal modes of vibration, whose frequency eigenvalues and displacement eigenvectors depend on the crystal symmetry, atomic separation, and the detailed form of the interatomic forces. The frequency of lattice vibrations in solids are typically in the 100 to 1000 cm^{-1} range (wavelengths between 10 and 100 μm). Longitudinal and doubly degenerate transverse vibrational modes have different natural frequencies due to long range Coulomb interactions. Infrared or Raman activity can be determined for a given crystal symmetry by representing the modes of vibration as irreducible representations of the space group of the crystal lattice.

Infrared Dipole Active Modes

If the displacement of atoms in a normal mode of vibration produces an oscillating dipole moment, then the motion is dipole active. Thus, harmonic vibrations in ionic crystals contribute directly to the dielectric function, whereas higher order contributions are needed in nonpolar crystals. Since photons have small wavevectors compared to the size of the Brillouin zone in solids, only zone center lattice vibrations (i.e., long wavelength phonons) can couple to the radiation. This conservation of wavevector (or momentum) also implies that only optical phonons interact. In a dipole-active, long wavelength optical mode, oppositely charged ions within each primitive cell undergo oppositely directed displacements giving rise to a nonvanishing polarization. Group theory shows that, within the harmonic approximation, the infrared active modes have irreducible representations with the same transformation properties as x, y, or z. The strength of the light-dipole coupling will depend on the degree of charge redistribution between the ions, i.e., the relative ionicity of the solid.

Classical dispersion theory leads to a phenomenological model for the optical interaction with dipole active lattice modes. Because of the transverse nature of electromagnetic radiation, the electric field vector couples with the transverse optical (TO) phonons and the maximum absorption therefore occurs at this resonance. The resonance frequency, ω_{TO}, is inserted into the solution of the equation of motion, Eq. (59). Since electronic transitions typically occur at frequencies 10^2 to 10^3 higher than the frequency of vibration of the ions, the atomic polarizability can be represented by a single high frequency permittivity, $\varepsilon(\infty)$. The dispersion relation for a crystal with several zone center TO phonons may be written

$$\tilde{\varepsilon}(\omega) = \varepsilon(\infty) + \sum_{\mathrm{j}} \frac{S_{\mathrm{j}}}{(\omega_{\mathrm{TOj}}^2 - \omega^2 - i\Gamma_{\mathrm{j}}\omega)} \qquad (71)$$

By defining a low frequency permittivity, $\varepsilon(0)$, the oscillator strength for a crystal possessing two atoms with opposite charge, Ze, per unit cell of volume, V, is

$$S = \frac{(\varepsilon(\infty)/\varepsilon_0 + 2)^2(Ze)^2}{9m_{\mathrm{r}}V} = \omega_{\mathrm{TO}}^2(\varepsilon(0) - \varepsilon(\infty)) \qquad (72)$$

where Ze represents the "effective charge" of the ions, m_{r} is the reduced mass of the ions, and the local field has been included based on Eq. (31). Figure 4 shows the form of the

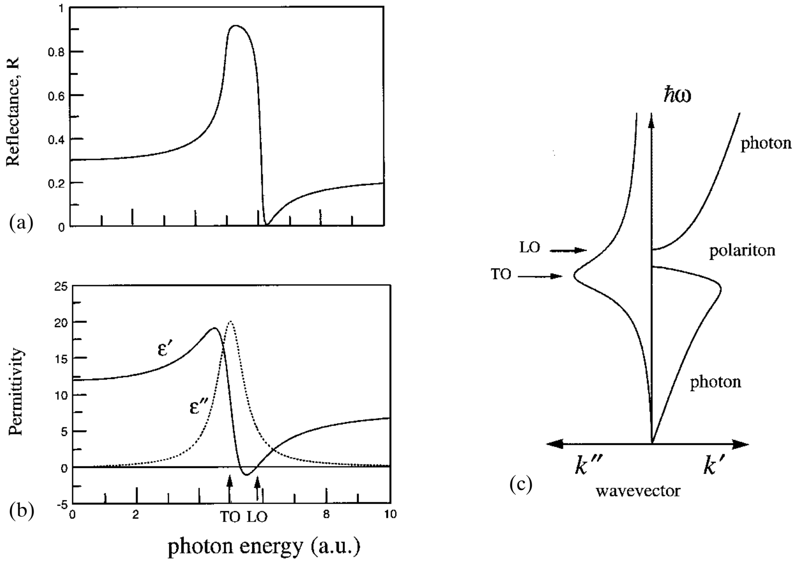

FIGURE 4 (*a*) Reflectance; and (*b*) real and imaginary parts of the permittivity of a solid with a single infrared active mode. (*c*) polariton dispersion curves (real and imaginary parts) showing the frequencies of the longitudinal and transverse optical modes.

real and imaginary parts of the dielectric constant, the reflectivity and the polariton dispersion curve. Observing that the real part of the dielectric constant is zero at longitudinal phonon frequencies, ω_{LO}, the Lyddane-Sachs-Teller relation may be derived, which in its general form for a number of dipole active phonons, is given by

$$\frac{\varepsilon(0)}{\varepsilon(\infty)} = \prod_{\mathrm{j}} \left(\frac{\omega_{\mathrm{Lj}}}{\omega_{\mathrm{Tj}}}\right)^2 \tag{73}$$

These relations [Eqs. (71) to (73)] give good fits to measured reflectivities in a wide range of ionically (or partially ionically) bonded solids. The LO-TO splitting and effective charge, *Ze,* depend on the ionicity of the solid; however the magnitude of *Ze* determined from experiments does not necessarily quantify the ionicity since this ''rigid ion'' model does not account for the change of polarizability due to the distortion of the electron shells during the vibration.

In uniaxial and biaxial crystals, the restoring forces on the ions are anisotropic, resulting in different natural frequencies depending on the direction of light propagation as well as the transverse or longitudinal nature of the vibration. Similar to the propagation of light, ''ordinary'' and ''extraordinary'' transverse phonons may be defined with respect to the principal axes. For instance, in a uniaxial crystal under the condition that the anisotropy in phonon frequency is smaller than the LO-TO frequency splitting, infrared radiation of frequency ω propagating at an angle θ to the optic axis will couple to TO phonons according to the relation

$$\omega_{\mathrm{T}}^2 = \omega_{\mathrm{T}\|}^2 \sin^2\theta + \omega_{\mathrm{T}\perp}^2 \cos^2\theta \tag{74}$$

where $\omega_{\mathrm{T}\|}$ is a TO phonon propagating with atomic displacements parallel to the optic axis, and $\omega_{\mathrm{T}\perp}$ is a TO phonon propagating with atomic displacements perpendicular to the optic axis. The corresponding expression for LO modes is

$$\omega_{\mathrm{L}}^2 = \omega_{\mathrm{L}\|}^2 \cos^2\theta + \omega_{\mathrm{L}\perp}^2 \sin^2\theta \tag{75}$$

In Table 2, the irreducible representations of the infrared normal modes for the different crystal symmetries are labeled *x, y,* or *z.*

Brillouin and Raman Scattering

Inelastic scattering of radiation by acoustic phonons is known as Brillouin scattering, while the term Raman scattering is normally reserved for inelastic scattering from optic phonons in solids. In the case of Brillouin scattering, long wavelength acoustic modes produce strain and thereby modulate the dielectric constant of the medium, thus producing a frequency shift in scattered light. In a Raman active mode, an incident electric field produces a dipole by polarizing the electron cloud of each atom. If this induced dipole is modulated by a lattice vibrational mode, coupling occurs between the light and the phonon and inelastic scattering results. Each Raman or Brillouin scattering event involves the destruction of an incident photon of frequency, ω_{i}, the creation of a scattered photon, ω_{s}, and the creation or destruction of a phonon of frequency, ω_{p}. The frequency shift, $\omega_{\mathrm{i}} \pm \omega_{\mathrm{s}} = \omega_{\mathrm{p}}$, is typically 100 to 1000 cm^{-1} for Raman scattering, but only a few wavenumbers for Brillouin scattering.

Atomic polarizability components have exactly the same transformation properties as the quadratic functions x^2, xy, . . . , z^2. The Raman activity of the modes of vibration of a crystal with a given point group symmetry can thus be deduced from the Raman tensors given in Table 2. The scattering efficiency, S_R, for a mode corresponding to one of the irreducible representations listed is given by

$$S_{\mathrm{R}} = A\left[\sum_{\rho,\sigma} e_{\mathrm{i}}^{\sigma} R_{\sigma,\mathrm{p}} e_{\mathrm{s}}^{\rho}\right]^2 \tag{76}$$

where A is a constant of proportionality, $R_{\sigma,\rho}$ is the Raman coefficient of the representation, and e_{i}^{σ} and e_{s}^{ρ} are components of the unit vectors of polarization of the incident, *i*, and scattered, *s*, radiation along the principal axes, where σ and $\rho = x, y,$ and z.

Not all optic modes of zero wavevector are Raman active. Raman activity is often complementary to infrared activity. For instance, since the optic mode in the diamond lattice has even parity, it is Raman active, but not infrared active, whereas the zone center mode in sodium chloride is infrared active, but not Raman active because the inversion center is on the atom site and so the phonon has odd parity. In piezoelectric crystals, which lack a center of inversion, some modes can be both Raman and infrared active. In this case the Raman scattering can be anomalous due to the long-range electrostatic forces associated with the polar lattice vibrations.

The theory of Brillouin scattering is based on the elastic deformation produced in a crystal by a long wavelength acoustic phonon. The intensity of the scattering depends on the change in refractive index with the strain induced by the vibrational mode. A strain, s_{ij} in the lattice produces a change in the component of permittivity, $\varepsilon_{\mu\nu}$, given by

$$\delta\varepsilon_{\mu\nu} = -\sum_{\rho,\sigma} \varepsilon_{\mu\rho} p_{\rho\sigma,\mathrm{ij}} \varepsilon_{\sigma\nu} s_{\mathrm{ij}} \tag{77}$$

where $p_{\rho\sigma,\mathrm{ij}}$ is an elasto-optical coefficient.[3] The velocity of the acoustic phonons and their anisotropy can be determined from Brillouin scattering measurements.

9.6 FREE ELECTRON PROPERTIES

Fundamental optical properties of metals and semiconductors with high densities of free carriers are well described using a classical model. Reflectivity is the primary property of interest because of the high absorption.

Drude Model

The Drude model for free electrons is a special condition of the classical Lorentz model (Sec. 9.4) with the Hooke's law force constant, $\xi = 0$, so that the resonant frequency is zero. In this case

$$\frac{\varepsilon_1}{\varepsilon_0} = n^2 - \kappa^2 = 1 - \frac{\omega_{\mathrm{p}}^2}{\omega^2 + \tau^{-2}} \tag{78}$$

and

$$\frac{\varepsilon_2}{\varepsilon_0} = 2n\kappa = \frac{\omega_p^2}{\omega^2 + \tau^{-2}}\left(\frac{1}{\omega\tau}\right) \tag{79}$$

where ω_p is the plasma frequency,

$$\omega_p = \sqrt{\frac{Ne^2}{\varepsilon_0 m}} = \sqrt{\frac{\mu_0 \sigma c^2}{\tau}} \tag{80}$$

and τ ($=1/\Gamma$) is the scattering or relaxation time for the electrons. In ideal metals ($\sigma \rightarrow \infty$), $n = \kappa$. Figure 5a shows the form of the dispersion in the real and imaginary parts

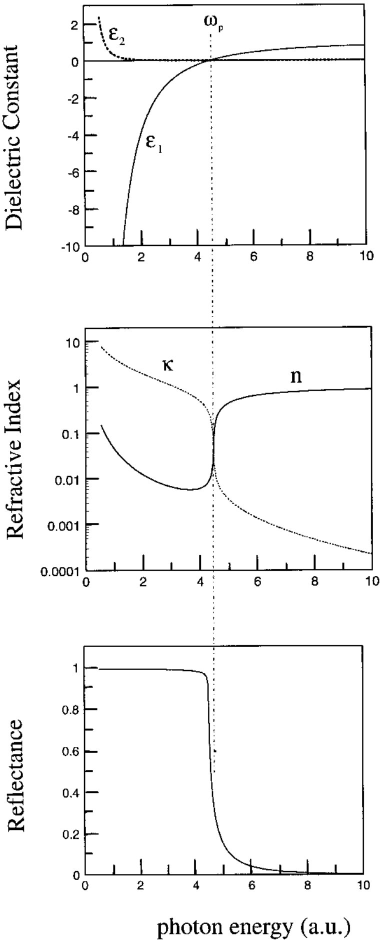

FIGURE 5 Dispersion of: (a) the real and imaginary parts of the dielectric constant; (b) real and imaginary parts of the refractive index; and (c) the reflectance according to the Drude model where ω_p is the plasma frequency.

of the dielectric constant for free electrons, while the real and imaginary parts of the refractive index are illustrated in Fig. 5*b*. The plasma frequency is defined by the point at which the real part changes sign. The reflectance is plotted in Fig. 5*c* and shows a magnitude close to 100 percent below the plasma frequency, but falls rapidly to a small value above ω_p. The plasma frequency determined solely by the free electron term is typically on the order of 10 eV in metals accounting for their high reflectivity in the visible.

Interband Transitions in Metals

Not all metals are highly reflective below the plasma frequency. The nobel metals possess optical properties which combine free electron intraband (Drude) and interband contributions. A typical metal has *d*-levels at energies a few electron volts below the electron Fermi level. Transitions can be optically induced from these *d*-states to empty states above the Fermi level. These transitions normally occur in the ultraviolet spectral region, but can have a significant influence on the optical properties of metals in the visible spectral region via the real part of the dielectric constant. Describing the interband effects, $\delta\varepsilon_b$, within a classical (Lorentz) model, the combined effects on the dielectric constant may be added:

$$\tilde{\varepsilon} = 1 + \delta\tilde{\varepsilon}_b + \delta\tilde{\varepsilon}_f \tag{81}$$

The interband contribution to the real part of the dielectric constant is positive and shows a resonance near the transition frequency. On the other hand, the free electron contribution is negative below the plasma frequency. The interband contribution can cause a shift to shorter wavelengths of the zero crossover in ε_1, thus causing a reduction of the reflectivity in the blue. For instance *d*-states in copper lie only 2 eV below the Fermi level, which results in copper's characteristic color.

Reflectivity

Absorption in metals is described by complex optical constants. The reflectivity is accompanied by a phase change and the penetration depth is

$$d_M = \frac{c}{2\omega\kappa} = \frac{\lambda}{4\pi\kappa} \tag{82}$$

At normal incidence at an air-metal interface, the reflectance is given by

$$R = \frac{(n-1)^2 + \kappa^2}{(n+1)^2 + \kappa^2} = 1 - \frac{2}{\kappa} = 1 - 2\sqrt{\frac{2\varepsilon_0}{\varepsilon_2}} \tag{83}$$

By analogy with the law of refraction (Snell's Law) a complex refractive index can be defined by the refraction equation

$$\sin\theta_t = \frac{1}{\tilde{\eta}}\sin\theta_i \tag{84}$$

Since $\tilde{\eta}$ is complex, θ_t is also complex and the phase change on reflection can take values other than 0 and π. For nonnormal incidence, it can be shown that the surfaces of constant amplitude inside the metal are parallel to the surface, while surfaces of constant phase are at an angle to the surface. The electromagnetic wave in a metal is thus inhomogeneous. The real and imaginary parts of the refractive index can be determined by measuring the amplitude and phase of the reflected light. Writing the s and p components of the complex reflected fields in the form

$$E_{rp} = \rho_p e^{i\phi_p}; \qquad E_{rs} = \rho_s e^{i\phi_s} \tag{85}$$

and defining the real amplitude ratio and phase difference as

$$P_M = \tan\psi = \frac{\rho_s}{\rho_p}; \qquad \Delta_M = \phi_p - \phi_s \tag{86}$$

then the real and imaginary parts of the refractive index are given by

$$n \approx -\frac{\sin\theta_i \tan\theta_i \cos 2\psi}{1+\sin 2\psi \cos\Delta_M} = -\sin\bar{\theta}_i \tan\bar{\theta}_i \cos 2\bar{\psi} \tag{87}$$

$$\kappa \approx \tan 2\psi \sin\Delta_M = -\tan 2\bar{\psi} \tag{88}$$

$\bar{\theta}_i$ is the principal angle which occurs at the maximum in P_M at the condition $\Delta_M = \pi/2$ (see Fig. 3*c* and *d*), which is equivalent to Brewster's angle at an interface between two nonabsorbing dielectrics (see Fig. 3*a* and *b*).

Plasmons

Plasmons are oscillations of fluctuations in charge density. The condition for these oscillations to occur is the same as the condition for the onset of electromagnetic propagation at the plasma frequency. Volume plasmons are not excited by light at normal incidence since they are purely longitudinal. Oscillations cannot be produced by transverse electromagnetic radiation with zero divergence. However, at the surface of a solid, an oscillation in surface charge density is possible. At an interface between a metal with permittivity, ε_m, and a dielectric with permittivity, ε_d, the condition $\varepsilon_m = -\varepsilon_d$ such that (neglecting damping and assuming a free electron metal) a surface plasmon can be created with frequency

$$\omega_s = \frac{\omega_p}{(\varepsilon_d/\varepsilon_0 + 1)^{1/2}} \tag{89}$$

By altering the angle of incidence, the component of the electromagnetic wavevector can be made to match the surface plasmon mode.

9.7 BAND STRUCTURES AND INTERBAND TRANSITIONS

Advances in semiconductors for electronic and optoelectronic applications have encouraged the development of highly sophisticated theories of interband absorption in semiconductors. In addition, the development of low-dimensional structures (quantum wells, quantum wires, and quantum dots) have provided the means of "engineering" the optical properties of solids. The approach here has been to outline the basic quantum mechanical development for interband transitions in solids.

Quantum Mechanical Model

The quantum theory of absorption considers the probability of an electron being excited from a lower energy level to a higher level. For instance, an isolated atom has a characteristic set of electron levels with associated wavefunctions and energy eigenvalues. The absorption spectrum of the atom thus consists of a series of lines whose frequencies are given by

$$\hbar\omega_{fi} = \mathscr{E}_f - \mathscr{E}_i\ (\mathscr{E}_f > \mathscr{E}_i) \tag{90}$$

where $\mathscr{E}_f$ and $\mathscr{E}_i$ are a pair of energy eigenvalues. We also know that the spontaneous lifetime, τ, for transitions from any excited state to a lower state sets a natural linewidth of order $\hbar/\tau$ based on the uncertainty principle. The Schrödinger equation for the ground state with wavefunction, φ_i, in the unperturbed system,

$$\mathscr{H}_0 \varphi_i = \mathscr{E}_i \varphi_i \tag{91}$$

is represented by the time-independent hamiltonian, $\mathscr{H}_0$. The optical interaction can be treated by first order perturbation theory. By introducing a perturbation term based on the classical oscillator

$$\mathscr{H}' = e\mathbf{E} \cdot \mathbf{r} \tag{92}$$

this leads to a similar expression to the Lorentz model, Eq. (59),

$$\tilde{\eta}^2 = \frac{\varepsilon}{\varepsilon_0} = 1 + \frac{Ne^2}{m\varepsilon_0} \sum_{\mathrm{m}} \frac{f_{\mathrm{fi}}}{(\omega_{\mathrm{fi}}^2 - \omega^2 - i\Gamma_{\mathrm{fi}}\omega)} \tag{93}$$

where

$$f_{j'j} = \frac{2\,|\mathbf{p}_{j'j}|^2}{m\hbar\omega_{j'j}} \tag{94}$$

and $\mathbf{p}_{j'j}$ are momentum matrix elements defined by

$$\mathbf{p}_{j'j} = \langle \varphi_{j'} \,|\, \mathbf{p} \,|\varphi_j\rangle = \int \varphi_{j'}^*(i\hbar\nabla)\varphi_j \, d\mathbf{r} \tag{95}$$

Perturbation theory to first order gives the probability per unit time that a perturbation of the form $\mathscr{H}(t) = \mathscr{H}_p \exp(i\omega t)$ induces a transition from the initial to final state:

$$W_{\mathrm{fi}} = \frac{2\pi}{\hbar} |\langle\varphi_f|\, \mathscr{H}_p \,|\varphi_i\rangle|^2 \delta(\mathscr{E}_f - \mathscr{E}_i - \hbar\omega) \tag{96}$$

This is known as Fermi's Golden Rule.

Energy Band Structures

If we imagine N similar atoms brought together to form a crystal, each degenerate energy level of the atoms will spread into a band of N levels. If N is large, these levels can be treated as a continuum of energy states. The wavefunctions and electron energies of these energy bands can be calculated by various approximate methods ranging from nearly free electron to tight-binding models. The choice of approach depends on the type of bonding between the atoms.

Within the one electron and adiabatic assumptions, each electron moves in the periodic potential, $V(\mathbf{r})$, of the lattice leading to the Schrödinger equation for a single particle wavefunction

$$\left[\frac{p^2}{2m} + V(\mathbf{r})\right]\psi(\mathbf{r}) = \mathscr{E}\psi(\mathbf{r}) \tag{97}$$

where the momentum operator is given by $\mathbf{p} = -i\hbar\nabla$. The simple free electron solution of the Schrödinger equation (i.e., for $V(\underline{r}) = 0$) is a parabolic relationship between energy and wavevector. The solution including a periodic potential, $V(\underline{r})$ has the form

$$\psi_{\mathrm{k}}(\mathbf{r}) = \exp\,(i\mathbf{k}\cdot\mathbf{r})\cdot u_{\mathrm{k}}(\mathbf{r}) \tag{98}$$

where $\underline{\mathbf{k}}$ is the electron wavevector and $u_{\mathrm{k}}(\mathbf{r})$ has the periodicity of the crystal lattice. This is known as the Bloch solution. The allowed values of k are separated by $2\pi/L$ where L is the length of the crystal. The wavevector is not uniquely defined by the wavefunction, but the energy eigenvalues are a periodic function of $\mathbf{k}$. For an arbitrarily weak periodic potential

$$\mathscr{E} = \frac{\hbar^2}{2m}\,|\mathbf{k} + \mathbf{G}|^2 \tag{99}$$

where $\mathbf{G}$ is a reciprocal lattice vector (in one dimension $G = 2\pi n/a$ where a is the lattice spacing and n is an θ integer). Thus we need only consider solutions which are restricted to a reduced zone, refered to as the first Brillouin zone, in reciprocal space (between $k = -\pi/a$ and π/a in one dimension). Higher energy states are folded into the first zone consistent with Eq. (99) to form a series of energy bands. Figure 6 shows the first Brillouin zones for face centered cubic (fcc) crystal lattices and energy levels for a weak lattice potential.

A finite periodic potential, $V(\underline{r})$, alters the shape of the free electron bands. The

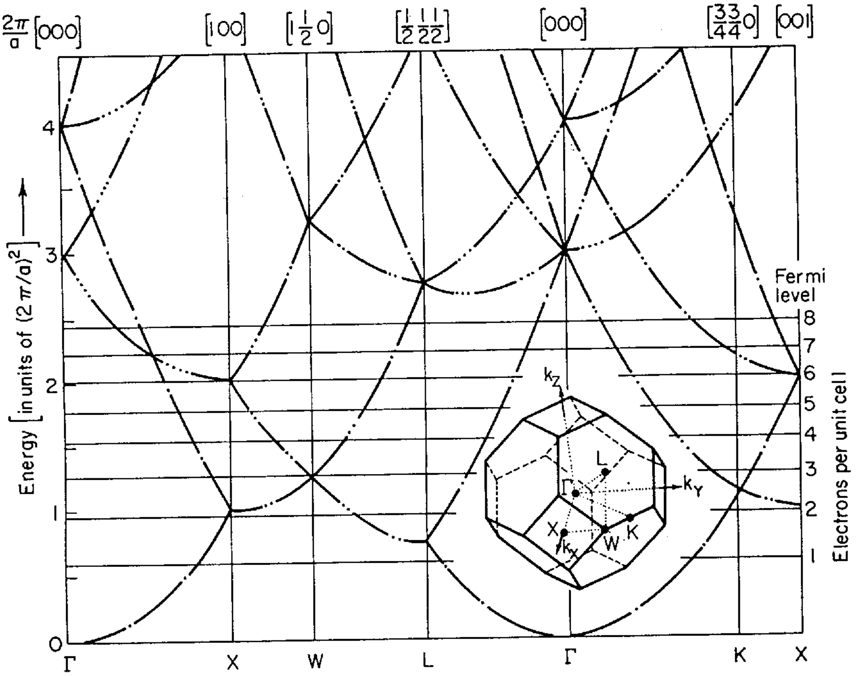

FIGURE 6 Free electron band structure in the reduced Brillouin zone for face-centered-cubic lattices. The insert shows the first Brillouin zone with principal symmetry points labeled. This applies to crystals such as Al, Cu, Ag, Si, Ge, and GaAs.[5]

curvature of the bands are described by m^*, an "effective mass," which is defined by the slope of the dispersion curve at a given $\mathbf{k}$:

$$\frac{1}{m^*_{\mathrm{k}}} = \frac{1}{\hbar^2 k}\frac{d\mathscr{E}}{dk} \tag{100}$$

At the zone center, $\mathbf{k} = 0$, this reduces to the parabolic relationship

$$\mathscr{E} = \frac{\hbar^2 k^2}{2m^*_0} \tag{101}$$

Effective masses can be related to interband momentum matrix elements and energy gaps using perturbation theory. Substituting the Bloch function [see Eq. (98)] into the Schrödinger equation [see Eq. (97)] and identifying each band by an index, j, gives

$$\left[\frac{p^2}{2m} + \frac{\hbar}{m}\mathbf{k}\cdot\mathbf{p} + \frac{\hbar^2 k^2}{2m} + V(\mathbf{r})\right]u_{\mathrm{j}\mathbf{k}}(\mathbf{r}) = \mathscr{E}_{j\mathbf{k}}(\mathbf{r})u_{j\mathbf{k}}(\mathbf{r}) \tag{102}$$

The $\mathbf{k}\cdot\mathbf{p}$ term can be treated as a perturbation about a specific point in k-space. For any $\mathbf{k}$, the set of all $u_{j\mathbf{k}}(r)$ (corresponding to the N energy levels) forms a complete set, i.e., the wavefunction at any value of $\mathbf{k}$ can be expressed as a linear combination of all wavefunctions at another $\mathbf{k}$. Second order perturbation theory then predicts an effective mass given by

$$\frac{1}{m^*} = \frac{1}{m} + \frac{2}{m}\sum_{\mathrm{j}'}\frac{|\mathbf{p}_{\mathrm{j}'\mathrm{j}}|^2}{\mathscr{E}_{\mathrm{j}}(\mathbf{k}) - \mathscr{E}_{\mathrm{j}'}(\mathbf{k})} \tag{103}$$

In principle the summation in Eq. (103) is over all bands, however, this can usually be reduced to a few nearest bands because of the resonant denominator. For example, in diamond and zinc blende structured semiconductors, the Kane momentum matrix element, P, defined by

$$P = -\frac{i\hbar}{m}\langle S_{\mathrm{CO}}\,|p_{\mathrm{x}}|\,X_{\mathrm{VO}}\rangle \tag{104}$$

successfully characterizes the band structure and optical properties close to zone center. Here, S_{CO} is a spherically symmetric s-like atomic wavefunction representing the lowest zone center conduction band state and X_{VO} is a p-like function with x symmetry from the upper valence bands. In this case, including only the three highest valence bands and the lowest conduction band in the summation of Eq. (91), the conduction band effective mass is given by

$$\frac{1}{m^*_{\mathrm{CO}}} = \frac{1}{m} + \frac{2}{3\hbar^2}\left[\frac{2P^2}{\mathscr{E}_{\mathrm{g}}} + \frac{P^2}{\mathscr{E}_{\mathrm{g}} + \Delta_{\mathrm{SO}}}\right] \tag{105}$$

where $\mathscr{E}_{\mathrm{g}}$ is the band gap energy and Δ_{SO} is the spin-orbit splitting. By inverting this expression, the momentum matrix element may be determined from measurements of effective mass and the band gaps. P is found to have similar magnitudes for a large number of semiconductors. Equation (105) illustrates the general rule that the effective mass of the conduction band is approximately proportional to the band gap energy.

Direct Interband Absorption

In the case of a solid, the first order perturbation of the single electron hamiltonian by electromagnetic radiation is more appropriately described by

$$\mathcal{H}'(t) = \frac{e}{mc}\mathbf{A}\cdot\mathbf{p} \tag{106}$$

rather than Eq. (92). **A** is the vector potential,

$$\mathbf{A}(\mathbf{r}, t) = A_0\hat{\boldsymbol{\xi}}\exp\left[i(\mathbf{q}\cdot\mathbf{r} - \omega t)\right] + \text{c.c.} \tag{107}$$

q is the wavevector, and $\hat{\xi}$ is the unit polarization vector of the electric field. (Note that this perturbation is of a similar form to the **k · p** perturbation described above.) Using Fermi's Golden Rule, the transition probability per unit time between a pair of bands is given by

$$W_{\text{fi}} = \frac{2\pi}{\hbar}\left(\frac{eA_0}{mc}\right)^2 |\langle\psi_{\text{f}}|\,\hat{\boldsymbol{\xi}}\cdot\mathbf{p}\,|\psi_{\text{i}}\rangle|^2\,\delta(\mathscr{E}_{\text{f}}(\mathbf{k}) - \mathscr{E}_{\text{i}}(\mathbf{k}) - \hbar\omega) \tag{108}$$

Conservation of momentum requires a change of electron momentum after the transition, however, the photon momentum is very small, so that vertical transitions in k-space can be assumed in most cases (the electric dipole approximation). The total transition rate per unit volume, $W_{\text{T}}(\omega)$, is obtained by integrating over all possible vertical transitions in the first Brillouin zone taking account of all contributing bands:

$$W_{\text{T}}(\omega) = \frac{2\pi}{\hbar}\left(\frac{2\pi e^2 I}{ncm^2\omega^2}\right)\sum_{\text{f}}\int\frac{d\mathbf{k}}{(2\pi)^3}|\hat{\boldsymbol{\xi}}\cdot\mathbf{p}_{\text{fi}}(\mathbf{k})|^2\,\delta(\mathscr{E}_{\text{f}}(\mathbf{k}) - \mathscr{E}_{\text{i}}(\mathbf{k}) - \hbar\omega) \tag{109}$$

Here the vector potential has been replaced with the irradiance, I, of the radiation through the relation

$$A_0 = \frac{2\pi c}{n\omega^2}I \tag{110}$$

Note that the momentum matrix element as defined in Eq. (95) determines the oscillator strength for the absorption. $\mathbf{p}_{\text{fi}}$ can often be assumed slowly varying in **k** so that the zone center matrix element can be employed for interband transitions and the frequency dependence of the absorption coefficient is dominated by the density of states.

Joint Density of States

The delta function in the integration of Eq. (109) represents energy conservation for the transitions between any two bands. If the momentum matrix element can be assumed slowly varying in k, then the integral can be rewritten in the form

$$J_{\text{fi}}(\omega) = \frac{1}{(2\pi)^3}\int d\mathbf{k}\,\delta(\mathscr{E}_{\text{f}}(\mathbf{k}) - \mathscr{E}_{\text{i}}(\mathbf{k}) - \hbar\omega) = \frac{1}{(2\pi)^3}\int\frac{d\mathbf{S}}{|\nabla_{\text{k}}\mathscr{E}_{\text{fi}}(\mathbf{k})|} \tag{111}$$

where $d\underline{\mathbf{S}}$ is a surface element on the equal energy surface in **k**-space defined by $\mathscr{E}_{\text{fi}}(\mathbf{k}) = \mathscr{E}_{\text{f}}(\mathbf{k}) - \mathscr{E}_{\text{i}}(\mathbf{k}) = \hbar\omega$. Written in this way, $J(\omega)$ is the joint density of states between the two bands (note the factor of two for spin is excluded in this definition). Points in k-space for which the condition

$$\nabla_{\text{k}}\mathscr{E}_{\text{fi}}(\mathbf{k}) = 0 \tag{112}$$

hold form critical points called van Hove singularities which lead to prominent features in the optical constants. In the neighborhood of a critical point at $\mathbf{k}_c$, a constant energy surface may be described by the Taylor series

$$\mathscr{E}_{\text{fi}}(\mathbf{k}) = \mathscr{E}_c(\mathbf{k}_c) + \sum_{\mu=1}^{3} \beta_\mu k_\mu^2 \tag{113}$$

where μ represents directional coordinates. Minimum, maximum, and saddle points arise depending on the relative signs of the coefficients, β_μ. Table 3 gives the frequency dependence of the joint density of states in three dimensional (3-D), two-dimensional (2-D),

TABLE 3 Density of States in 3, 2, 1, and 0 Dimensions

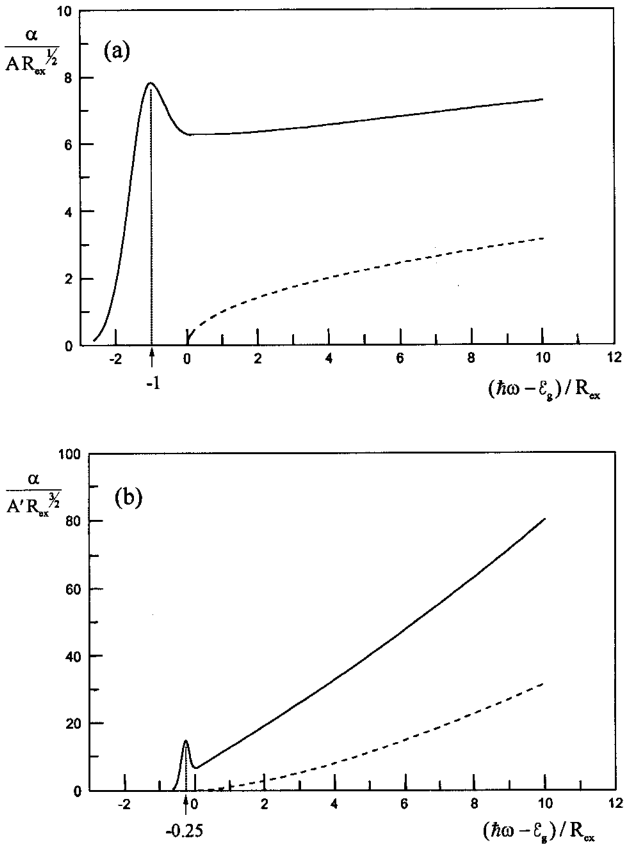

FIGURE 7 Illustration of absorption edge of crystals with: (*a*) direct allowed transitions; and (*b*) direct forbidden transitions, based on density of state (dashed lines) and excitonic enhanced absorption models (solid lines).

one-dimensional (1-D), and zero-dimensional (0-D) solids. The absorption coefficient, α, defined by Beer's Law may now be related to the transition rate by

$$\alpha(\omega) = I^{-1}\frac{dI}{dz} = \frac{\hbar\omega}{I}W_T \tag{114}$$

Thus, the minimum fundamental absorption edge of semiconductors and insulators (in the absence of excitonic effects) has the general form (see Fig. 7*a*)

$$\alpha(\omega) = C_0(\hbar\omega - \mathscr{E}_c)^{1/2} \tag{115}$$

Selection Rules and Forbidden Transitions

Direct interband absorption is allowed when the integral in Eq. (95) is nonzero. This occurs when the wavefunctions of the optically coupled states have opposite parity for single photon transitions. Transitions may be forbidden for other wavefunction symmetries. Although the precise form of the wavefunction may not be known, the selection rules can be determined by group theory from a knowledge of the space group of the crystal and symmetry of the energy band. Commonly, a single photon transition, which is not allowed at the zone center because two bands have like parity, will be allowed at finite k because wavefunction mixing will give mixed parity states. In this case, the momentum matrix element may have the form

$$p_{\mathrm{fi}}(\mathbf{k}) = (\mathbf{k} - \mathbf{k}_0) \cdot \nabla_{\mathbf{k}}[\mathrm{p}_{\mathrm{fi}}(\mathbf{k})]_{\mathbf{k}=\mathbf{k}_0} \tag{116}$$

i.e., the matrix element is proportional to **k**. For interband transitions at an M_0 critical point, the frequency dependence of the absorption coefficient can be shown to be (see Fig. 7*b*)

$$\alpha(\omega) = C_0'(\hbar\omega - \mathscr{E}_{\mathrm{c}})^{3/2} \tag{117}$$

Indirect Transitions

Interband transitions may also take place with the assistance of a phonon. The typical situation is a semiconductor or insulator which has a lowest conduction band minimum near a Brillouin zone boundary. The phonon provides the required momentum to move the electron to this location, but supplies little energy. The phonon may be treated as an additional perturbation and therefore second order perturbation theory is needed in the analysis of this two step process. Theory predicts a frequency dependence for the absorption of the form

$$\alpha(\omega) \sim (\hbar\omega \pm \hbar\omega_{\mathrm{ph}} - \mathscr{E}_{\mathrm{c}})^2 \tag{118}$$

where ω_{ph} is the phonon frequency, absorption or emission being possible. For forbidden indirect transitions, this relationship becomes

$$\alpha(\omega) \sim (\hbar\omega \pm \hbar\omega_{\mathrm{ph}} - \mathscr{E}_{\mathrm{c}})^3 \tag{119}$$

Multiphoton Absorption

Multiphoton absorption can be treated by higher order perturbation theory. For instance, second order perturbation theory gives a transition rate between two bands

$$W_{\mathrm{fi}}^{(2)} = \frac{2\pi}{\hbar}\left(\frac{eA_0}{mc}\right)^4 \left|\sum_{\mathrm{t}} \frac{\langle\psi_{\mathrm{f}}|\hat{\boldsymbol{\xi}}\cdot\mathbf{p}\,|\psi_{\mathrm{t}}\rangle\langle\psi_{\mathrm{t}}|\hat{\boldsymbol{\xi}}\cdot\mathbf{p}\,|\psi_{\mathrm{i}}\rangle}{\mathscr{E}_{\mathrm{t}} - \mathscr{E}_{\mathrm{i}} - \hbar\omega}\right|^2 \delta(\mathscr{E}_{\mathrm{f}}(\mathbf{k}) - \mathscr{E}_{\mathrm{i}}(\mathbf{k}) - 2\hbar\omega) \tag{120}$$

where the summation spans all intermediate states, t. The interaction can be regarded as two successive steps. An electron first makes a transition from the initial state to an intermediate level of the system, t, by absorption of one photon. Energy is not conserved at this stage (momentum is) so that the absorption of a second photon must take the electron to its final state in a time determined by the energy mismatch and the uncertainty principle. In multiphoton absorption, one of the transitions may be an intraband self-transition. Since the probability depends on the arrival rate of the second photon, multiphoton absorption is intensity dependent. The total transition rate is given by

$$W_{\mathrm{T}}^{(2)}(\omega) = \frac{2\pi}{\hbar}\left(\frac{4\pi^2e^4I^2}{n^2c^2m^4\omega^4}\right)\sum_{\mathrm{f}}\int\frac{d\mathbf{k}}{(2\pi)^3}\left|\sum_{\mathrm{t}}\frac{\hat{\boldsymbol{\xi}}\cdot\mathbf{p}_{\mathrm{ft}}(\mathbf{k})\hat{\boldsymbol{\xi}}\cdot\mathbf{p}_{\mathrm{ti}}(\mathbf{k})}{\mathscr{E}_{\mathrm{t}} - \mathscr{E}_{\mathrm{i}} - \hbar\omega}\right|^2 \delta(\mathscr{E}_{\mathrm{f}}(\mathbf{k}) - \mathscr{E}_{\mathrm{i}}(\mathbf{k}) - 2\hbar\omega) \tag{121}$$

The two photon absorption coefficient is defined by the relation

$$-\frac{dI}{dz} = \alpha I + \beta I^2 \tag{122}$$

so that

$$\beta(\omega) = \frac{2\hbar\omega}{I^2} W_{\mathrm{T}}^{(2)}(\omega) \tag{123}$$

Excitons

The interband absorption processes discussed previously do not take into account Coulomb attraction between the excited electron and hole state left behind. This attraction can lead to the formation of a hydrogen-like bound electron-hole state or exciton. The binding energy of free (Wannier) excitons is typically a few meV. If not thermally washed out, excitons may be observed as a series of discrete absorption lines just below the band gap energy. The energy of formation of an exciton is

$$\mathscr{E}_{\mathrm{ex}} = \mathscr{E}_{\mathrm{g}} + \frac{\hbar^2 |\mathbf{K}|^2}{2(m_{\mathrm{e}}^* + m_{\mathrm{h}}^*)} - \frac{R_{\mathrm{ex}}}{n^2} \tag{124}$$

where R_{ex} is the exciton Rydberg

$$R_{\mathrm{ex}} = \frac{m_{\mathrm{r}}^* e^4}{2\hbar^2 \varepsilon_1^2} \tag{125}$$

m_{r}^* is the reduced effective mass, and n is a quantum number. Optically created electron-hole pairs have equal and opposite momentum which can only be satisfied if $\mathbf{K} = 0$ for the bound pair and results in discrete absorption lines. Coulomb attraction also modifies the absorption above the band gap energy. The theory of exciton absorption developed by Elliot predicts a modification to Eq. (115) for the direct allowed absorption coefficient above the band edge (see Fig. 7*a*)

$$\alpha = \frac{\pi C_0 R_{\mathrm{ex}}^{1/2} e^{\pi\gamma}}{\sinh \pi\gamma} \tag{126}$$

where

$$\gamma = \left(\frac{R_{\mathrm{ex}}}{\hbar\omega - \mathscr{E}_{\mathrm{g}}}\right)^{1/2} \tag{127}$$

Excitons associated with direct forbidden interband transitions do not show absorption at the lowest ($n = 1$) state, but transitions to excited levels are allowed. Above the band edge for direct forbidden transitions the absorption has the frequency dependence (see Fig. 7*b*)

$$\alpha = \frac{\pi C_0' R_{\mathrm{ex}}^{3/2}\left(1 + \frac{1}{\gamma^2}\right) e^{\pi\gamma}}{\sinh \pi\gamma} \tag{128}$$

Figure 7 compares the form of the absorption edge based on the density of states functions and a discrete exciton absorption line (dashed lines) with the absorption functions based on the Elliot theory and a typically broadened exciton (solid lines). Figure 7*a* is an illustration of a direct allowed gap, e.g., GaAs with the $n = 1$ exciton visible, and 7*b* shows a forbidden direct absorption edge, e.g., Cu_2O. In the latter case, optical excitation of the $n = 1$ exciton is forbidden, but the $n = 2$ and higher exciton transitions are allowed.

10.1 GLOSSARY

k	factor
R	radius of the interior
r	radius of the aperture
S	interior surface area
s	aperture area
ϵ	emissivity
ϵ_o	uncorrected emissivity

10.2 INTRODUCTION

This section deals with artificial sources of radiation as subdivided into two classes: laboratory and field sources. Much of the information on commercial sources is taken from a chapter previously written by the author.[1] Where it was feasible, similar information here has been updated. When vendors failed to comply to requests for information, the older data were retained to maintain completeness, but the reader should be aware that some sources cited here may no longer exist, or perhaps may not exist in the specification presented. Normally, laboratory sources are used in some standard capacity and field sources are used as targets. Both varieties appear to be limitless. Only laboratory sources are covered here.

The sources in this chapter were chosen arbitrarily, often depending upon manufacturer response to requests for information. The purpose of this chapter is to consolidate much of this information to assist the optical-systems designer in making reasonable choices. To attempt to include the hundreds of types of lasers, however, and the thousands of varieties, would be useless for several reasons, but particularly because they change often. A fairly comprehensive source of information on lasers can be found in the recently published CRC *Handbook of Laser Science and Technology,* Supplement I: Lasers, published by the CRC Press, Inc., 2000 Corporate Blvd., N.W., Boca Raton, FL 33431. According to the advertising, ‘‘This book updates Volumes I and II of the *Handbook of Laser Science and*

Technology by presenting the latest developments in laser sources. Together, these volumes constitute the most comprehensive and up-to-date listing available of lasers and laser transitions . . . .''

Regarding the selection of a source, Worthing[2] suggests that one ask the following questions:

1. Does it supply energy at such a rate or in such an amount as to make measurements possible?
2. Does it yield an irradiation that is generally constant or that may be varied with time as desired?
3. Is it reproducible?
4. Does it yield irradiations of the desired magnitudes over areas of the desired extent?
5. Has it the desired spectral distribution?
6. Has it the necessary operating life?
7. Has it sufficient ruggedness for the proposed problem?
8. Is it sufficiently easy to obtain and replace, or is its purchase price or its construction cost reasonable?

10.3 LABORATORY SOURCES

Standard Sources

Blackbody Cavity Theory. Radiation levels can be standardized by the use of a source that will emit a quantity of radiation that is both reproducible and predictable. Cavity configurations can be produced to yield radiation theoretically sufficiently close to Planckian that it is necessary only to determine what the imprecision is. Several theories have been expounded over the years to calculate the quality of a blackbody simulator.* Two of the older, most straightforward, and demonstrable theories are those of Gouffé and DeVos.

The Method of Gouffé.[3] For the total emissivity of the cavity forming a blackbody (disregarding temperature variations) Gouffé gives:

$$\epsilon_0 = \epsilon_0'(1 + k) \tag{1}$$

where

$$\epsilon_0' = \frac{\epsilon}{\epsilon\left(1 - \dfrac{s}{S}\right) + \dfrac{s}{S}} \tag{2}$$

and $k = (1 - \epsilon)[(s/S) - (s/S_0)]$, and is always nearly zero—it can be either positive or negative.

* Generically used to describe those sources designed to produce radiation that is nearly Planckian.

ϵ = emissivity of materials forming the blackbody surface

s = area of aperture

S = area of interior surface

S_0 = surface of a sphere of the same depth as the cavity in the direction normal to the aperture

Figure 1 is a graph for determining the emissivities of cavities with simple geometric shapes. In the lower section, the value of the ratio s/S is given as a function of the ratio $1/r$. (Note the scale change at the value for $1/r = 5$.) The values of ϵ_0' is found by reading up from this value of the intrinsic emissivity of the cavity material. The emissivity of the cavity is found by multiplying ϵ_0' by the factor $(1 + k)$.

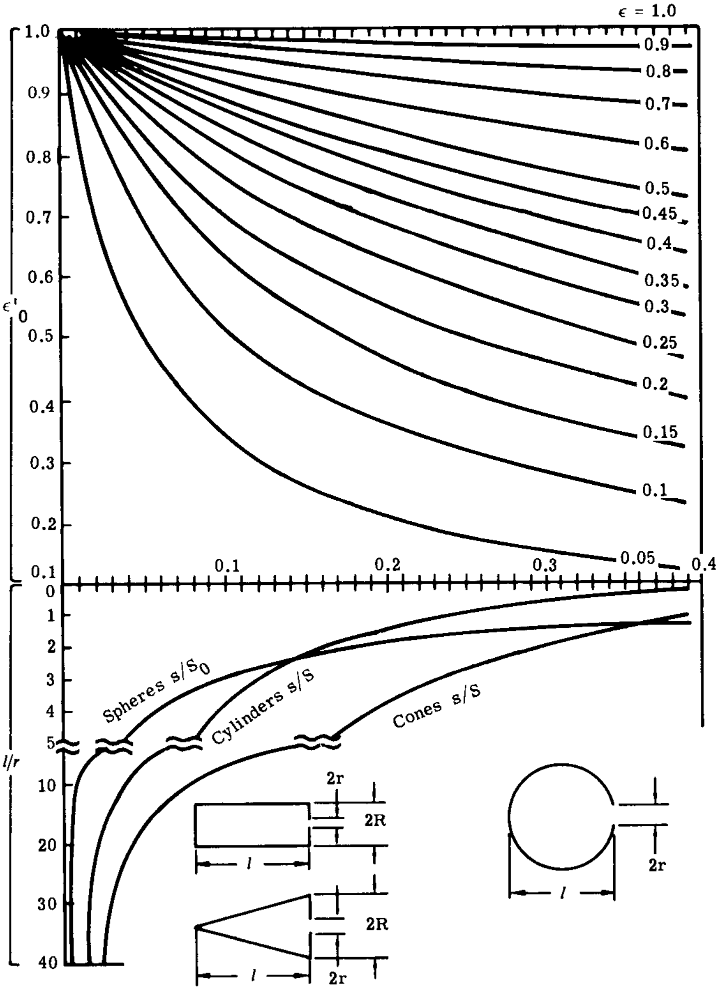

FIGURE 1 Emissivities of conical, spherical, and cylindrical cavities.

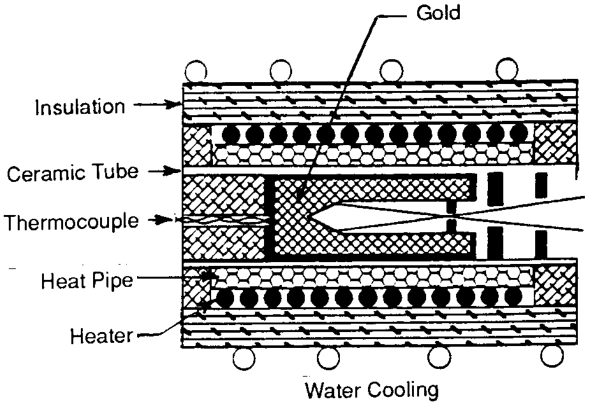

FIGURE 2*a* Cross section of heat-pipe blackbody furnace.

When the aperture diameter is smaller than the interior diameter of the cylindrical cavity, or the base diameter of a conical cavity, it is necessary to multiply the value of s/S determined from the graph by $(r/R)^2$, which is the ratio of the squares of the aperture and cavity radii (Fig. 1).

It is important to be aware of the effect of temperature gradients in a cavity. This factor is the most important in determining the quality of a blackbody, since it is not very difficult to achieve emissivities as near to unity as desired.

Manufacturers of blackbody simulators strive to achieve uniform heating of the cavity because it is only under this condition that the radiation is Planckian. The ultimate determination of a radiator that is to be used as the standard is the quality of the radiation that it emits.

A recent investigation on comparison of IR radiators is presented by Leupin et al.[4] There has been, incidentally, a division historically between the standards of photometry and those used to establish thermal radiation and the thermodynamic temperature scale. Thus, in photometry the standard has changed from the use of candles, the Carcel lamp, the Harcourt pentane lamp, and the Hefner lamp[5] to more modern radiators.

Baseline Standard of Radiation. Although there is no internationally accepted standard of radiation, the National Institute of Standards and Technology (NIST) uses as its substitute standard the goldpoint blackbody (see Fig. 2),[6] which fixes one point on the international temperature scale, now reported to be 1337.33 + 0.34 K. Starting from this

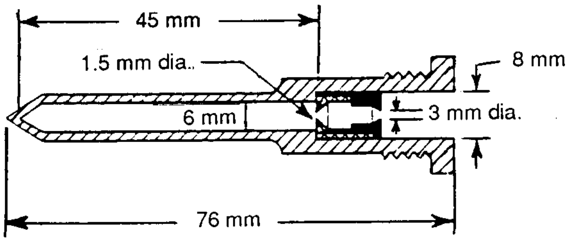

FIGURE 2*b* Blackbody inner cavity dimensions.

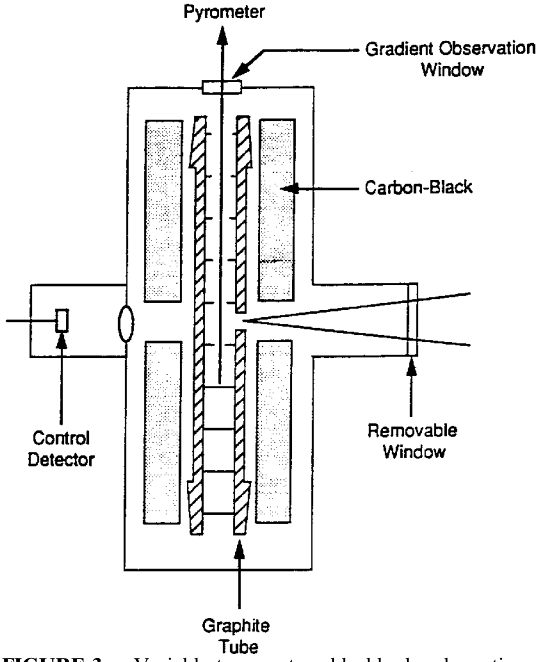

FIGURE 3*a* Variable temperature blackbody schematic.

point, NIST is able to transfer fixed radiation values to working standards of radiation through an accurately constructed variable-temperature radiator as shown in Fig. 3.[7]

The goldpoint blackbody is shown mainly for information. It is quite feasible to build a replica of the variable-temperature radiator, especially in the laboratory equipped to do fundamental radiation measurements.

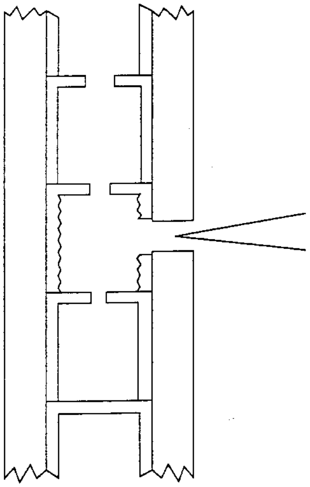

FIGURE 3*b* Central section of variable temperature blackbody.

Working Standards of Radiation. For the calibration of instruments in the ordinary laboratory, the user is likely to use a source which is traceable to NIST, and generally supplied by NIST or one of the recognized vendors of calibrated sources, mainly in the form of a heated filament, a gaseous arc enclosed in an envelope of glass or quartz (or fused silica), or in glass with a quartz or sapphire window.

Any source whose radiation deviates from that described by Planck's law is nonblackbody. Even the sources previously described are not strictly blackbodies, but can come as close as the user desires within the constraints of bulk and price. Any other source has an emissivity less than unity and can, and usually does, have a highly variable spectral emissivity. The lamps used by NIST, for example (see the following), fit into this category, but they differ in one large respect. They are transfer standards which have been carefully determined to emit specified radiation within certain specific spectral regions.

The following discussion of these types of sources is reproduced (in some cases with slight modifications), with permission, from the NIST Special Publication 250.[8] For specific details of calibration, and for the exact source designations, the user should contact NIST at:

Photometric Standards

1. Sources/Lamps

Luminous Intenity Standard (100-W Frosted Tungsten Lamp, 90 candelas)

Luminous Intensity Standard (100-W Frosted Tungsten Lamp, color temp., 2700K)

Luminous Intensity Standard (100-W Frosted Tungsten Lamp, color temp., 2856K)

Luminous Intensity Standard (500-W Frosted Tungsten Lamp, 700 candelas)

Luminous Intensity Standard (1000-W Frosted Tungsten Lamp, 1400 candelas)

Luminous Intensity Standard (1000-W Frosted Tungsten Lamp, color temp., 2856K)

Luminous Flux Standard (25-W Vacuum Lamp about 270 lumens)

Luminous Flux Standard (60-W Gas-filled Lamp about 870 lumens)

Luminous Flux Standard (100-W Gas-Filled Lamp about 1600 lumens)

Luminous Flux Standard (200-W Gas-Filled Lamp about 3300 lumens)

Luminous Flux Standard (500-W Gas-Filled Lamp about 10,000 lumens)

Luminous Flux Standard (Miniature Lamps 7 sizes 6 to 400 lumens)

Airway Beacon Lamps for Color Temperature (500-W, 1 point in range, 2000–3000K)

2. General Information

Calibration services provide access to the photometric scales realized and maintained at NIST. Lamp standards of luminous intensity, luminous flux, and color temperature, as described next, are calibrated on a routine basis.

a. Luminous Intensity Standards

Luminous intensity standard lamps supplied by NIST [100-W (90-140 cd), 500-W (approximately 700 cd), and 1000-W (approximately 1400 cd) tungsten filament lamps with C-13B filaments in inside-frosted bulbs and having medium bipost bases] are calibrated at either a set current or a specified color temperature in the range 2700 to 3000 K. Approximate 3-sigma uncertainties are 1 percent relative to the SI unit of luminous intensity and 0.8 percent relative to NIST standards.

b. Luminous Flux Standards

Vacuum tungsten lamps of 25 W and 60-, 100-, 200-, and 500-W gas-filled tungsten lamps that are submitted by customers are calibrated. Lamps must be base-up burning and rated at 120 V. Approximate 3-sigma uncertainties are 1.4 percent relative to SI units and 1.2 relative to NIST standards. Luminous flux standards for miniature lamps producing 6 to 400 lm are calibrated with uncertainties of about 2 percent.

c. Airway Beacon Lamps

Color temperature standard lamps supplied by NIST (airway beacon 500-W meduim bipost lamps) are calibrated for color temperature in the range 2000 to 3000 K with 3-sigma uncertainties ranging from 10 to 15 degrees.

IR Radiometric Standards

1. Sources/Lamps

Spectral Radiance Ribbon Filament Lamps (225 to 2400 nm)

Spectral Radiance Ribbon Filament Lamps (225 to 800 nm)

Spectral Radiance Ribbon Filament Lamps (650 to 2400 nm)

Spectral Irradiance Quartz-Halogen Lamps (250 to 1600 nm)

Spectral Irradiance Quartz-Halogen Lamps (250 to 2400 nm)

Spectral Irradiance Deuterium Lamps (200 to 350 nm)

2. General Information

a. Spectral Radiance Ribbon Filament Lamps

These spectral radiance standards are supplied by NIST. Tungsten, ribbon filament lamps (30A/T24/13) are provided as lamp standards of spectral radiance. The lamps are calibrated at 34 wavelengths from 225 to 2400 nm, with a target area 0.6 mm wide by 0.8 mm high. Radiance temperature ranges from 2650 K at 225 nm, and 2475 K at 650 nm to 1610 K at 2400 nm, with corresponding uncertainties of 2, 0.6, and 0.4 percent. For spectral radiance lamps, errors are stated as the quadrature sum of individual uncertainties at the three standard deviation level.

Figure 4 summarizes the measurement uncertainty for NIST spectral radiance calibrations.

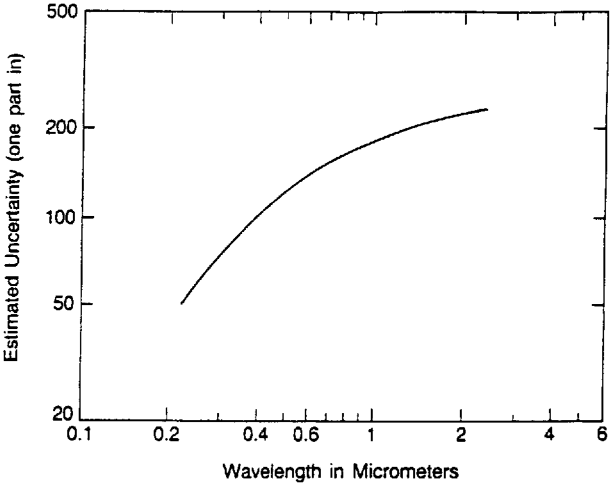

FIGURE 4 Uncertainties for NIST spectral radiance calibrations.

b. Spectral Irradiance Lamps

These spectral irradiance standards are supplied by NIST. Lamp standards of spectral irradiance are provided in two forms. Tungsten filament, 1000-watt quartz halogen type FEL lamps are calibrated at 31 wavelengths in the range 250 to 2400 nm. At the working distance of 50 cm, the lamps produce 0.2 W/cm^2/cm at 250 nm, 220 W/cm^2/cm at 900 nm, 115 W/cm^2/cm at 1600 nm, and 40 W/cm^2/cm at 2400 nm, with corresponding uncertainties of 2.2, 1.3, 1.9, and 6.5 percent. For spectral irradiance lamps, errors are stated as the quadrature sum of individual uncertainties at the three standard deviation level. Deuterium lamp standards of spectral irradiance are also provided and are calibrated at 16 wavelengths from 200 to 350 nm. At the working distance of 50 cm, the spectral irradiance produced by the lamp ranges from about 0.5 W/cm^2/cm at 200 nm and 0.3 W/cm^2/cm at 250 nm to 0.07 W/cm^2/cm at 350 nm. The deuterium lamps are intended primarily for the spectral region 200 to 250 nm. The approximate uncertainty relative to SI units is 7.5 percent at 200 nm and 5 percent at 250 nm. The approximate uncertainty in relative spectral distribution is 3 percent. It is strongly recommended that the deuterium standards be compared to an FEL tungsten standard over the range 250 to 300 nm each time the deuterium lamp is lighted to take advantage of the accuracy of the relative spectral distribution.

Figure 5 summarizes the measurement uncertainty for NIST spectral irradiance calibrations of type FEL lamps.

Radiometric Sources in the Far Ultraviolet

1. Sources

Spectral Irradiance Standard, Argon Mini-Arc (140 to 330 nm)

Spectral Radiance Standard, Argon Mini-Arc (115 to 330 nm)

Spectral Irradiance Standard, Deuterium Arc Lamp (165 to 200 nm)

2. General Information

a. Source Calibrations in the Ultraviolet

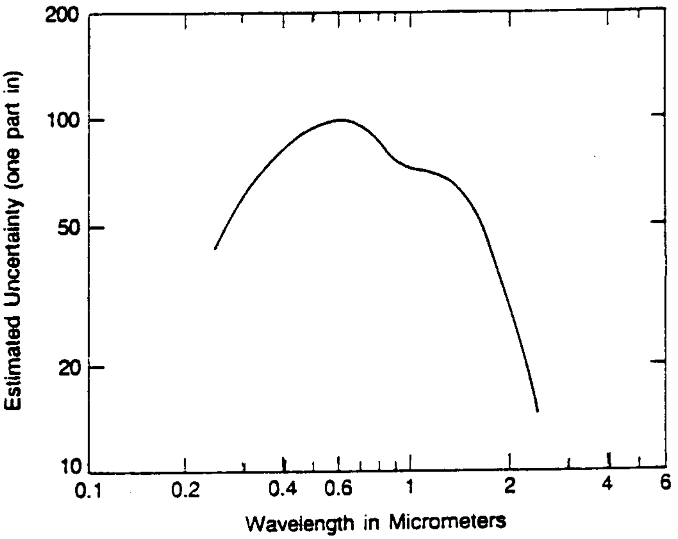

FIGURE 5 Uncertainties for NIST spectral irradiance calibrations of type FEL lamps.

NIST maintains a collection of secondary sources such as argon maxi-arcs, argon mini-arcs, and deuterium arc lamps in the near and vacuum ultraviolet radiometric standards program to provide calibrations for user-supplied sources. The calibrations of these sources are traceable to a hydrogen arc whose radiance is calculable and which NIST maintains as a primary standard. The collection also includes tungsten strip lamps and tungsten halogen lamps whose calibrations are based on a blackbody rather than a hydrogen arc. Customer-supplied sources are calibrated in both radiance and irradiance by comparing them with NIST secondary standards.

Argon arcs are used to calibrate other sources in the wavelength range 115 to 330 nm for radiance and 140 to 330 nm for irradiance. The lower wavelength limit is determined in radiance by the cutoff of the magnesium fluoride windows used in the arcs, and in irradiance by the decrease in signal produced by the addition of a diffuser. Deuterium arc lamps are used in the range 165 to 200 nm, with the low wavelength cutoff due to the onset of blended molecular lines.

The high wavelength limit is the starting point of the range for the Radiometric Standards group. The tungsten lamps are used at 250 nm and above, since their signals are too weak at shorter wavelengths. It should be noted that the wavelength range of the NIST arcs partially overlap the range of tungsten lamps, thus providing an independent check on calibrations.

An argon mini-arc lamp supplied by the customer is calibrated for spectral irradiance at 10-nm intervals in the wavelength region 140 to 300 nm. Absolute values are obtained by comparison of the radiative output with laboratory standards of both spectral irradiance and spectral radiance. The spectral irradiance measurement is made at a distance of 50 cm from the field stop. Uncertainties are estimated to be less than ±10 percent in the wavelength region 140 to 200 nm and within ±5 percent in the wavelength region 200 to 330 nm. A measurement of the spectral transmission of the lamp window is included in order that the calibration be independent of possible window deterioration or damage. The uncertainties are taken to be two standard deviations.

The spectral radiance of argon mini-arc radiation sources is determined to within an uncertainty of less than 7 percent over the wavelength range 140 to 330 nm and 20 percent over the wavelength range 115 to 140 nm. The calibrated area of the 4-mm diameter radiation source is the central 0.3-mm diameter region. Typical values of the spectral radiance are: at 250 nm, $\mathrm{L}(\lambda) = 30\,\mathrm{mW/cm^2/nm/sr}$; and at 150 nm, $L(\lambda) = 3\,\mathrm{mW/cm^2/nm/sr}$. The transmission of the demountable lamp window and that of an additional $\mathrm{MgF_2}$ window are determined individually so that the user may check periodically for possible long-term variations.

The deuterium arc lamp is calibrated at 10 wavelengths from 165 to 200 nm, at a distance of 50 cm, at a spectral irradiance of about $0.5\,\mathrm{W/cm^2/cm}$ at 165 nm, $0.5\,\mathrm{W/cm^2/cm}$ at 170 nm, and $0.5\,\mathrm{W/cm^2/cm}$ at 200 nm. The approximate uncertainty relative to SI units is estimated to be less than 10 percent. The lamp is normally supplied by NIST and requires 300 mA at about 100 V.

10.4 COMMERCIAL SOURCES

Blackbody Simulators

Virtually any cavity can be used to produce radiation of high quality, but practicality limits the shapes to a few. The most popular shapes are cones and cylinders, the former being more popular. Spheres, combinations of shapes, and even flat-plate radiators are used occasionally. Blackbodies can be bought rather inexpensively, but there is a fairly direct correlation between cost and quality (i.e., the higher the cost the better the quality).

Few manufacturers specialize in blackbody construction. Some, whose products are

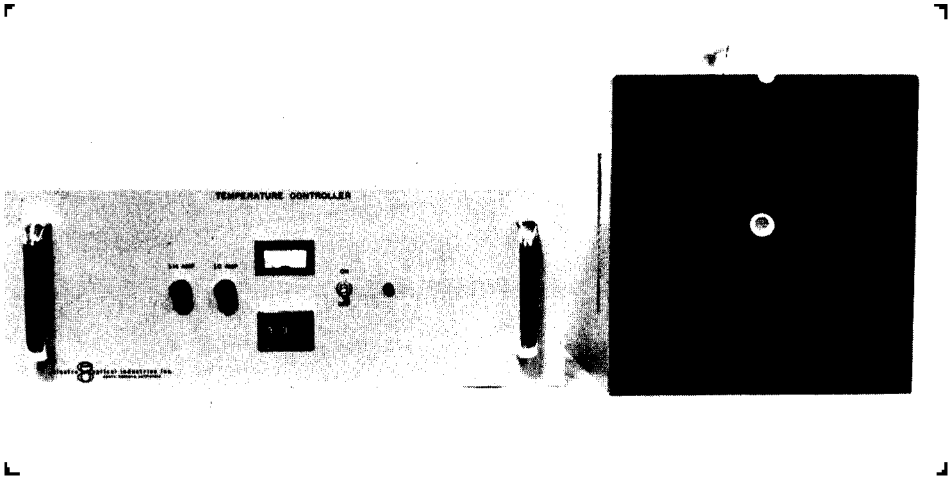

FIGURE 6 EOI blackbody.

specifically described here, have been specializing in blackbody construction for many years. Other companies of this description may be found, for example, in the latest Lasers and Optronics Buying Guide[9] or the latest Photonics Directory of Optical Industries.[10] These references are the latest as of the writing of this work. It is expected that they will continue in succeeding years.

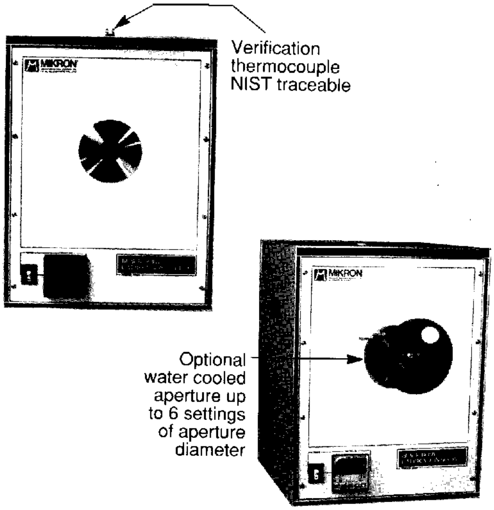
A large selection of standard (or blackbody) radiators is offered by Electro-Optical Industries, Inc. (EOI), Santa Barbara, California.* Most blackbodies can be characterized as one of the following: primary, secondary, or working standard. The output of the primary must, of course, be checked with those standards retained at NIST. Figure 6 pictures an EOI blackbody and its controller. Figure 7 pictures a similar blackbody from Mikron, Inc. and its controller. All of the companies sell separate apertures (some of which are water cooled) for controlling the radiation output of the radiators. Another piece of auxiliary equipment which can be purchased is a multispeed chopper. It is impossible to cite all of the companies that sell these kinds of sources; therefore, the reader is referred to one of the Buyers' Guides already referenced for a relatively complete list. It is prudent to shop around for the source that suits one's own purpose.

Figure 8 demonstrates a less-conventional working standard manufactured by EOL. Its grooves-and-honeycomb structure is designed to improve the absorptance of such a large and open structure. A coating with a good absorbing paint increases its absorptance further.

Incandescent Nongaseous Sources (Exclusive of High-Temperature Blackbodies)

Nernst Glower. The Nernst glower is usually constructed in the form of a cylindrical rod or tube from refractory materials (usually zirconia, yttria, beria, and thoria) in various sizes. Platinum leads at the ends of the tube conduct power to the glower from the source.

* Many of the sources in the text are portrayed using certain specific company products, only for the sake of demonstration. This does not necessarily imply an endorsement of these products by the author. The reader is encouraged in all cases to consult the *Photonics Directory of Optical Industries*[10] or a similar directory for competitive products.



Verification thermocouple NIST traceable
MIKRON
MIKRON
Optional water cooled aperture up to 6 settings of aperture diameter

FIGURE 7 Mikron blackbody.

Since the resistivity of the material at room temperature is quite high, the working voltage is insufficient to get the glower started. Once started, its negative temperature coefficient-of-resistance tends to increase current, which would cause its destruction, so that a ballast is required in the circuit. Starting is effected by applying external heat, either with a flame or an adjacent electrically heated wire, until the glower begins to radiate.

Data from a typical glower are as follows:

1. Power requirements: 117 V, 50 to 60 A, 200 W
2. Color temperature range: 1500 to 1950 K
3. Dimension: 0.05 in. diameter by 0.3 in.

The spectral characteristics of a Nernst glower in terms of the ratio of its output to that of a 900°C blackbody are shown in Fig. 9.

The life of the Nernst glower diminishes as the operating temperature is increased. Beyond a certain point, depending on the particular glower, no great advantage is gained by increasing the current through the element. The glower is fragile, with low tensile strength, but can be maintained intact with rigid support. The life of the glower depends on the operating temperature, care in handling, and the like. Lifetimes of 200 to 1000 hours are claimed by various manufacturers.

Since the Nernst glower is made in the form of a long thin cylinder, it is particularly useful for illuminating spectrometer slits. Its useful spectral range is from the visible region to almost 30 μm, although its usefulness compared with other sources diminishes beyond about 15 μm. As a rough estimate, the radiance of a glower is nearly that of a graybody at the operating temperature with an emissivity in excess of 75 percent, especially below about 15 μm. The relatively low cost of the glower makes it a desirable source of moderate radiant power for optical uses in the laboratory. The makers of spectroscopic equipment constitute the usual source of supply of glowers (or of information about suppliers).

Globar. The globar is a rod of bonded silicon carbide usually capped with metallic caps which serve as electrodes for the conduction of current through the globar from the power source. The passage of current causes the globar to heat, yielding radiation at a temperature above 1000°C. A flow of water through the housing that contains the rod is

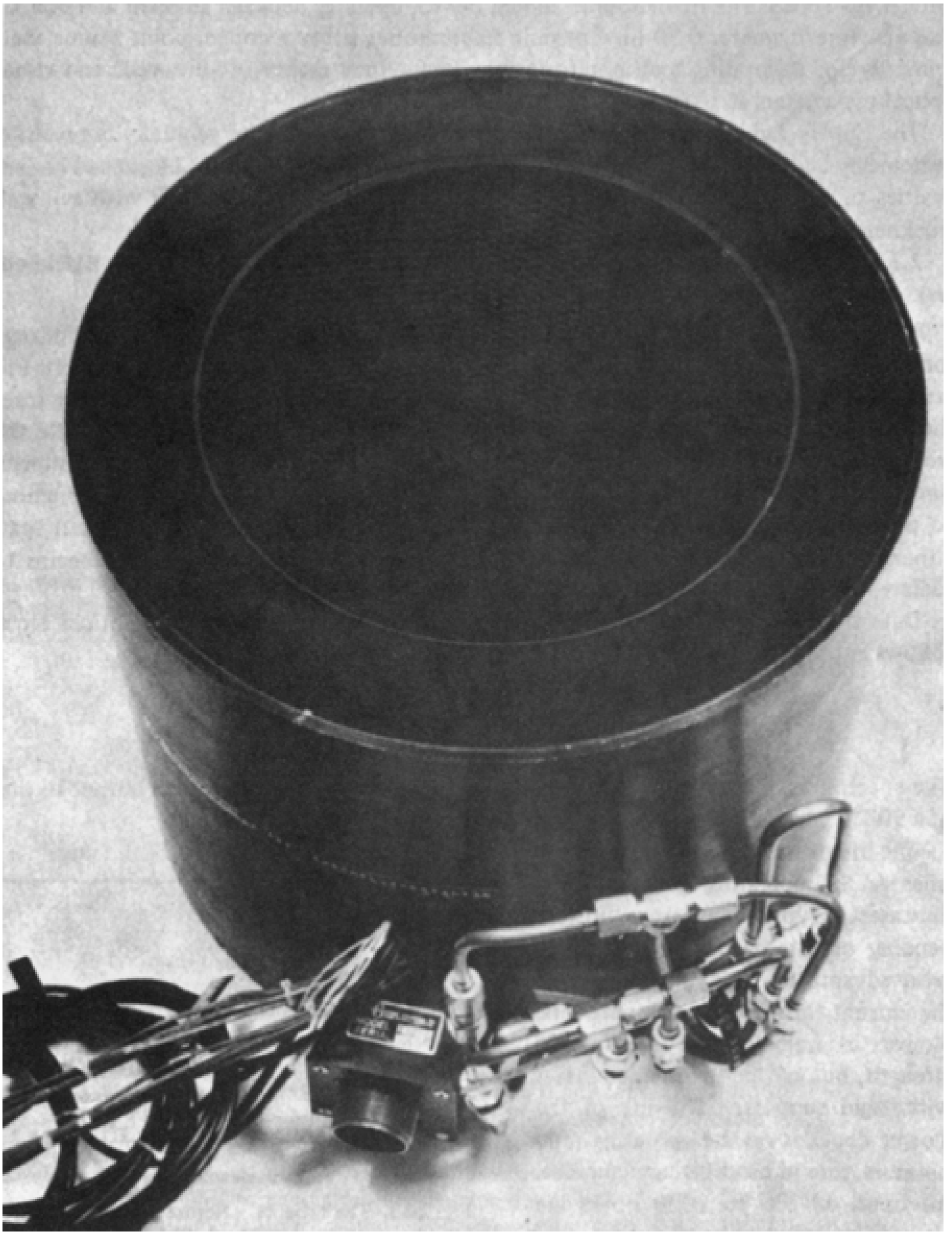


FIGURE 8 EOI model 1965. This model is 12 in. in diameter and 9 in. deep. The base is an array of intersecting conical cavities. The walls are hex-honeycomb and the temperature range is 175 to 340 K.

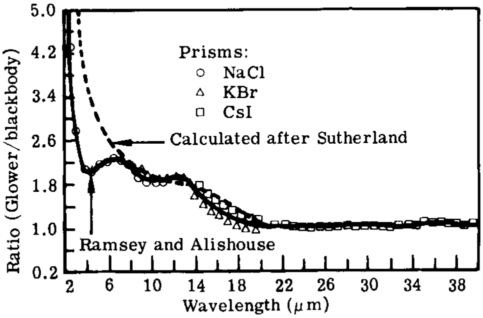

FIGURE 9 The ratio of a Nernst glower to a 900°C blackbody versus wavelength.

needed to cool the electrodes (usually silver). This complexity makes the globar less convenient to use than the Nernst glower and necessarily more expensive. This source can be obtained already mounted, from a number of manufacturers of spectroscopic equipment. Feedback in the controlled power source makes it possible to obtain high radiation output.

Ramsey and Alishouse[11] provide information on a particular sample globar as follows:

1. Power consumption: 200 W, 6 A
2. Color temperature: 1470 K

They also provide the spectral characteristics of the globar in terms of the ratio of its output to that of a 900°C blackbody. This ratio is plotted as a function of wavelength in Fig. 10. Figure 11[12] is a representation of the spectral emissivity of a globar as a function of wavelength. The emissivity values are only representative and can be expected to change considerably with use.

Gas Mantle. The Welsbach mantle is typified by the kind found in high-intensity gasoline lamps used where electricity is not available. The mantle is composed of thorium oxide with some additive to increase its efficiency in the visible region. Its near-infrared emissivity is quite small, except for regions exemplified by gaseous emission, but increases considerably beyond 10 micrometers.

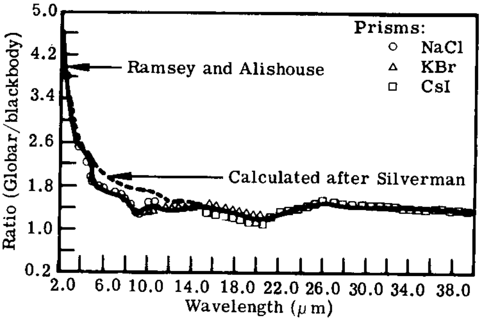

FIGURE 10 The ratio of a globar to a 900°C blackbody versus wavelength.

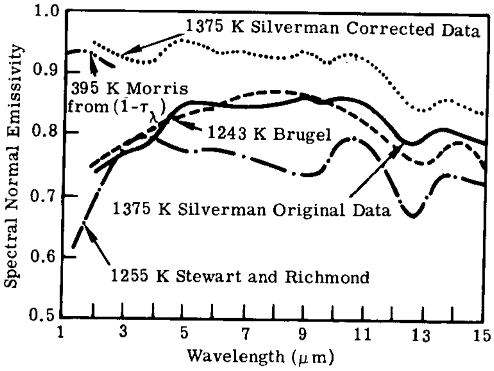

FIGURE 11 The spectral emissivity of a globar.

Ramsey and Alishouse[11] provide information on a propane-heated sample from an experiment in which a comparison of several sources is made:

1. Color temperature: 1670 K
2. Dimensions: 25.4 by 38.1 mm

The spectral characteristics of the mantle in terms of the ratio of its output to that of a 900°C blackbody are shown in Fig. 12.

Pfund modified the gas mantle so that it became more a laboratory experimental source than an ordinary radiator. By playing a gas flame on an electrically heated mantle, he was able to increase its radiation over that from the gas mantle itself.[13] Figure 13 shows a comparison of the gas mantle and the electrically heated gas mantle, with a Nernst glower. Strong[14] points out that playing a flame against the mantle at an angle produces an elongated area of intense radiation useful for illuminating the slits of a spectrometer.

Comparison of Nernst Glower, Globar, and Gas Mantle. Figure 14 compares these three types of sources, omitting a consideration of differences in the instrumentation used in making measurements of the radiation from the sources.

Availability, convenience, and cost usually influence a choice of sources. At the very long wavelength regions in the infrared, the gas mantle and the globar have a slight edge

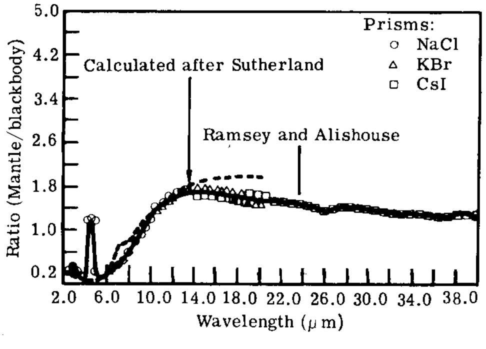

FIGURE 12 The ratio of the gas mantle to a 900°C blackbody versus wavelength.

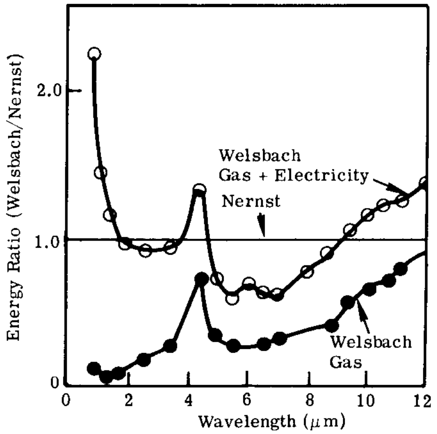

FIGURE 13 Emission relative to that of a Nernst glower (2240 K) of the gas-heated mantle (lower curve) and that of the mantle heated by gas plus electricity (upper curve).

over the Nernst glower because the Nernst glower (a convenient, small, and inexpensive source) does not have the power of the gas mantle and globar.

Tungsten-Filament Lamps. A comprehensive discussion of tungsten-filament lamps is given by Carlson and Clark.[15] Figures 15 to 17 show the configurations of lamp housings and filaments. The types and variations of lamps are too numerous to be meaningfully included in this chapter. The reader is referred to one of the Buyer's Guides for a comprehensive delineation of manufacturers from whom unlimited literature can be obtained.

Tungsten lamps have been designed for a variety of applications; few lamps are directed toward scientific research, but some bear directly or indirectly on scientific pursuits insofar as they can provide steady sources of numerous types of radiation. One set of sources cited here, particularly for what the manufacturer calls their scientific usefulness, is described in "Lamps for Scientific Purposes."[16] Their filament structures are similar to those already described, but their designs reduce extraneous radiation and ensure the quality and

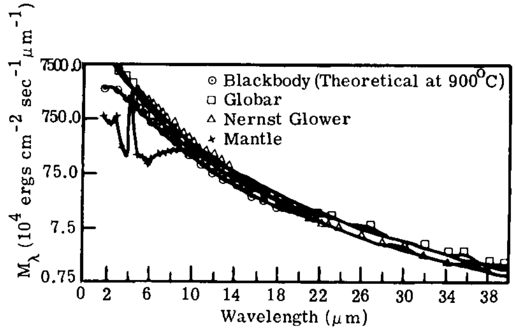

FIGURE 14 The spectral radiant emittances of a globar, Nernst glower, 900°C blackbody, and gas mantle versus wavelength.

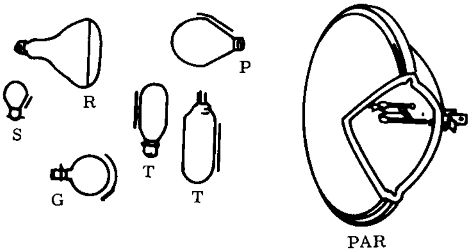

FIGURE 15 Bulk shapes most frequently used for lamps in optical devices. Letter designations are for particular shapes.

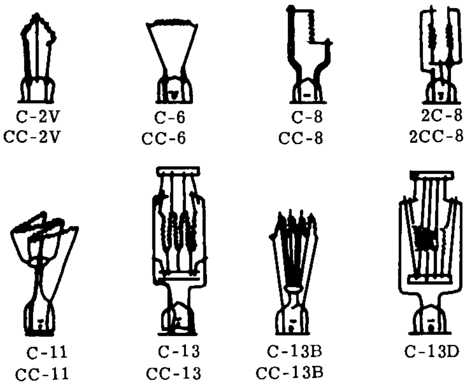

FIGURE 16 Most commonly used filament forms. Letters designate the type of filament.

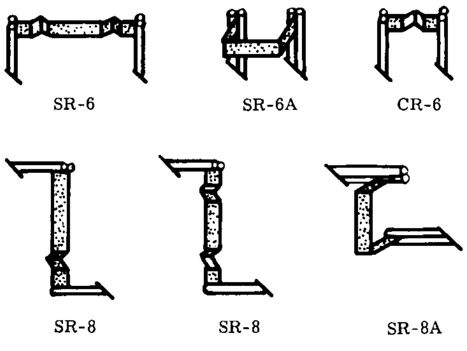

FIGURE 17 Ribbon-type tungsten filaments. Type designations are by number.

stability of the desired radiation. The lamps can be obtained with a certification of their calibration values.

The physical descriptions of some of these sources are given in Fig. 18. Applications (according to the manufacturer, Osram) are photometry, pyrometry, optical radiometry, sensitometry, spectroscopy, spectrometry, polarimetry, saccharimetry, spectrophotometry, colorimetry, microscopy, microphotography, microprojection, and stroboscopy.

Quartz Envelope Lamps. These are particularly useful as standards because they are longer lasting (due to action of iodine in the quartz-iodine series), can be heated to higher temperatures, are sturdier, and can transmit radiation to longer wavelengths in the infrared than glass-envelope lamps. Studer and Van Beers[17] have shown the spectral deviation to be expected of lamps containing no iodine. The deviation, when known, is readily acceptable in lieu of the degradation in the lamp caused by the absence of iodine. The particular tungsten-quartz-iodine lamps used in accordance with the NIST are described earlier in this chapter. Others can be obtained in a variety of sizes and wattages from General Electric, Sylvania, and a variety of other lamp manufacturers and secondary sources.

Carbon Arc

The carbon arc has been passed down from early lighting applications in three forms: low-intensity arc, flame, and high-intensity arc. The low- and high-intensity arcs are usually operated on direct current; the flame type adapts to either direct or alternating current. In all cases, a ballast must be used. "In the alternating current arc, the combined radiation from the two terminals is less than that from the positive crater of the direct-current arc of the same wattage.[2]

Spatial variation in the amount of light energy across the crater of dc arcs for different currents is shown in Fig. 19.

The carbon arc is a good example of an open arc, widely used because of its very high radiation and color temperatures (from approximately 3800 to 6500 K, or higher). The rate at which the material is consumed and expended during burning (5 to 30 cm per hour) depends on the intensity of the arc. The arc is discharged between two electrodes that are moved to compensate for the rate of consumption of the material. The anode forms a crater of decomposing material which provides a center of very high luminosity. Some electrodes are hollowed out and filled with a softer carbon material which helps keep the arc fixed in the anode and prevents it from wandering on the anode surface.

In some cored electrodes, the center is filled with whatever material is needed to produce desired spectral characteristics in the arc. In such devices, the flame between the electrodes becomes the important center of luminosity, and color temperatures reach values as high as 8000 K.[18] An example of this so-called flaming arc is shown in Fig. 20*a*. Figure 20*b* and *c* shows the low-intensity dc carbon arc and the high-intensity dc carbon arc with rotating positive electrodes. Tables 1 and 2 give characteristics of dc high intensity and flame carbon arcs.

A spectrum of low-intensity arc (Fig. 21) shows the similarity between the radiation from it and a 3800 K blackbody, except for the band structure at 0.25 and 0.39 microns. In Koller[18] an assortment of spectra are given for cored carbons containing different materials. Those for a core of soft carbon and for a polymetallic core are shown in Figs. 22 and 23. Because radiation emitted from the carbon arc is very intense, this arc supplants, for many applications, sources which radiate at lower temperatures. Among the disadvantages in using the carbon arc are its inconvenience relative to the use of other sources (e.g., lamps) and its relative instability. However, Null and Lozier[19] have studied the properties of the low-intensity carbon arc extensively and have found that under the proper operating conditions the carbon arc can be made quite stable; in fact, in their treatise they recommend its use as a standard of radiation at high temperatures.

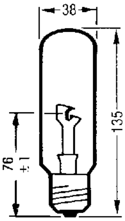
WI 41/G	31	6	2856 K	–	18	18	s+h	E 27

Lamps for scientific purposes are gas-filled, incandescent lamps for calibration of luminous intensity, luminous flux, luminance (spectral radiant temperature), color temperature (luminance temperature and spectral radiance distribution). A test certificate can be issued for these types of lamps.



WI 14
Base E 27/30
DIN 49620

Also for other types of lamp with sufficiently constant electric and photometric data, a test certificate can be issued. To order a test certificate, the order reference of the lamp, the type of measurement, and the desired burning position have to be given. Example: Lamp 41/G, measurement of the electric data and the luminous intensity for T_f = 2856 K (light-type A), burning position vertical, base up.

Variables for which test certificates can be issued are shown in the following tablc by +. The sign (+) indicates that certificates can be issued for variables although the lamps were not designed for such measurements.

Type of lamp	Light intensity	Luminous flux	Luminance	Color temperature	Spectral radiance distribution [3]

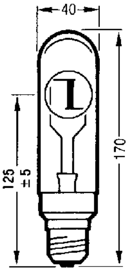
Description

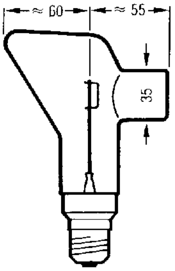
WI 9:
Lamp with uncoiled straight filament.

WI 14:
Tungsten ribbon lamp with tubular bulb. The portion of the tungsten ribbon to be utilized for measurement is mounted parallel to the lamp axis and positioned approx. 8 mm off-axis in the measuring direction.

[1] The color temperature of 2856 K corresponds with light-type A (DIN 5035).
[2] s = vertical (base down); h = vertical (base up)
[3] Only for additional measurement of luminance or color temperature.

FIGURE 18*a* Lamps for scientific purposes.





WI 17/G
Base E 27/51 x 39

WI 16/G:
Tungsten ribbon lamp with spherical bulb. Horizontal tungsten ribbon with a small notch to indicate the measuring point. The ribbon is positioned approx. 3 mm off axis.

WI 17/G:
Tungsten ribbon lamp with horn-shaped bulb. The bulb has a tubular extension with a sealed-on quartz glass window (homogenized ultrasil). Vertical tungsten ribbon with a small notch to indicate the measuring point.

WI 40/G:
Standard lamp for total radiation, luminous flux and color temperatures with conic bulb. The bulb shape prevents reflections in the direction of the plane normal of the luminous area, which is formed by the meandrous-shaped filament.

WI 41/G:
Standard lamp for light intensity and color temperature with conic bulb. Differs from the WI 40/G lamp by a black, opaque coating which covers one side of the bulb. A window is left open in the coating opposite the filament, through which over an angle of approx. ±3° a constant light intensity is emitted. The black coating prevents stray light being reflected in the measuring direction.

Enclosed Arc and Discharge Sources (High-Pressure)

Koller[18] states that the carbon arc is generally desired if a high intensity is required from a single unit but that it is less efficient than the mercury arc. Other disadvantages are the short life of the carbon with respect to mercury, and combustion products which may be undesirable. Worthing[2] describes a number of the older, enclosed, metallic arc sources, many of which can be built in the laboratory for laboratory use. Today, however, it is rarely necessary to build one's own source unless it is highly specialized.

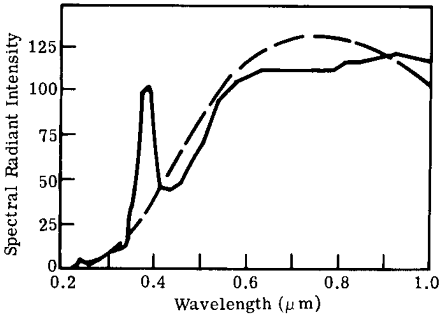

FIGURE 21 Spectral distribution of radiant flux from 30-A, 55-V dc low-intensity arc with 12-mm positive carbon (solid line) and a 3800 K blackbody radiator (broken line).

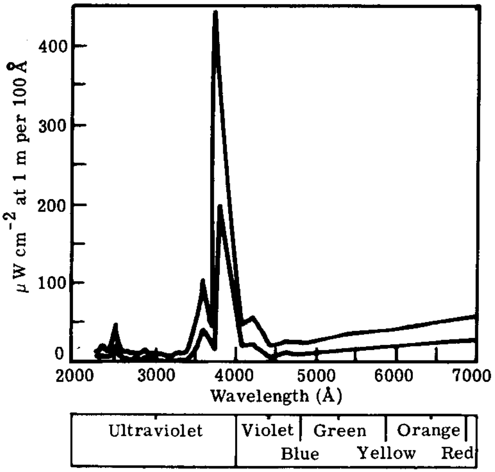

FIGURE 22 Spectral energy distribution of carbon arc with core of soft carbon. Upper curve: 60-A ac 50-V across the arc; lower curve: 30-A ac 50-V across the arc.

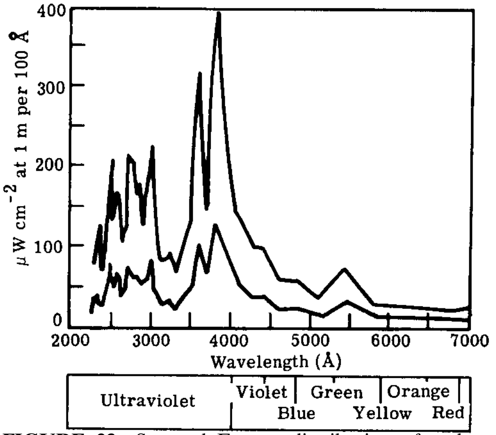

FIGURE 23 Spectral Energy distribution of carbon arc with polymetallic-cored carbons. Upper curve: 60-A ac 50-V across the arc; lower curve: 30-A ac 50-V across the arc.

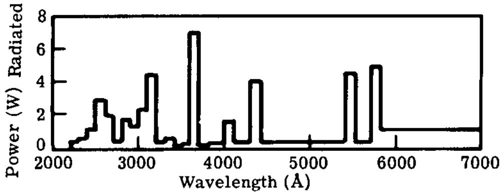

FIGURE 24 Intensity distribution of UA-2 intermediate-pressure lamp.

The Infrared Handbook[1] compiles a large number of these types of sources, some of which will be repeated here, in case that publication would not be currently available to the reader. However, the reader should take caution that many changes might have occurred in the characteristics of these sources and in the supplier whose product is preferred. Consultation with the Photonics Directory (see preceding) is usually a good procedure. In some cases a certain type of source described previously may not still exist. Thus, whereas some manufacturers were less compliant in providing data, they should be expected to respond more readily to a potential customer.

Uviarc.* This lamp is an efficient radiator of ultraviolet radiation. The energy distribution of one type is given in Fig. 24. Since the pressure of this mercury-vapor lamp is intermediate between the usual high- and the low-pressure lamps, little background (or continuum) radiation is present. In the truly high-pressure lamp, considerable continuum radiation results from greater molecular interaction. Figure 25[20] shows the dependence on pressure of the amount of continuum in mercury lamps of differing pressure. Bulb shapes and sizes are shown in Fig. 26.

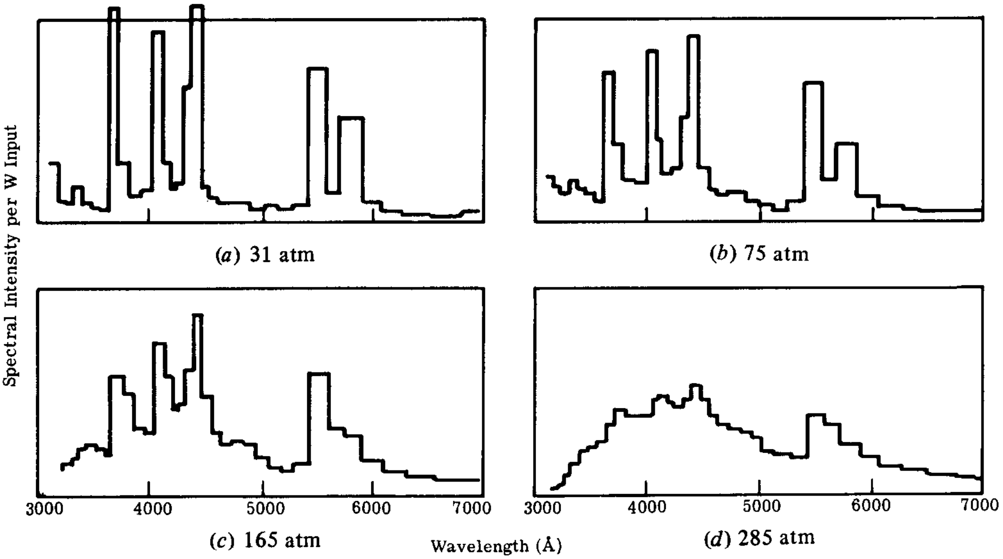

FIGURE 25 Emission spectrum of high-pressure mercury-arc lamps showing continuum background.

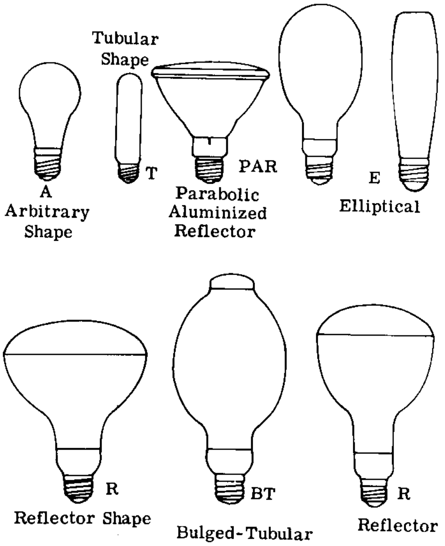

FIGURE 26 Bulb shapes and sizes (not to scale).

Mercury Arcs. A widely used type of high-pressure, mercury-arc lamp and the components necessary for its successful operation are shown in Fig. 27. The coiled tungsten cathode is coated with a rare-earth material (e.g., thorium). The auxiliary electrode is used to help in starting. A high resistance limits the starting current. Once the arc is started, the operating current is limited by ballast supplied by the high reactance of the power transformer. Spectral data for clear, 400 W mercury lamps of this type are given in Fig. 28.

Multivapor Arcs. In these lamps, argon and mercury provide the starting action. Then sodium iodide, thallium iodide, and indium iodide vaporize and dissociate to yield the bulk of the lamp radiation. The physical appearance is like that of mercury lamps of the same general nature. Ballasts are similar to their counterparts for the mercury lamp. Up-to-date

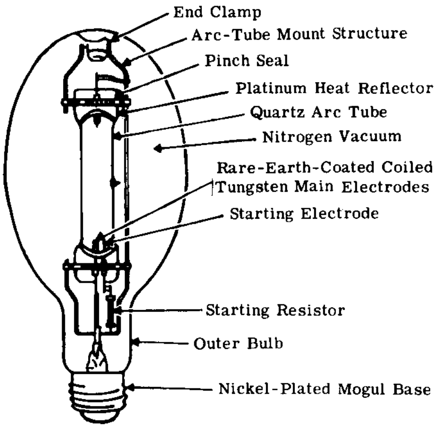

FIGURE 27 High-pressure mercury lamp showing various components.

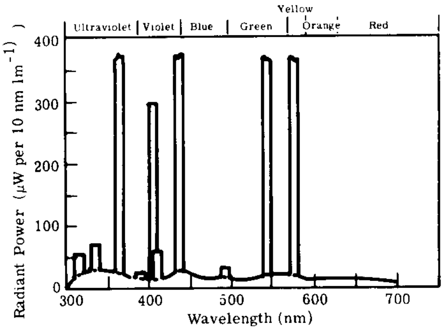

FIGURE 28 Spectral energy distribution for clear mercury-arc lamp.

information on these sources should be obtained from the General Electric Corporation Lamp Division in Nela Park near Cleveland, Ohio. Spectral features of these sources are given in Fig. 29.

Lucalox*®* *Lamps. The chief characteristics of this lamp are high-pressure sodium discharge and a high-temperature withstanding ceramic, Lucalox (translucent aluminum oxide), to yield performance typified in the spectral output of the 400-W Lucalox lamp shown in Fig. 30. Ballasts for this lamp are described in the General Electric *Bulletin TP-109R.*[21]

Capillary Mercury-Arc Lamps.[18] As the pressure of the arc increases, cooling is required to avoid catastrophic effects on the tube. The AH6 tube (Fig. 31) is constructed with a quartz bulb wall and a quartz outer jacket, to allow 2800 K radiation to pass, or a Pyrex®† outer jacket to eliminate ultraviolet. Pure water is forced through at a rapid rate, while the tube is maintained at a potential of 840 V. The spectral characteristics of certain tubes[22] are shown in Fig. 32. This company does not appear in the *Photonics Guide of 1989,* so the catalog referenced in the figure may not be current.

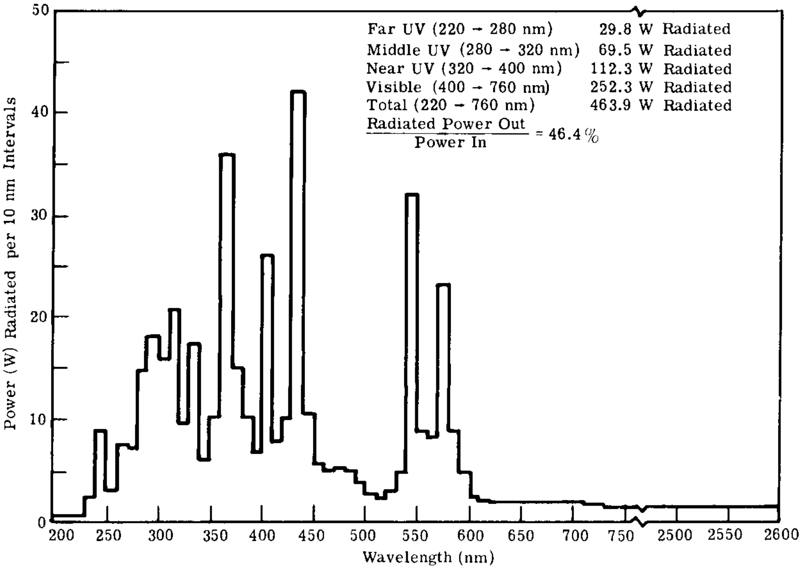

FIGURE 32 Spectral energy distribution of type BH6-1 mercury capillary lamp.

Compact-Source Arcs.[15,23] Some common characteristics of currently available compact-source arc lamps are as follows:

1. A clear quartz bulb of roughly spherical shape with extensions at opposite ends constituting the electrode terminals. In some cases, the quartz bulb is then sealed within a larger glass bulb, which is filled with an inert gas.
2. A pair of electrodes with relatively close spacing (from less than 1 mm to about 1 cm); hence the sometimes-used term short-arc lamps.
3. A filling of gas or vapor through which the arc discharge takes place.
4. Extreme electrical loading of the arc gap, which results in very high luminance, internal pressures of many atmospheres, and bulb temperatures as high as 900°C. Precautions are necessary to protect people and equipment in case the lamps should fail violently.
5. The need for a momentary high-voltage ignition pulse, and a ballast or other auxiliary equipment to limit current during operation.
6. Clean, attention-free operation for long periods of time.

These lamps are designated by the chief radiating gases enclosed as mercury, mercury xenon, and xenon lamps.

Figure 33 shows a compact-source construction for a 1000-W lamp. Since starting may be a problem, some lamps (Fig. 34) are constructed with a third (i.e., a starting) electrode, to

which a momentary high voltage is applied for starting (and especially restarting) while hot. The usual ballast is required for compact-source arcs. For stability, these arcs, particularly mercury and mercury-xenon, should be operated near rated power on a well-regulated power supply.[23]

The spatial distribution of luminance from these lamps is reported in the literature already cited, and typical contours are shown in Fig. 35. Polar distributions are similar to those shown in Fig. 36. Spectral distributions are given in Figs. 37 through 39 for a 1000-W ac mercury lamp, a 5-kW dc xenon lamp, and 1000-W dc mercury-xenon lamp. Lamps are available at considerably less wattage.

Cann[23] reports on some interesting special lamps tested by Jet Propulsion Laboratories for the purpose of obtaining a good spectral match to the solar distribution. The types of lamps tested were: Xe; Xe-Zn; Xe-Cd; Hg-Xe-Zn; Hg-Xe-Cd; Kr; Kr-Zn; Kr-Cd;

Hg-Kr-Zn; Hg-Kr-Cd; Ar; Ne; and Hg-Xe with variable mercury-vapor pressure. For details, the reader should consult the literature.

A special design of a short-arc lamp manufactured by Varian[24] is shown in Fig. 40. Aside from its compactness and parabolic sector, it has a sapphire window which allows a greater amount of IR energy to be emitted. It is operated either dc or pulsed, but the user should obtain complete specifications, because the reflector can become contaminated, with a resultant decrease in output.

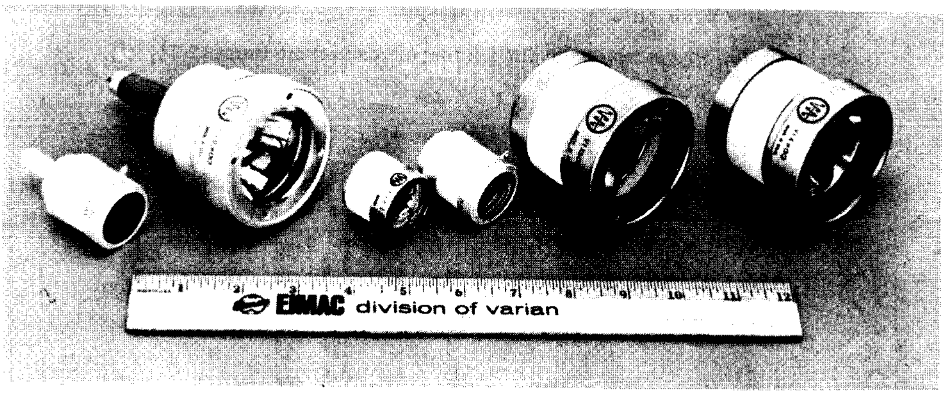

FIGURE 40 High-pressure, short-arc xenon illuminators with sapphire windows. Low starting voltage, 150 through 800 watt; VIX150, VIX300, VIX500, VIX800.

Enclosed Arc and Discharge Sources (Low-Pressure)[18]

With pressure reduction in a tube filled with mercury vapor, the 2537 Å line becomes predominant so that low-pressure mercury tubes are usually selected for their ability to emit ultraviolet radiation.

Germicidal Lamps. These are hot-cathode lamps which operate at relatively low voltages. They differ from ordinary fluorescent lamps which are used in lighting in that they are designed to transmit ultraviolet, whereas the wall of the fluorescent lamp is coated with a material that absorbs ultraviolet and reemits visible light. The germicidal lamp is constructed of glass of 1-mm thickness which transmits about 65 percent of the 2537 Å radiation and virtually cuts off shorter-wavelength ultraviolet radiation.

Sterilamp®* Types. These cold cathode lamps start and operate at higher voltages than the hot-cathode type and can be obtained in relatively small sizes as shown in Fig. 41. Operating characteristics of the Sterilamps should be obtained from the manufacturer.

Black-Light Fluorescent Lamps. This fluorescent lamp is coated with a phosphor efficient in the absorption of 2537 Å radiation, emitting ultraviolet radiation in a broad

band around 3650 Å. The phosphor is a cerium-activated calcium phosphate, and the glass bulb is impervious to shorter wavelength ultraviolet radiation. Characteristics of one type are given in Table 3.

Hollow Cathode Lamps. A device described early in this century and used for many years by spectroscopists is the hollow-cathode tube. The one used by Paschen[2] consisted of a hollow metal cylinder and contained a small quantity of inert gas, yielding an intense cathode-glow characteristic of the cathode constituents. Materials that vaporize easily can be incorporated into the tube so that their spectral characteristics predominate.[2]

Several companies sell hollow-cathode lamps which do not differ significantly from those constructed in early laboratories. The external appearance of these modern tubes shows the marks of mass production and emphasis on convenience. They come with a large number of vaporizable elements, singly or in multiples, and with Pyrex® or quartz windows. A partial list of the characteristics or the lamps available from two manufacturers is given in Table 4. Their physical appearance is shown in Fig. 42*a*. A schematic of the different elements obtainable in various lamps is shown in Fig. 42*b*.[25]

Electrodeless Discharge Lamps.[26,27,28] The electrodeless lamp gained popularity when Meggers used it in his attempt to produce a highly precise standard of radiation. Simplicity of design makes laboratory construction of this type of lamp easy. Some of the simplest lamps consist of a tube, containing the radiation-producing element, and a microwave generator, for producing the electric field (within the tube) which in turn excites the

elemental spectra. Lamps of this type can be purchased with specially designed microwave cavities for greater efficiency in coupling. Those made of fused quartz can transmit from ultraviolet to near infrared. The electrodeless lamp is better able than the arc lamp to produce stable radiation of sharp spectral lines; this makes it useful in spectroscopy and interferometry. The Hg 198 lamp makes a suitable secondary standard of radiation.

Spectral Lamps.[27] Some manufacturers produce groups of arc sources, which are similar in construction and filled with different elements and rare gases, and which yield discontinuous or monochromatic radiation throughout most of the ultraviolet and visible spectrum. They are called spectral lamps. The envelopes of these lamps are constructed of glass or quartz, depending on the part of the spectrum desired. Thus, discrete radiation can be obtained from around 2300 Å into the near infrared. Figure 43[27] represents the various atomic lines observable from Osram spectral lamps. Figure 44[29] gives a physical description of various spectral lamps obtainable from Philips. Table 5 lists the characteristics of the various types of lamps obtainable from Philips.

Pluecker Spectrum Tubes.[30] These are inexpensive tubes made of glass (Fig. 45) with an overall length of 25 cm and capillary portion of 8.5 to 10 cm long. They operate from an ordinary supply with a special transformer which supports the tubes in a vertical position

and maintains the voltage and current values adequate to operate the discharge and regulate the spectral intensity. Table 6 lists the various gases in available tubes.

Concentrated Arc Lamps

Zirconium Arc.[21] The cathodes of these lamps are made of a hollow refractory metal containing zirconium oxide. The anode, a disk of metal with an aperture, resides directly above the cathode with the normal to the aperture coincident with the longitudinal axis of the cathode. Argon gas fills the tube. The arc discharge causes the zirconium to heat (to about 3000 K) and produce an intense, very small source of light. These lamps have been demonstrated in older catalogs from the Cenco Company in a number of wattages (from 2 to 300). The end of the bulk through which the radiation passes comes with ordinary curvature or (for a slight increase in price) flat. Examples are shown in Fig. 46.

Tungsten-Arc (Photomicrographic) Lamp.[21] The essential elements of this discharge type lamp (see Fig. 47) are a ring electrode and a pellet electrode, both made of tungsten. The arc forms between these electrodes, causing the pellet to heat incandescently. The ring also incandesces, but to a lesser extent. Thus, the hot pellet (approximately 3100 K) provides an intense source of small-area radiation. A plot of the spectral variation of this radiation is given in Fig. 48. As with all tungsten sources, evaporation causes a steady

erosion of the pellet surface with the introduction of gradients, which is not serious if the pellet is used as a point source.

General Electric, manufacturer of the 30A/PS22 photomicrographic lamp, which uses a 30 Å operating current, states that this lamp requires a special heavy-duty socket obtainable through certain manufacturers suggested in its brochure, which may now be out of print in the original, but obtainable presumably as a copy from GE.

Glow Modulator Tubes[31]

According to technical data supplied by Sylvania, these are cold-cathode light sources uniquely adaptable to high-frequency modulation. (These tubes are now manufactured by The English Electric Valve Company, Elmsford, New York.) Pictures of two types are shown in Fig. 49. The cathode is a small hollow cylinder, and the high ionization density in the region of the cathode provides an intense source of radiation. Figure 50 is a graph of the light output as a function of tube current. Figure 51 is a graph depicting the response of the tube to a modulating input. The spectral outputs of a variety of tubes are shown in Fig. 52. Table 7 gives some of the glow-modulator specifications.

FIGURE 47 Construction of tungsten arc lamp. The lamp must be operated base-up on a well-ventilated housing and using a special high-current socket which does not distort the position of the posts.

Hydrogen and Deuterium Arcs

For applications requiring a strong continuum in the ultraviolet region, the hydrogen arc at a few millimeters pressure provides a useful source. It can be operated with a cold or hot cathode. One hot-cathode type is shown in Fig. 53. Koller[18] plots a distribution for this lamp down to about 200 Å.

Deuterium lamps (Fig. 54) provide a continuum in the ultraviolet with increased intensity over the hydrogen arc. Both lamps have quartz envelopes. The one on the left is designed for operation down to 2000 Å; the one on the right is provided with a Suprasil®* window to increase the ultraviolet range down to 1650 Å. NIST is offering a deuterium lamp standard of spectral irradiance between 200 and 350 nm. The lamp output at 50 cm from its medium bipost base is about 0.7 W cm^{-3} at 200 nm and drops off smoothly to 0.3 W cm^{-3} at 250 nm and 0.07 W cm^{-3} at 350 nm. A working standard of the deuterium lamp can be obtained also, for example, from Optronic Laboratories, Incorporated, Orlando, Florida.

Other Commercial Sources

Activated-Phosphor Sources. Of particular importance and convenience in the use of photometers are sources composed of a phosphor activated by radioactive substances. Readily available, and not subject to licensing with small quantities of radioactive material, are the $_{14}$C-activated phosphor light sources. These are relatively stable sources of low intensity, losing about 0.02 percent per year due to the half-life of $_{14}$C and the destruction of phosphor centers.

[a] Type R-1166 is opaque-coated with the exception of a circle 3/8 inch in diameter at end of lamp. All other types have clear-finish bulb.
[b] Pins 1 and 3 are anode; pin 2 cathode.
[c] Pin 7 anode; pin 3 cathode.

Other (High-Energy) Sources. Radiation at very high powers can be produced. Sources are synchrotrons, plasmatrons, arcs, sparks, exploding wires, shock tubes, and atomic and molecular beams, to name but a few. Among these, one can purchase in convenient, usable form precisely controlled spark-sources for yielding many joules of energy in a time interval of the order of microseconds. The number of vendors will be few, but check the directories.

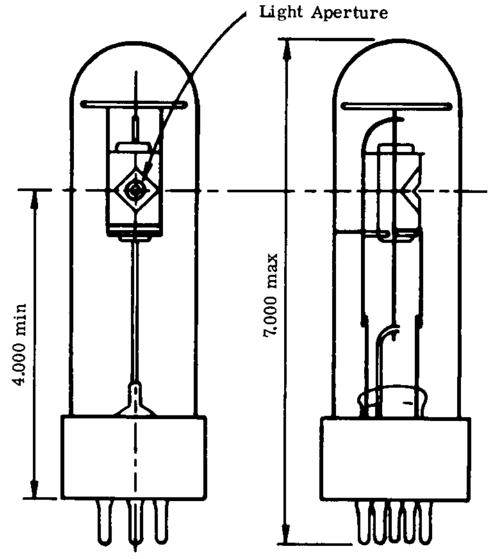

FIGURE 53 Hydrogen arc lamp.

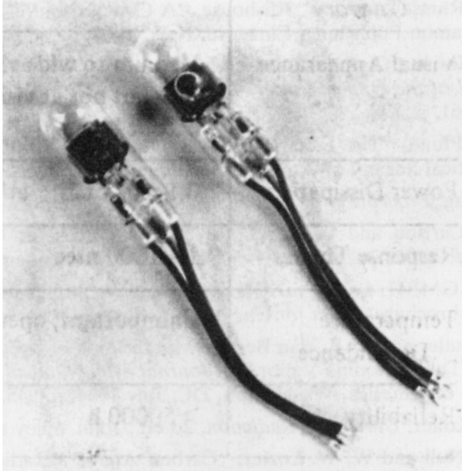

FIGURE 54 Two types of deuterium arc lamps.

Other Special Sources. An enormous number of special-purpose sources are obtainable from manufacturers and scientific instrument suppliers. One source that remains to be mentioned is the so-called miniature, sub-, and microminiature lamps. These are small, even tiny, incandescent bulbs of glass or quartz, containing tungsten filaments. They serve excellently in certain applications where small, intense radiators of visible and near-infrared radiation are needed. Second-source vendors advertise in the trade magazines.

CHAPTER 11
LASERS

William T. Silfvast
Center for Research and Education in Optics and Lasers (CREOL)
University of Central Florida
Orlando, Florida

11.1 GLOSSARY

A_2 radiative transition probability from level 2 to all other possible lower-lying levels

A_{21} radiative transition probability from level 2 to level 1

a_L scattering losses within a laser cavity for a single pass through the cavity

B_{12} Einstein B coefficient associated with absorption

B_{21} Einstein B coefficient associated with stimulated emission

E_1, E_2 energies of levels 1 and 2 above the ground state energy for that species

g_1, g_2 stability parameters for laser modes when describing the laser optical cavity

g_1, g_2 statistical weights of energy levels 1 and 2 that indicate the degeneracy of the levels

g_{21} gain coefficient for amplification of radiation within a medium at a wavelength of λ_{21}

I_{sat} saturation intensity of a beam in a medium; intensity at which exponential growth will cease to occur even though the medium has uniform gain (energy/time-area)

N_1, N_2 population densities (number of species per unit volume) in energy levels 1 and 2

r_c radius of curvature of the expanding wavefront of a gaussian beam

R_1, R_2 reflectivities of mirrors 1 and 2 at the desired wavelength

T_1 lifetime of a level when dominated by collisional decay

T_2 average time between phase-interrupting collisions of a species in a specific excited state

t_{opt} optimum mirror transmission for a laser of a given gain and loss

$w(z)$ beam waist at a distance z from the minimum beam waist for a gaussian beam

w_o minimum beam waist radius for a gaussian mode

α_{12} absorption coefficient for absorption of radiation within a medium at wavelength λ_{21}

γ_{21} angular frequency bandwidth of an emission or absorption line

Δt_p pulse duration of a mode-locked laser pulse

$\Delta\nu$ frequency bandwidth over which emission, absorption, or amplification can occur

$\Delta\nu_D$ frequency bandwidth (FWHM) when the dominant broadening process is Doppler or motional broadening

η index of refraction of the laser medium at the desired wavelength

λ_{21} wavelength of a radiative transition occurring between energy levels 2 and 1

ν_{21} frequency of a radiative transition occurring between energy levels 2 and 1

σ_{21} stimulated emission cross section (area)

σ_{21}^D stimulated emission cross section at line center when Doppler broadening dominates (area)

σ_{21}^H stimulated emission cross section at line center when homogeneous broadening dominates (area)

τ_2 lifetime of energy level 2

τ_{21} lifetime of energy level 2 if it can only decay to level 1

11.2 INTRODUCTION

A laser is a device that amplifies light and produces a highly directional, high-intensity beam that typically has a very pure frequency or wavelength. It comes in sizes ranging from approximately one-tenth the diameter of a human hair to the size of a very large building, in powers ranging from 10^{-9} to 10^{20} watts, and in wavelengths ranging from the microwave to the soft-x-ray spectral regions with corresponding frequencies from 10^{11} to 10^{17} Hz. Lasers have pulse energies as high as 10^4 joules and pulse durations as short as 6×10^{-15} seconds. They can easily drill holes in the most durable of materials and can weld detached retinas within the human eye.

Lasers are a key component of some of our most modern communication systems and are the ‘‘phonograph needle’’ of compact disc players. They are used for heat treatment of high-strength materials, such as the pistons of automobile engines, and provide a special surgical knife for many types of medical procedures. They act as target designators for military weapons and are used in the checkout scanners we see everyday at the supermarket.

The word *laser* is an acronym for *L*ight *A*mplification by *S*timulated *E*mission of *R*adiation. The laser makes use of processes that increase or amplify light signals after those signals have been generated by other means. These processes include (1) stimulated emission, a natural effect that arises out of considerations relating to thermodynamic

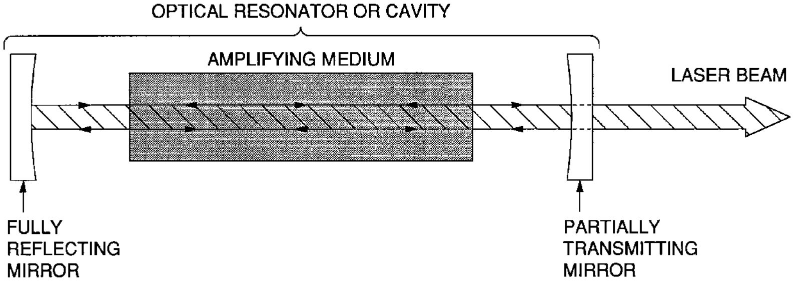

FIGURE 1 Simplified diagram of a laser, including the amplifying medium and the optical resonator.

equilibrium, and (2) optical feedback (present in most lasers) that is usually provided by mirrors. Thus, in its simplest form, a laser consists of a gain or amplifying medium (where stimulated emission occurs) and a set of mirrors to feed the light back into the amplifier for continued growth of the developing beam (Fig. 1).

The entire spectrum of electromagnetic radiation is shown in Fig. 2, along with the region covered by currently existing lasers. Such lasers span the wavelength range from the far infrared part of the spectrum ($\lambda = 1000\ \mu\text{m}$) to the soft-x-ray region ($\lambda = 3\ \text{nm}$), thereby covering a range of almost six orders of magnitude! There are several types of units that are used to define laser wavelengths. These range from micrometers (μm) in the infrared to nanometers (nm) and angstroms (Å) in the visible, ultraviolet (UV), vacuum ultraviolet (VUV), extreme ultraviolet (EUV or XUV), and soft-x-ray (SXR) spectral regions.

This chapter provides a brief overview of how a laser operates. It considers a laser as having two primary components: (1) a region where light amplification occurs which is referred to as a *gain medium* or an *amplifier,* and (2) a *cavity,* which generally consists of two mirrors placed at either end of the amplifier.

Properties of the amplifier include the concept of discrete excited energy levels and their associated finite lifetimes. The broadening of these energy levels will be associated with the emission linewidth which is related to decay of the population in these levels.

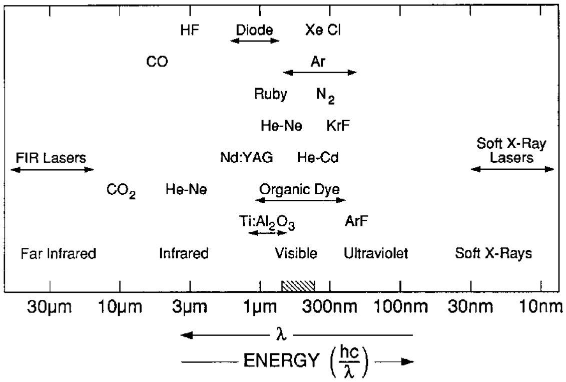

FIGURE 2 The portion of the electromagnetic spectrum that involves lasers, along with the general wavelengths of operation of most of the common lasers.

Stimulated emission will be described, and the formulas for calculating the amount of gain that can occur via stimulated emission will be given in terms of the radiative properties of the medium. The concept of the saturation intensity will be introduced and related to the amount of gain that is necessary for laser output. The addition of mirrors at the ends of the amplifier will be used to increase the gain length and to reduce the divergence of the amplified beam. The threshold conditions for laser output will be described in terms of the amplifier properties and the mirror reflectivities. This section will conclude with a review of excitation or pumping processes that are used to produce the necessary population density in the upper laser level.

Cavity properties will begin with a discussion of both longitudinal and transverse cavity modes which provide the laser beam with a gaussian-shaped transverse profile. The properties of those gaussian beams will be reviewed. The types of optical cavities that allow stable operation of laser modes will then be described. A number of special types of laser cavity arrangements and techniques will be reviewed, including unstable resonators, Q-switching, mode-locking, and ring lasers. A brief review will then be given of the various common types of gaseous, liquid, and solid-state lasers.

Additional information related to spectral lineshape and the mechanisms of spectral broadening can be found in Chap. 8 (Vol. I), ''Optical Spectroscopy and Spectroscopic Lineshapes.'' Other related material can be found in Chap. 9 (Vol. I), ''Fundamental Optical Properties of Solids,'' and Chap. 23 (Vol. II) ''Holography and Holographic Instruments.'' As lasers are widely used in many of the devices and techniques discussed in other chapters in this *Handbook,* the reader is directed to those topics for information on specific lasers.

11.3 LASER PROPERTIES ASSOCIATED WITH THE LASER GAIN MEDIUM

Energy Levels and Radiation[1,2]

Nearly all lasers involve electronic charge distributions of atoms, molecules, organic dye solutions, or solids that make transitions from one energy state or level E_2 to another lower-lying level E_1. The loss of energy resulting from this transition is given off in the form of electromagnetic radiation. The relationship between the energy difference between the levels, $E_2 - E_1$ or ΔE_{21}, and the frequency ν_{21} of radiation occurring as a result of the transition, is determined by the Einstein relationship $E_{21} = h\nu_{21}$ where h is Planck's constant. It was first shown by Bohr in 1913 that the discrete set of emission wavelengths from a hydrogen discharge could be explained by the occurrence of discrete energy levels in the hydrogen atom that have a fixed relationship. This discrete arrangement of energy levels was later shown to occur in other atoms, in molecules, and also in liquids and solids. In atoms these energy levels are very precisely defined and narrow in width ($\approx 10^9$ Hz) and can be accurately calculated with sophisticated atomic physics codes. In molecules and high-density materials the locations of the levels are more difficult to calculate and they tend to be much broader in width, the largest widths occurring in liquids and solids (up to 5×10^{13} Hz).

The lowest energy level of a species is referred to as the *ground state* and is usually the most stable state of the species. There are some exceptions to this, for example, ground states of ionized species or unstable ground states of some molecular species such as excimer molecules. Energy levels above the ground state are inherently unstable and have lifetimes that are precisely determined by the arrangement of the atoms and electrons associated with any particular level as well as to the particular species or material. Thus, when an excited state is produced by applying energy to the system, that state will eventually decay by emitting radiation over a time period ranging from 10^{-15} seconds or less to times as long as seconds or more, depending upon the particular state or level involved. For *strongly allowed* transitions that involve the electron charge cloud changing from an atomic energy level of energy E_2 to a lower-lying level of energy E_1, the radiative decay time τ_{21} can be approximated by $\tau_{21} \approx 10^4 \lambda_{21}^2$ where τ_{21} is in seconds and λ_{21} is the wavelength of the emitted radiation in meters. λ_{21} is related to ν_{21} by the relationship $\lambda_{21}\nu_{21} = c/\eta$ where c is the velocity of light (3×10^8 m/sec) and η is the index of refraction of the material. For most gases, η is near unity and for solids and liquids it ranges between 1 and 10, with most values ranging from ≈1.3–2.0.

Using the expression suggested above for the approximate value of the lifetime of an excited energy level, one obtains a decay time of several nsec for green light ($\lambda_{21} = 5 \times 10^{-7}$ m). This represents a minimum radiative lifetime since most excited energy levels have a weaker radiative decay probability than mentioned above and would therefore have radiative lifetimes one or two orders of magnitude longer. Other laser materials such as molecules, organic dye solutions, and semiconductor lasers have similar radiative lifetimes. The one exception is the class of dielectric solid-state laser materials (both crystalline and glass) such as ruby and Nd:YAG, in which the lifetimes are of the order of 1–300 μsec. This much longer radiative lifetime in solid-state laser materials is due to the nature of the particular state of the laser species and to the crystal matrix in which it is contained. This is a very desirable property for a laser medium since it allows excitation and energy storage within the laser medium over a relatively long period of time.

Emission Linewidth and Line Broadening of Radiating Species[1,3]

Assume that population in energy level 2 decays to energy level 1 with an exponential decay time of τ_{21} and emits radiation at frequency ν_{21} during that decay. It can be shown by Fourier analysis that the exponential decay of that radiation requires the frequency width of the emission to be of the order of $\Delta\nu \cong 1/2\pi\tau_{21}$. This suggests that the energy width ΔE_2 of level 2 is of the order of $\Delta E_2 = h/2\pi\tau_{21}$. If the energy level 2 can decay to more levels than level 1, with a corresponding decay time of τ_2, then its energy is broadened by an amount $\Delta E_2 = h/2\pi\tau_2$. If the decay is due primarily to radiation at a rate A_{2i} to one or more individual lower-lying levels i, then $1/\tau_2 = A_2 = \sum_i A_{2i}$. A_2 represents the total radiative decay rate of level 2, whereas A_{2i} is the specific radiative decay rate from level 2 to a lower-lying level i.

If population in level 2 decays radiatively at a radiative rate A_2 and population in level 1 decays radiatively at a rate A_1, then the emission linewidth of radiation from level 2 to 1 is given by

$$\Delta\nu_{21} = \frac{\sum_i A_{2i} + \sum_j A_{1j}}{2\pi} \tag{1}$$

which is referred to as the *natural linewidth* of the transition and represents the sum of the widths of levels 2 and 1 in frequency units. If, in the above example, level 1 is a ground state with infinite lifetime or a long-lived metastable level, then the natural linewidth of the emission from level 2 to level 1 would be represented by

$$\Delta\nu_{21} = \frac{\sum_i A_{2i}}{2\pi} \tag{2}$$

since the ground state would have an infinite lifetime and would therefore not contribute to the broadening. This type of linewidth or broadening is known as *natural broadening* since it results specifically from the radiative decay of a species. Thus the natural linewidth associated with a specific transition between two levels has an inherent value determined only by the factors associated with specific atomic and electronic characteristics of those levels.

The emission-line broadening or natural broadening described above is the minimum line broadening that can occur for a specific radiative transition. There are a number of mechanisms that can increase the emission linewidth. These include collisional broadening, phase-interruption broadening, Doppler broadening, and isotope broadening. The first two of these, along with natural broadening, are all referred to as *homogeneous broadening.* Homogeneous broadening is a type of emission broadening in which all of the atoms radiating from the specific level under consideration participate in the same way. In other words, all of the atoms have the identical opportunity to radiate with equal probability.

The type of broadening associated with either Doppler or isotope broadening is referred to as *inhomogeneous broadening.* For this type of broadening, only certain atoms radiating from that level that have a specific property such as a specific velocity, or are of a specific isotope, participate in radiation at a certain frequency within the emission bandwidth.

Collisional broadening is a type of broadening that is produced when surrounding atoms, molecules, solvents (in the case of dye lasers), or crystal structures interact with the radiating level and cause the population to decay before it has a chance to decay by its normal radiative processes. The emission broadening is then associated with the faster decay time T_1, or $\Delta\nu = 1/2\pi T_1$.

Phase-interruption broadening or *phonon broadening* is a type of broadening that does not increase the decay rate of the level, but it does interrupt the phase of the rotating electron cloud on average over a time interval T_2 which is much shorter than the radiative decay time τ_2 which includes all possible radiative decay channels from level 2. The result of this phase interruption is to increase the emission linewidth beyond that of both natural broadening and T_1 broadening (if it exists) to an amount $\Delta\nu = 1/2\pi T_2$.

Doppler broadening is a type of inhomogeneous broadening in which the Doppler effect shifts the frequencies of atoms moving toward the observer to a higher value and the frequencies of atoms moving away from the observer to a lower value. This effect occurs only in gases since they are the only species that are moving fast enough to produce such broadening. Doppler broadening is the dominant broadening process in most visible gas lasers. The expression for the Doppler linewidth (FWHM) is given by

$$\Delta\nu_D = 7.16 \cdot 10^{-7} \nu_o \sqrt{\frac{T}{M}} \tag{3}$$

in which ν_o is the center frequency associated with atoms that are not moving either toward or away from the observer, T is the gas temperature in kelvin and M is the atomic or molecular weight (number of nucleons/atom or molecule) of the gas atoms or molecules.

Isotope broadening also occurs in some gas lasers. It becomes the dominant broadening process if the specific gas consists of several isotopes of the species and if the isotope shifts for the specific radiative transition are broader than the Doppler width of the transition. The helium-cadmium laser is dominated more by this effect than any other laser since the naturally occurring cadmium isotopic mixture contains eight different isotopes and the isotope shift between adjacent isotopes (adjacent neutron numbers) is approximately equal to the Doppler width of the individual radiating isotopes. This broadening effect can be eliminated by the use of isotopically pure individual isotopes, but the cost for such isotopes is often prohibitive.

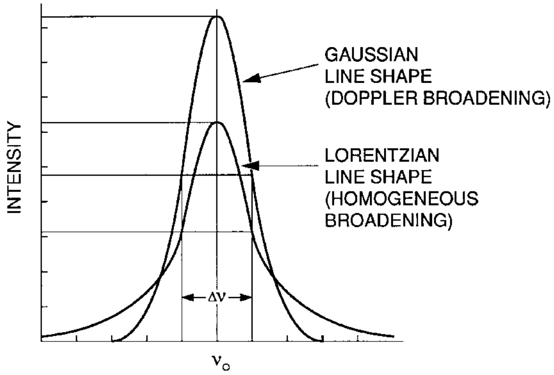

FIGURE 3 Lineshape functions for both homogeneous broadening, with a lorentzian shape, and Doppler broadening (inhomogeneous), with a gaussian shape. Both lines are arranged with equal linewidths (FWHM) and equal total intensities.

All homogeneous broadening processes have a frequency distribution that is described by a lorentzian mathematical function

$$I_{21}(\nu) = I_o \frac{\gamma_{21}/4\pi^2}{(\nu - \nu_0)^2 + (\gamma_{21}/4\pi)^2} \tag{4}$$

in which γ_{21} represents the decay rate of level 2, I_o is the total emission intensity of the transition over the entire linewidth, and ν_o is the center frequency of the emission line. In Eq. (4), γ_{21} is determined by the relationship $\gamma_{21} = 2\pi\Delta\nu_{21}$. For natural broadening, $\Delta\nu_{21}$ is given by either Eq. (1) or Eq. (2), whichever is applicable. For T_1 dominated broadening, $\Delta\nu_{21} = 1/2\pi T_1$, and for T_2 dominated broadening, $\gamma_{21} = 1/2\pi T_2$.

The frequency distribution for Doppler broadening is described by a gaussian function

$$I(\nu) = \frac{2(\ln 2)^{1/2}}{\pi^{1/2}\,\Delta\nu_D} I_o \exp - \left[\frac{4 \ln 2(\nu - \nu_o)^2}{\Delta\nu_D^2}\right] \tag{5}$$

Both of these lineshape functions are indicated in Fig. 3. In this figure, both the total emission intensity integrated over all frequencies and the emission linewidth (full width at half maximum or FWHM) for both functions are identical.

Isotope broadening involves the superposition of a series of either lorentzian shapes or gaussian shapes for each isotope of the species, separated by the frequencies associated with the isotope shifts of that particular transition.

Table 1 gives examples of the dominant broadening process and the value of the broadening for most of the common commercial lasers.

Stimulated Radiative Processes—Absorption and Emission[1,2]

Two types of stimulated radiative processes, absorption and stimulated emission, occur between energy levels 1 and 2 of a gain medium when light of frequency ν_{21} corresponding to an energy difference $\Delta E_{21} = (E_2 - E_1) = h\nu_{21}$ passes through the medium. These processes are proportional to the light intensity I as indicated in Fig. 4 for a two-level system as well as to the stimulated absorption and emission coefficients B_{12} and B_{21},

TABLE 1 Amplifier Parameters for a Wide Range of Lasers

Type of Laser	λ_{21}(nm)	τ_2(sec)	$\Delta\nu_{21}$(Hz)	$\Delta\lambda_{21}$(nm)	σ_{21}(m^2)	ΔN_{21}(m^{-3})	L(m)	g_{21}(m^{-1})
Helium-Neon	632.8	3x10^{-7}	2x10^{9}	2.7x10^{-3}	3x10^{-17}	5x10^{15}	0.2	0.15
Argon	488.0	1x10^{-8}	2x10^{9}	1.6x10^{-3}	5x10^{-16}	1x10^{15}	0.2-1.0	0.5
He-Cadmium	441.6	7x10^{-7}	2x10^{9}	1.3x10^{-3}	8x10^{-18}	4x10^{16}	0.2-1.0	0.3
Copper Vapor	510.5	5x10^{-7}	2x10^{9}	1.3x10^{-3}	8x10^{-18}	6x10^{17}	1.0-2.0	5
CO_2	10,600	4	6x10^{7}	2.2x10^{-2}	1.6x10^{-20}	5x10^{19}	0.2-2.0	0.8
Excimer	248.0	9x10^{-9}	1x10^{13}	2	2.6x10^{-20}	1x10^{20}	0.5-1.0	2.6
Dye (Rh6G)	577.0	5x10^{-9}	5x10^{13}	60	1.2x10^{-20}	2x10^{22}	0.01	240
Semiconductor	800	1x10^{-9}	1x10^{13}	20	1x10^{-19}	10^{24}	0.00025	100,000
Nd:YAG	1064.1	2.3x10^{-4}	1.2x10^{11}	0.4	6.5x10^{-23}	1.6x10^{23}	0.1	10
Nd:Glass	1054	3.0x10^{-4}	7.5x10^{12}	26	4.0x10^{-24}	8x10^{23}	0.1	3
Cr:LiSAF	840	6.7x10^{-5}	9.0x10^{13}	250	5.0x10^{-24}	2x10^{24}	0.1	10
$Ti:Al_2O_3$	760	3.2x10^{-6}	1.5x10^{14}	400	4.1x10^{-23}	5x10^{23}	0.1	20

respectively. These coefficients are related to the frequency ν_{21} and the spontaneous emission probability A_{21} associated with the two levels. A_{21} has units of (1/sec).

Absorption results in the loss of light of intensity I when the light interacts with the medium. The energy is transferred from the beam to the medium by raising population from level 1 to the higher-energy level 2. In this situation, the species within the medium can either reradiate the energy and return to its initial level 1, it can reradiate a different energy and decay to a different level, or it can lose the energy to the surrounding medium via collisions, which results in the heating of the medium, and return to the lower level. The absorption probability is proportional to the intensity I which has units of energy/sec-m^2 times B_{12}, which is the absorption probability coefficient for that transition. B_{12} is one of the Einstein B coefficients and has the units of m^3/energy-sec^2.

Stimulated emission results in the increase in the light intensity I when light of the appropriate frequency ν_{21} interacts with population occupying level 2 of the gain medium. The energy is given up by the species to the radiation field. In the case of stimulated

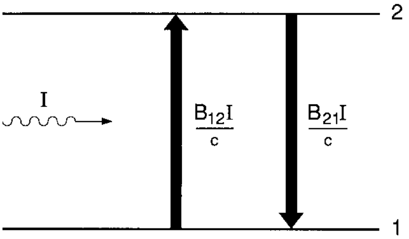

FIGURE 4 Stimulated emission and absorption processes that can occur between two energy levels, 1 and 2, and can significantly alter the population densities of the levels compared to when a beam of intensity I is not present.

emission, the emitted photons or bundles of light have exactly the same frequency ν_{21} and direction as the incident photons of intensity I that produce the stimulation. B_{21} is the associated stimulated emission coefficient and has the same units as B_{12}. It is known as the other Einstein B coefficient.

Einstein showed the relationship between B_{12}, B_{21}, and A_{21} as

$$g_2 B_{21} = g_1 B_{12} \tag{6}$$

and

$$A_{21} = \frac{8\pi h \nu_{21}^3}{c^3} B_{21} \tag{7}$$

where g_2 and g_1 are the statistical weights of levels 2 and 1 and h is Planck's constant. Since $A_{21} = 1/\tau_{21}$ for the case where radiative decay dominates and where there is only one decay path from level 2, B_{21} can be determined from lifetime measurements or from absorption measurements on the transition at frequency ν_{21}.

Population Inversions[1,2]

The two processes of absorption and stimulated emission are the principal interactions involved in a laser amplifier. Assume that a collection of atoms of a particular species is energized to populate two excited states 1 and 2 with population densities N_1 and N_2 (number of species/m^3) and state 2 is at a higher energy than state 1 by an amount ΔE_{21} as described in the previous section. If a photon beam of energy ΔE_{21}, with an intensity I_o and a corresponding wavelength $\lambda_{21} = c/\nu_{21} = hc/\Delta E_{21}$, passes through this collection of atoms, then the intensity I after the beam emerges from the medium can be expressed as

$$I = I_o e^{\sigma_{21}(N_2 - (g_2/g_1)N_1)L} = I_o e^{\sigma_{21}\Delta N_{21} L} \tag{8}$$

where σ_{21} is referred to as the *stimulated emission cross section* with dimensions of m^2, L is the thickness of the medium (in meters) through which the beam passes, and $N_2 - (g_2/g_1)N_1 = \Delta N_{21}$ is known as the *population inversion density*. The exponents in Eq. (8) are dimensionless quantities than can be either greater or less than unity, depending upon whether N_2 is greater than or less than $(g_2/g_1)N_1$.

The general form of the stimulated emission cross section per unit frequency is given as

$$\sigma_{21} = \frac{\lambda_{21}^2 A_{21}}{8\pi\, \Delta\nu} \tag{9}$$

in which $\Delta\nu$ represents the linewidth over which the stimulated emission or absorption occurs.

For the case of homogeneous broadening, at the *center* of the emission line, σ_{21} is expressed as

$$\sigma_{21}^H = \frac{\lambda_{21}^2 A_{21}}{4\pi^2\, \Delta\nu_{21}^H} \tag{10}$$

where $\Delta\nu_{21}^H$ is the homogeneous emission linewidth (FWHM) which was described earlier for several different situations.

For the case of Doppler broadening, σ_{21}^{D} can be expressed as

$$\sigma_{21}^{D}=\sqrt{\frac{\ln 2}{16\pi^{3}}}\frac{\lambda_{21}^{2}A_{21}}{\Delta\nu_{21}^{D}} \tag{11}$$

at the *center* of the emission line and $\Delta\nu_{21}^{D}$ is the Doppler emission linewidth expressed earlier in Eq. (3).

For all types of matter, the population density ratio of levels 1 and 2 would normally be such that $N_2 \ll N_1$. This can be shown by the Boltzmann relationship for the population ratio in thermal equilibrium which provides the ratio of N_2/N_1 to be

$$\frac{N_2}{N_1}=\frac{g_2}{g_1}e^{-\Delta E_{21}/kT} \tag{12}$$

in which T is the temperature and k is Boltzmann's constant. Thus, for energy levels separated by energies corresponding to visible transitions, in a medium at or near room temperature, the ratio of $N_2/N_1 \cong e^{-100} = 10^{-44}$. For most situations in everyday life we can ignore the population N_2 in the upper level and rewrite Eq. (8) as

$$I = I_o e^{-\sigma_{12}N_1L} = I_o e^{-\alpha_{12}L} \tag{13}$$

where $\sigma_{21}=(g_2/g_1)\sigma_{12}$ and $\alpha_{12}=\sigma_{12}N_1$. Equation (13) is known as Beer's law, which is used to describe the absorption of light within a medium. α_{12} is referred to as the absorption coefficient with units of m^{-1}.

In laser amplifiers we cannot ignore the population in level 2. In fact, the condition for amplification and laser action is

$$N_2-(g_2/g_1)N_1>0 \qquad \text{or} \qquad g_1N_2/g_2N_1>1 \tag{14}$$

since, if Eq. (14) is satisfied, the exponent of Eq. (8) will be greater than 1 and I will emerge from the medium with a greater value than I_o, or amplification will occur. The condition of Eq. (14) is a necessary condition for laser amplification and is known as a population inversion since N_2 is greater than $(g_2/g_1)N_1$. In most cases, (g_2/g_1) is either unity or close to unity.

Considering that the ratio of g_1N_2/g_2N_1 [Eq. (14)] could be greater than unity does not follow from normal thermodynamic equilibrium considerations [Eq. (12)] since it would represent a population ratio that could never exist in thermal equilibrium. When Eq. (14) is satisfied and amplification of the beam occurs, the medium is said to have *gain* or *amplification.* The factor $\sigma_{21}(N_2-(g_2/g_1)N_1)$ or $\sigma_{21}\,\Delta N_{21}$ is often referred to as the *gain coefficient* g_{21} and is given in units of m^{-1} such that $g_{21}=\sigma_{21}\,\Delta N_{21}$. Typical values of σ_{21}, ΔN_{21}, and g_{21} are given in Table 1 for a variety of lasers. The term g_{21} is also referred to as the *small-signal gain coefficient* since it is the gain coefficient determined when the laser beam intensity within the laser gain medium is small enough that stimulated emission does not significantly alter the populations in the laser levels.

Gain Saturation[2]

It was stated in the previous section that Eq. (14) is a necessary condition for making a laser but it is not a sufficient condition. For example, a medium might satisfy Eq. (14) by having a gain of $e^{g_{21}L} \approx 10^{-10}$, but this would not be sufficient to allow any reasonable beam to develop. Lasers generally start by having a pumping process that produces enough population in level 2 to create a population inversion with respect to level 1. As the population decays from level 2, radiation occurs spontaneously on the transition from level 2 to level 1 equally in all directions within the gain medium. In most of the directions very little gain or enhancement of the spontaneous emission occurs, since the length is not sufficient to cause significant growth according to Eq. (8). It is only in the elongated direction of the amplifier, with a much greater length, that significant gain exists and, consequently, the spontaneous emission is significantly enhanced. The requirement for a laser beam to develop in the elongated direction is that the exponent of Eq. (8) be large enough for the beam to grow to the point where it begins to significantly reduce the population in level 2 by stimulated emission. The beam will eventually grow, according to Eq. (8), to an intensity such that the stimulated emission rate is equal to the spontaneous emission rate. At that point the beam is said to reach its saturation intensity I_{sat}, which is given by

$$I_{\text{sat}} = \frac{h\nu_{21}}{\sigma_{21}^{H}\tau_{21}} \tag{15}$$

The saturation intensity is that value at which the beam can no longer grow exponentially according to Eq. (8) because there are no longer enough atoms in level 2 to provide the additional gain. When the beam grows above I_{sat} it begins to extract significant energy since at this point the stimulated emission rate exceeds the spontaneous emission rate for that transition. The beam essentially takes energy that would normally be radiated in all directions spontaneously and redirects it via stimulated emission, thereby increasing the beam intensity.

Threshold Conditions with No Mirrors

I_{sat} can be achieved by having any combination of values of the three parameters σ_{21}^{H}, ΔN_{21}, and L large enough that their product provides sufficient gain. It turns out that the requirement to reach I_{sat} can be given by making the exponent of Eq. (8) have the following range of values:

$$\sigma_{21}^{H}\Delta N_{21}L \approx 10-20 \qquad \text{or} \qquad g_{21}^{H}L \approx 10-20 \tag{16}$$

where the specific value between 10 and 20 is determined by the geometry of the laser cavity. Equation (16) suggests that the beam grows to a value of $I/I_o = e^{10-20} = 2\times10^{4}$ -5×10^{8}, which is a very large amplification.

Threshold Conditions with Mirrors

One could conceivably make L sufficiently long to always satisfy Eq. (16), but this is not practical. Some lasers can reach the saturation intensity over a length L of a few centimeters, but most require much longer lengths. Since one cannot readily extend the lasing medium to be long enough to achieve I_{sat}, the same result is obtained by putting mirrors around the gain medium. This effectively increases the path length by having the beam pass many times through the amplifier.

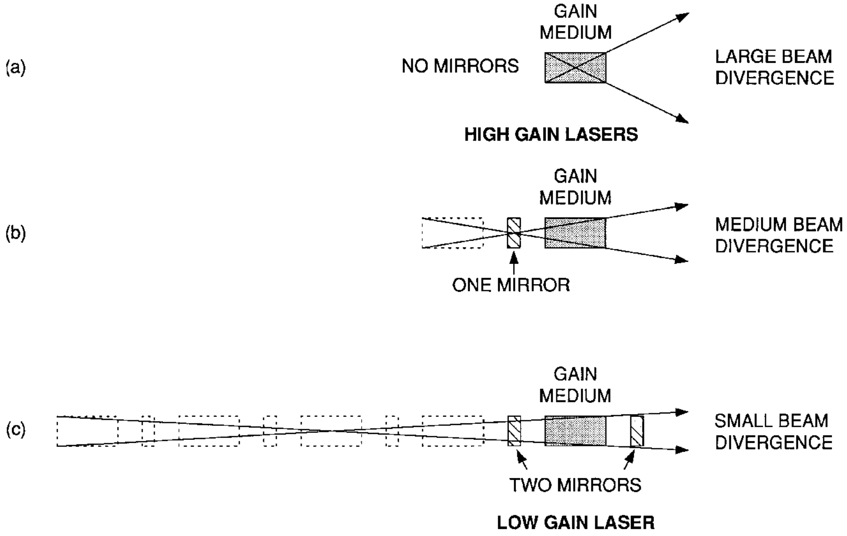

FIGURE 5 Laser-beam divergence for amplifier configurations having high gain and (*a*) no mirrors or (*b*) one mirror, and high or low gain and (*c*) two mirrors.

A simple understanding of how the mirrors affect the beam is shown in Fig. 5. The diagram effectively shows how multiple passes through the amplifier can be considered for the situation where flat mirrors are used at the ends of the amplifier. The dashed outlines that are the same size as the gain media represent the images of those gain media produced by their reflections in the mirrors. It can be seen that as the beam makes multiple passes, its divergence narrows up significantly in addition to the large increase in intensity that occurs due to amplification. For high-gain lasers, such as excimer or organic dye lasers, the beam only need pass through the amplifier a few times to reach saturation. For low-gain lasers, such as the helium-neon laser, it might take 500 passes through the amplifier in order to reach I_{sat}.

The laser beam that emerges from the laser is usually coupled out of the amplifier by having a partially transmitting mirror at one end of the amplifier which typically reflects most of the beam back into the medium for more growth. To ensure that the beam develops, the transmission of the output coupling mirror (as it is usually referred to) must be lower than the gain incurred by the beam during a round-trip pass through the amplifier. If the transmission is higher than the round-trip gain, the beam undergoes no net amplification. It simply never develops. Thus a relationship that describes the threshold for laser oscillation balances the laser gain with the cavity losses. In the most simplified form, those losses are due to the mirrors having a reflectivity less than unity. Thus, for a round-trip pass through the laser cavity, the threshold for inversion can be expressed as

$$R_1 R_2 e^{\sigma_{21}\Delta N_{21}2L} > 1 \qquad \text{or} \qquad R_1 R_2 e^{g_{21}2L} > 1 \tag{17a}$$

which is a similar requirement to that of Eq. (16) since it defines the minimum gain requirements for a laser.

A more general version of Eq. (17*a*) can be expressed as

$$R_1 R_2 (1 - a_L)^2 e^{(\sigma_{21}\Delta N_{21} - \alpha)2L} = 1 \qquad \text{or} \qquad R_1 R_2 (1 - a_L)^2 e^{(g_{21} - \alpha)2L} = 1 \tag{17b}$$

in which we have included a distributed absorption α throughout the length of the gain medium at the laser wavelength, as well as the total scattering losses a_L per pass through the cavity (excluding the gain medium and the mirror surfaces). The absorption loss α is essentially a separate absorbing transition within the gain medium that could be a separate molecule as in an excimer laser, absorption from either the ground state or from the triplet state in a dye laser, or absorption from the ground state in the broadband tunable solid-state lasers and in semiconductor lasers or from the upper laser state in most solid-state lasers. The scattering losses a_L, per pass, would include scattering at the windows of the gain medium, such as Brewster angle windows, or scattering losses from other elements that are inserted within the cavity. These are typically of the order of one or two percent or less.

Laser Operation Above Threshold

Significant power output is achieved by operating the laser at a gain greater than the threshold value defined above in Eqs. (16) and (17). For such a situation, the higher gain that would normally be produced by increased pumping is reduced to the threshold value by stimulated emission. The additional energy obtained from the reduced population inversion is transferred to the laser beam in the form of increased laser power. If the laser has low gain, as most cw (continuously operating) gas lasers do, the gain and also the power output tend to stabilize rather readily.

For solid-state lasers, which tend to have higher gain and also a long upper-laser-level lifetime, a phenomenon known as *relaxation oscillations*[7] occurs in the laser output. For pulsed (non-Q-switched) lasers in which the gain lasts for many microseconds, these oscillations occur in the form of a regularly repeated spiked laser output superimposed on a lower steady-state value. For cw lasers it takes the form of a sinusoidal oscillation of the output. The phenomenon is caused by an oscillation of the gain due to the interchange of pumped energy between the upper laser level and the laser field in the cavity. This effect can be controlled by using an active feedback mechanism, in the form of an intensity-dependent loss, in the laser cavity.

Laser mirrors not only provide the additional length required for the laser beam to reach I_{sat}, but they also provide very important resonant cavity effects that will be discussed in a later section. Using mirrors at the ends of the laser gain medium (or amplifier) is referred to as having the gain medium located within an optical cavity.

How Population Inversions Are Achieved[4]

It was mentioned earlier that population inversions are not easily achieved in normal situations. All types of matter tend to be driven towards thermal equilibrium. From an energy-level standpoint, to be in thermal equilibrium implies that the ratio of the populations of two excited states of a particular material, whether it be a gaseous, liquid, or solid material, is described by Eq. (12). For any finite value of the temperature this leads to a value of $N_2/(g_2/g_1)N_1$ that is always less than unity and therefore Eq. (14) can never be satisfied under conditions of thermal equilibrium. Population inversions are therefore produced in either one of two ways: (1) selective excitation (pumping) of the upper-laser-level 2, or (2) more rapid decay of the population of the lower-laser-level 1 than of the upper-laser-level 2, even if they are both populated by the same pumping process.

The first requirement mentioned above was met in producing the very first laser, the

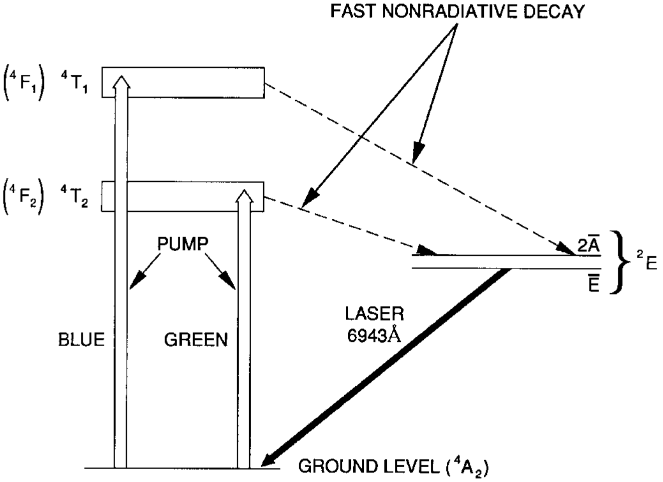

FIGURE 6 Energy-level diagram for a ruby laser showing the pump wavelength bands and the laser transition. The symbols $^4T_1$ and $^4T_2$ are shown as the appropriate designations for the pumping levels in ruby along with the more traditional designations in parenthesis.

ruby laser.[5] In this laser the flash lamp selectively pumped chromium atoms to the upper laser level (through an intermediate level) until the ground state (lower laser level) was depleted enough to produce the inversion (Fig. 6). Another laser that uses this selective pumping process is the copper vapor laser[6] (CVL). In this case, electrons in a gaseous discharge containing the copper vapor have a much preferred probability of pumping the upper laser level than the lower laser level (Fig. 7). Both of these lasers involve essentially three levels.

The second type of excitation is used for most solid-state lasers, such as the Nd^{3+} doped yttrium aluminum garnet laser[7] (commonly referred to as the Nd:YAG laser), for organic dye lasers,[8] and many others. It is probably the most common mechanism used to achieve

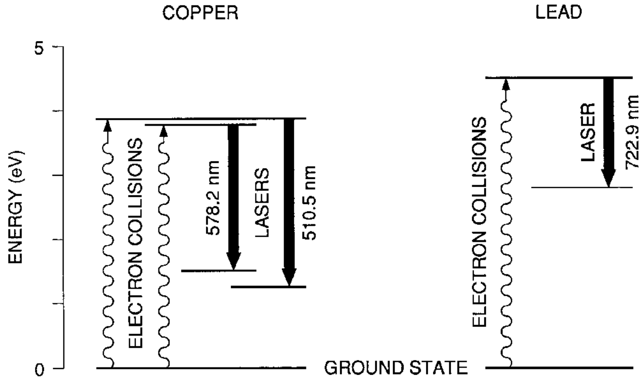

FIGURE 7 Energy-level diagrams of the transient three-level copper and lead vapor lasers showing the pump processes as well as the laser transitions.

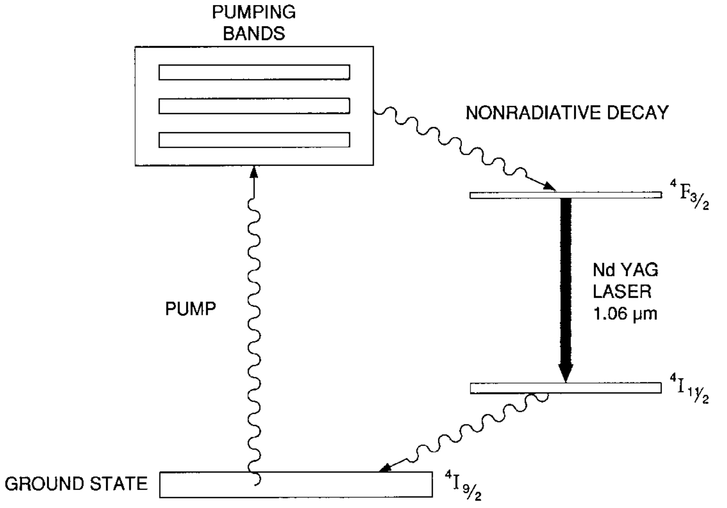

FIGURE 8 Energy-level diagram of the Nd:YAG laser indicating the four-level laser excitation process.

the necessary population inversion. This process involves four levels[2] (although it can include more) and generally occurs via excitation from the ground state 0 to an excited state 3 which energetically lies above the upper-laser-level 2. The population then decays from level 3 to level 2 by nonradiative processes (such as collisional processes in gases), but can also decay radiatively to level 2. If the proper choice of materials has been made, the lower-laser-level 1 in some systems will decay rapidly to the ground state (level 0) which allows the condition $N_2 > (g_2/g_1)N_1$ to be satisfied. This situation is shown in Fig. 8 for a Nd:YAG laser crystal.

Optimization of the Output Coupling from a Laser Cavity[9]

A laser will operate with any combination of mirror reflectivities subject to the constraints of the threshold condition of Eq. (17*a* or *b*). However, since lasers are devices that are designed to use the laser power in various applications, it is desirable to extract the most power from the laser in the most efficient manner. A simple expression for the optimum laser output coupling is given as

$$t_{\text{opt}} = (a_L g_{21} L)^{1/2} - a_L \tag{18}$$

in which a_L is the absorption and scattering losses per pass through the amplifier (the same as in Eq. (17*a* and *b*), g_{21} is the small signal gain per pass through the amplifier, and L is the length of the gain medium. This value of t_{opt} is obtained by assuming that equal output couplings are used for both mirrors at the ends of the cavity. To obtain all of the power from one end of the laser, the output transmission must be doubled for one mirror and the other mirror is made to be a high reflector.

The intensity of the beam that would be emitted from the output mirror can be estimated to be

$$I_{t_{\max}} = \frac{I_{\text{sat}} t_{\text{opt}}^2}{2a_L} \tag{19}$$

in which I_{sat} is the saturation intensity as obtained from Eq. (15). If all of the power is desired from one end of the laser, as discussed above, then $I_{t_{\max}}$ would be doubled in the above expression.

Pumping Techniques to Produce Inversions

Excitation or pumping of the upper laser level generally occurs by two techniques: (1) particle pumping and (2) optical or photon pumping. No matter which process is used, the goal is to achieve sufficient pumping flux and, consequently enough, population in the upper-laser-level 2 to satisfy or exceed the requirements of either Eq. (16) or Eq. (17).

Particle Pumping.[10] Particle pumping occurs when a high-speed particle collides with a laser species and converts its kinetic energy to internal energy of the laser species. Particle pumping occurs mostly with electrons as the pumping particle. This is especially common in a gas discharge where a voltage is applied across a low-pressure gas and the electrons flow through the tube in the form of a discharge current that can range from a few milliamps to tens of amperes, depending upon the particular laser and the power level desired. This type of excitation process is used for lasers such as the argon (Fig. 9) and krypton ion lasers, the copper vapor laser, excimer lasers, and the molecular nitrogen laser.

Two other well-known gas lasers, the helium-neon laser and the helium-cadmium laser, operate in a gas discharge containing a mixture of helium gas and the laser species (neon gas or cadmium vapor). When an electric current is produced within the discharge, the high-speed electrons first pump an excited metastable state in helium (essentially a storage reservoir). The energy is then transferred from this reservoir to the upper laser levels of

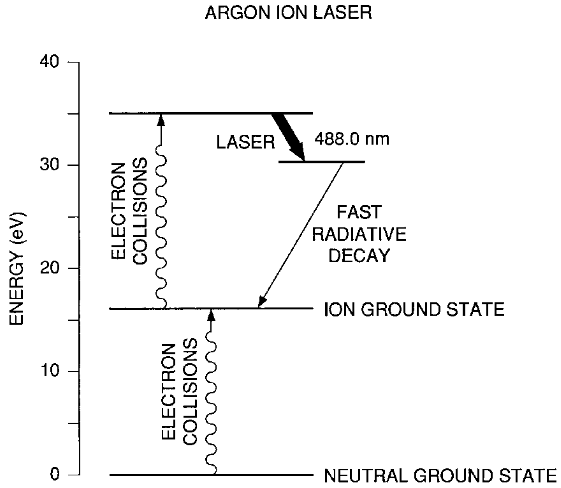

FIGURE 9 Energy-level diagram of the argon ion laser indicating the two-step excitation process.

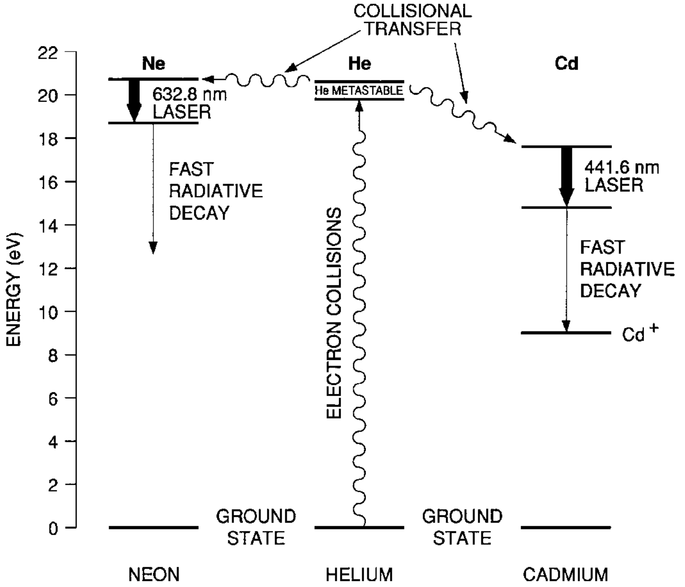

FIGURE 10 Energy-level diagrams of the helium-neon (He-Ne) laser and the helium-cadmium (He-Cd) laser that also include the helium metastable energy levels that transfer their energy to the upper laser levels by collisions.

neon or cadmium by collisions of the helium metastable level with the neon or cadmium ground-state atoms as shown in Fig. 10. Electron collisions with the cadmium ion ground state have also been shown to produce excitation in the case of the helium-cadmium laser.

In an energy-transfer process similar to that of helium with neon or cadmium, the CO_2 laser operates by using electrons of the gas discharge to produce excitation of molecular nitrogen vibrational levels that subsequently transfer their energy to the vibrational upper laser levels of CO_2 as indicated in Fig. 11. Helium is used in the CO_2 laser to control the

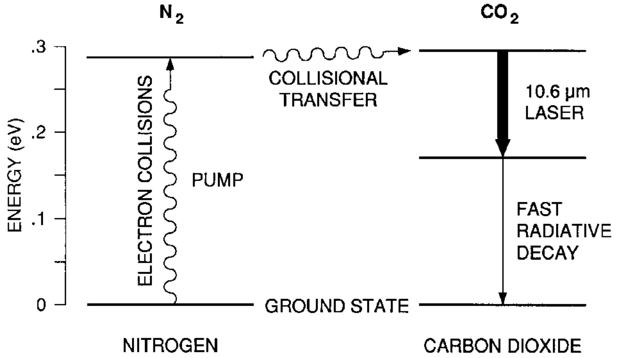

FIGURE 11 Energy-level diagram of the carbon dioxide (CO_2) laser along with the energy level of molecular nitrogen that collisionally transfers its energy to the CO_2 upper laser level.

electron temperature and also to cool (reduce) the population of the lower laser level via collisions of helium atoms with CO_2 atoms in the lower laser level.

High-energy electron beams and even nuclear reactor particles have also been used for particle pumping of lasers, but such techniques are not normally used in commercial laser devices.

Optical Pumping.[7] Optical pumping involves the process of focusing light into the gain medium at the appropriate wavelength such that the gain medium will absorb most (or all) of the light and thereby pump that energy into the upper laser level as shown in Fig. 12. The selectivity in pumping the laser level with an optical pumping process is determined by choosing a gain medium having significant absorption at a wavelength at which a suitable pump light source is available. This of course implies that the absorbing wavelengths provide efficient pumping pathways to the upper laser level. Optical pumping requires very intense pumping light sources, including flash lamps and other lasers. Lasers that are produced by optical pumping include organic dye lasers and solid-state lasers.

Flash lamps used in optically pumped laser systems are typically long, cylindrically shaped, fused quartz structures of a few millimeters to a few centimeters in diameter and 10 to 50 centimeters in length. The lamps are filled with gases such as xenon and are initiated by running an electrical current through the gas. The light is concentrated into the lasing medium by using elliptically shaped reflecting cavities that surround both the laser medium and the flash lamps as shown in Fig. 13. These cavities efficiently collect and transfer to the laser rod most of the lamp energy in wavelengths within the pump absorbing band of the rod. The most common flash-lamp-pumped lasers are Nd:YAG, Nd:glass, and organic dye lasers. New crystals such as Cr:LiSAF and HoTm:YAG are also amenable to flash-lamp pumping.

Solid-state lasers also use energy-transfer processes as part of the pumping sequence in a way similar to that of the He-Ne and He-Cd gas lasers. For example, Cr^{3+} ions are added into neodymium-doped crystals to improve the absorption of the pumping light. The energy is subsequently transferred to the Nd^{3+} laser species. Such a process of adding desirable impurities is known as *sensitizing.*

Lasers are used as optical pumping sources in situations where (1) it is desirable to be able to concentrate the pump energy into a small-gain region or (2) it is useful to have a narrow spectral output of the pump source in contrast with the broadband spectral distribution of a flash lamp.

Laser pumping is achieved by either transverse pumping (a direction perpendicular to the direction of the laser beam) or longitudinal pumping (a direction in the same direction as the emerging laser beam). Frequency doubled and tripled pulsed Nd:YAG lasers are

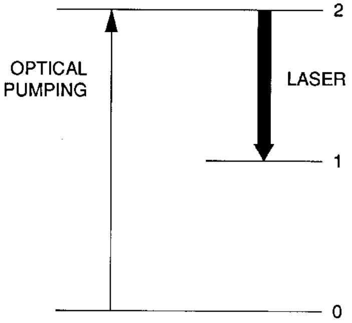

FIGURE 12 A general diagram showing optical pumping of the upper laser level.

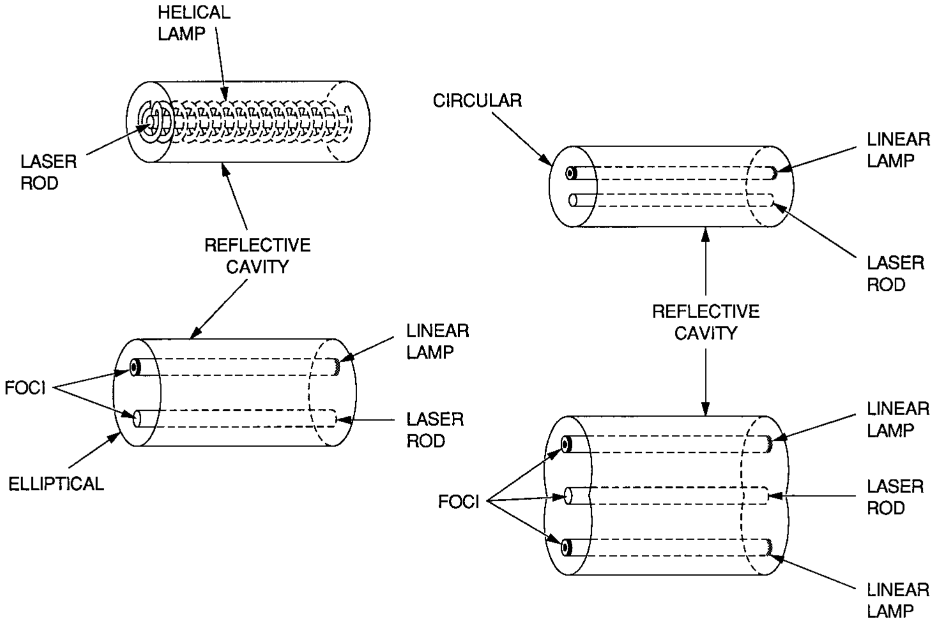

FIGURE 13 Flash-lamp pumping arrangements for solid-state laser rods showing the use of helical lamps as well as linear lamps in a circular cavity, a single elliptical cavity, and a double elliptical cavity.

used to transversely pump organic dye lasers[8] that provide continuously tunable laser radiation over the near-ultraviolet, visible, and near-infrared spectral regions (by changing dyes at appropriate wavelength intervals). For transverse pumping, the pump lasers are typically focused into the dye medium with a cylindrical lens to provide a 1–2-cm-long (but very narrow) gain medium in the liquid dye solution. The dye concentration is adjusted to absorb the pump light within a millimeter or so into the dye cell to provide the very high concentration of gain near the surface of the cell.

Both cw and mode-locked argon ion lasers and Nd:YAG lasers are typically used for longitudinal or end pumping of cw and/or mode-locked organic dye lasers and also of solid-state gain media. In this pumping arrangement the pump laser is focused into a very thin gain region, which is provided by either a thin jet stream of flowing dye solution (Fig. 14) or a solid-state crystal such as Ti:Al_2O_3. The thin gain medium is used, in the case of the generation of ultrashort mode-locked pulses, so as to allow precise timing of the

short-duration pump pulses with the ultrashort laser pulses that develop within the gain medium as they travel within the optical cavity.

Gallium arsenide semiconductor diode lasers, operating at wavelengths around 0.8 μm, can be effectively used to pump Nd : YAG lasers because the laser wavelength is near that of the strongest absorption feature of the pump band of the Nd:YAG laser crystal, thereby minimizing excess heating of the laser medium. Also, the diode lasers are very efficient light sources that can be precisely focused into the desired mode volume of a small Nd:YAG crystal (Fig. 15*a*) which results in minimal waste of the pump light. Figure 15*b* shows how close-coupling of the pump laser and the Nd:YAG crystal can be used to provide compact efficient diode laser pumping. The infrared output of the Nd:YAG laser can then also be frequency doubled as indicated in Fig. 15*a,* using nonlinear optical techniques to produce a green laser beam in a relatively compact package.

11.4 LASER PROPERTIES ASSOCIATED WITH OPTICAL CAVITIES OR RESONATORS

Longitudinal Laser Modes[1,2]

When a collimated optical beam of infinite lateral extent (a plane wave) passes through two reflecting surfaces of reflectivity *R* and also of infinite extent that are placed normal (or nearly normal) to the beam and separated by a distance *d,* as shown in Fig. 16*a,* the

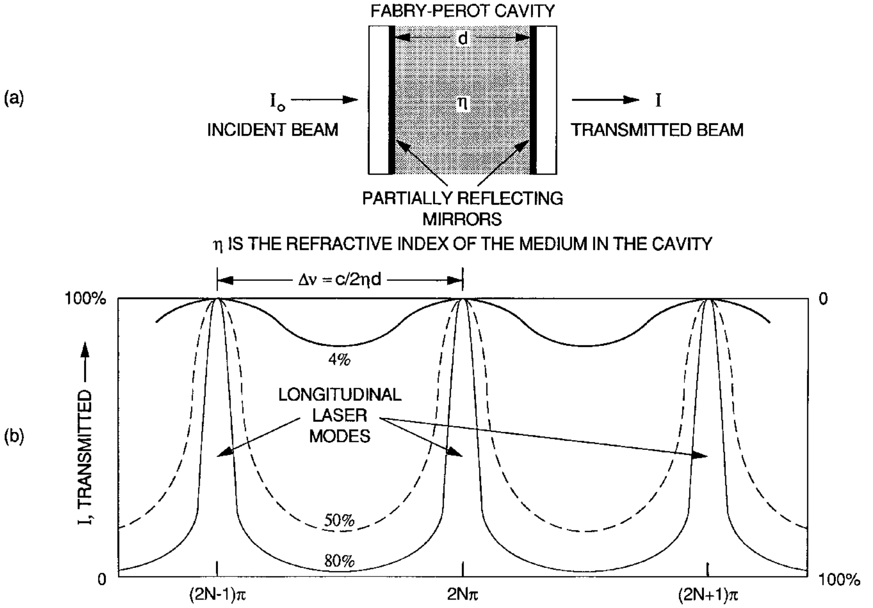

FIGURE 16 Fabry-Perot optical cavity consisting of two plane-parallel mirrors with a specific reflectivity separated by a distance *d* indicating the frequency spacing of longitudinal modes.

plot of transmission versus wavelength for the light as it emerges from the second reflecting surface is shown in Fig. 16*b*. The transmission reaches a maximum of 100 percent (if there are no absorption losses at the reflecting surfaces) at frequency spacings of $\Delta v = c/2\eta d$ where c is the speed of light in a vacuum, and η is the index of refraction of the medium between the mirrors. This frequency-selective optical device is known as a Fabry-Perot interferometer and has many useful applications in optics.

The transmission through this device, as shown in Fig. 16*b* is enhanced at regular frequency or wavelength intervals due to the development of standing waves that resonate within the optical cavity. The enhancement occurs at frequencies (or wavelengths) at which complete sinusoidal half-cycles of the electromagnetic wave exactly "fit" between the mirrors such that the value of the electric field of the wave is zero at the mirror surfaces.

If a laser amplifier is placed between two mirrors in the same arrangement as described above, the same standing waves tend to be enhanced at frequency intervals of

$$v = n(c/2\eta d) \tag{20}$$

where n is an integer that indicates the number of half wavelengths of the laser light that fit within the spacing d of the two mirrors. In a typical laser operating in the visible spectral region, n would be of the order of 30,000 to 40,000. In such a laser, the output of the laser beam emerging from the cavity is very strongly enhanced at the resonant wavelengths as shown in Fig. 17, since these are the wavelengths that have the lowest loss within the cavity. The widths of the resonances shown in Fig. 17 are those of a passive Fabry-Perot cavity. When an active gain medium is placed within the cavity, the linewidth of the beam that is continually amplified as it reflects back and forth between the mirrors is narrowed even further.

These enhanced regions of very narrow frequency output are known as *longitudinal*

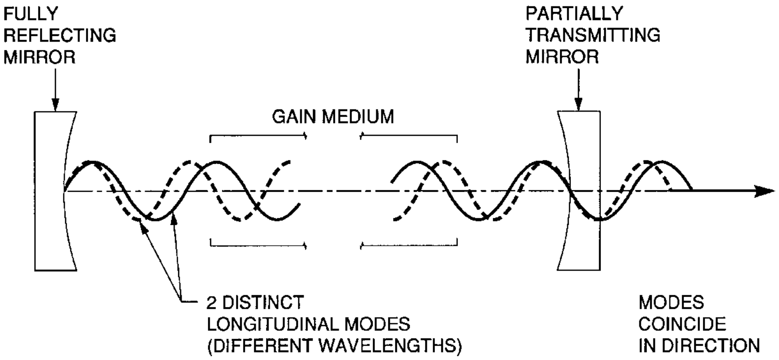

FIGURE 17 Laser resonator showing two distinct longitudinal modes traveling in the same direction but with slightly different frequencies.

modes of the laser. They are referred to as modes since they represent discrete values of frequency associated with the integral values of n at which laser output occurs. Lasers operating on a single longitudinal mode with ultrastable cavities and ultrahigh reflectivity mirrors have generated linewidths as narrow as a few hundred hertz or less. Since the longitudinal or temporal coherence length of a beam of light is determined by $c/\Delta v$, a very narrow laser linewidth can provide an extremely long coherence length and thus a very coherent beam of light.

For a typical gas laser (not including excimer lasers), the laser gain bandwidth is of the order of 10^9–10^{10} Hz. Thus, for a laser mirror cavity length of 0.5 m, the mode spacing would be of the order of 300 MHz and there would be anywhere from 3 to 30 longitudinal modes operating within the laser cavity. For an organic dye laser or a broadband solid-state laser, such as a Ti:Al_2O_3 laser, there could be as many as one million distinct longitudinal modes, each of a slightly different frequency than the next one, oscillating at the same time. However, if mode-locking is not present, typically only one or a few modes will dominate the laser output of a homogeneously broadened laser gain medium.

Transverse Laser Modes[11–14]

The previous section considered the implications of having a collimated or parallel beam of light of infinite lateral extent pass through two infinite reflecting surfaces that are arranged normal to the direction of propagation of the beam and separated by a specific distance d. We must now consider the consequences of having the light originate within the space between the two mirrors in an amplifier that has only a very narrow lateral extent limited by either the diameter of the mirrors or by the diameter of the amplifying medium. The beam evolves from the spontaneous emission within the gain medium and eventually becomes a nearly collimated beam when it reaches I_{sat} since only rays traveling in a very limited range of directions normal to the laser mirrors will experience enough reflections to reach I_{sat}. The fact that the beam has a restricted aperture in the direction transverse to the direction of propagation causes it to evolve with a slight transverse component due to diffraction, which effectively causes the beam to diverge. This slight divergence actually consists of one or more distinctly separate beams that can operate individually or in combination.

These separate beams that propagate in the z direction are referred to as *transverse*

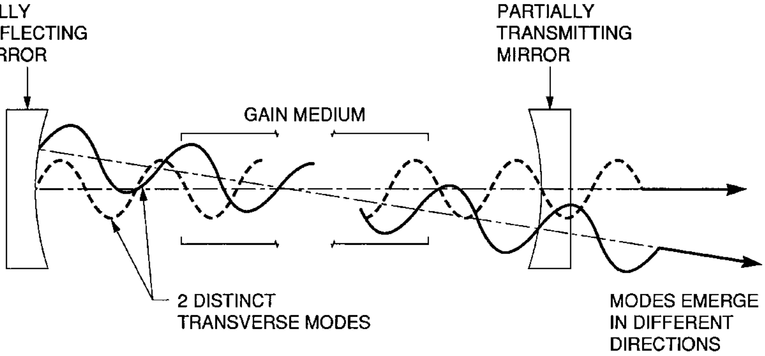

FIGURE 18 Laser resonator showing two distinct transverse modes traveling in different directions with slightly different frequencies.

modes as shown in Fig. 18. They are characterized by the various lateral spatial distributions of the electric field vector $\mathbf{E}(x, y)$ in the x-y directions as they emerge from the laser. These transverse amplitude distributions for the waves can be described by the relationship.

$$E_{pq}(x, y) = H_p\left(\frac{\sqrt{2}x}{w}\right)H_q\left(\frac{\sqrt{2}y}{w}\right)e^{-(x^2+y^2)/w^2} \tag{21}$$

In this solution, p and q are positive integers ranging from zero to infinity that designate the different modes which are associated with the order of the Hermite polynomials. Thus every set of p, q represents a specific distribution of wave amplitude at one of the mirrors, or a specific transverse mode of the open-walled cavity. We can list several Hermite polynomials as follows:

$$\begin{aligned} &H_0(u) = 1 \qquad H_1(u) = 2u \\ &H_2(u) = 2(2u^2 - 1) \\ &H_m(u) = (-1)^m e^{u^2}\frac{d^m(e^{-u^2})}{du^m} \end{aligned} \tag{22}$$

The spatial intensity distribution would be obtained by squaring the amplitude distribution function of Eq. (21). The transverse modes are designated TEM for transverse electromagnetic. The lowest-order mode is given by TEM_{00}. It could also be written as TEM_{n00} in which n would designate the longitudinal mode number [Equation (20)]. Since this number is generally very large for optical frequencies, it is not normally given.

The lowest order TEM_{00} mode, has a circular distribution with a gaussian shape (often referred to as the *gaussian mode*) and has the smallest divergence of any of the transverse modes. Such a mode can be focused to a spot size with dimensions of the order of the wavelength of the beam. It has a minimum width or waist $2w_o$ that is typically located between the laser mirrors (determined by the mirror curvatures and separation) and expands symmetrically in opposite directions from that minimum waist according to the following equation:

$$w(z) = w_o\left[1 + \left(\frac{\lambda z}{\eta\pi w_o^2}\right)^2\right]^{1/2} = w_o\left[1 + \left(\frac{z}{z_o}\right)^2\right]^{1/2} \tag{23}$$

where $w(z)$ is the beam waist at any location z measured from w_o, η is the index of

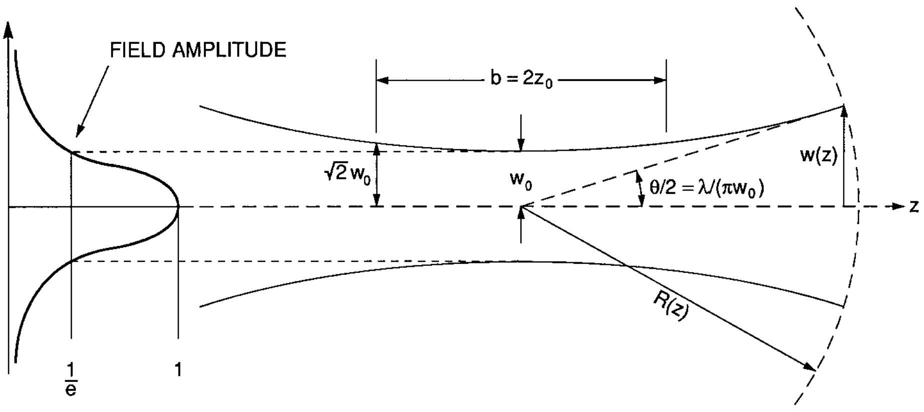

FIGURE 19 Parameters of a gaussian-shaped beam which are the features of a TEM_{00} transverse laser mode.

refraction of the medium, and $z_o = \eta\pi w_o^2/\lambda$ is the distance over which the beam waist expands to a value of $\sqrt{2}w_o$.

The waist $w(z)$ at any location, as shown in Fig. 19, describes the transverse dimension within which the electric field distribution of the beam decreases to a value of 37 percent $(1/e)$ of its maximum on the beam axis and within which 86.5 percent of the beam energy is contained. The TEM_{00} mode would have an intensity distribution that is proportional to the square of Eq. (21) for $p = q = 0$ and, since it is symmetrical around the axis of propagation, it would have a cylindrically symmetric distribution of the form

$$I(r, z) = I_o e^{-2r^2/w^2(z)} \tag{24}$$

where I_o is the intensity on the beam axis.

The beam also has a wavefront curvature given by

$$R(z) = z\left[1 + \left(\frac{\eta\pi w_o^2}{\lambda z}\right)^2\right] \tag{25}$$

which is indicated in Fig. 19, and a far-field angular divergence given by

$$\theta = \lim_{z\to\infty} \frac{2w(z)}{z} = \frac{2\lambda}{\pi w_o} = 0.64\frac{\lambda}{w_o} \tag{26}$$

For a symmetrical cavity formed by two mirrors, each of radius of curvature R, separated by a distance d and in a medium in which $\eta = 1$ the minimum beam waist w_o is given by

$$w_o^2 = \frac{\lambda}{2\pi}[d(2R - d)]^{1/2} \tag{27}$$

and the radius of curvature r_c of the wavefront is

$$r_c = z + \frac{d(2R - d)}{4z} \tag{28}$$

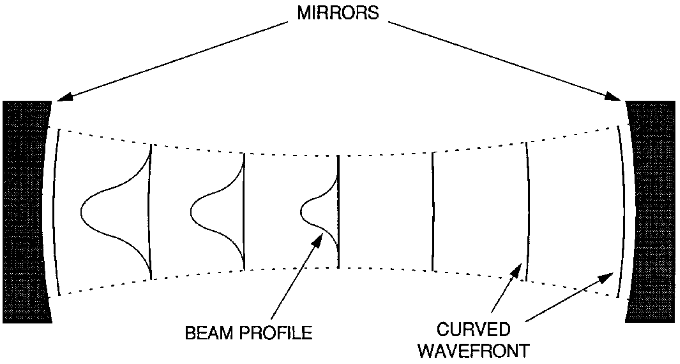

FIGURE 20 A stable laser resonator indicating the beam profile at various locations along the beam axis as well as the wavefront at the mirrors that matches the curvature of the mirrors.

For a confocal resonator in which $R = d$, w_o is given by

$$w_o = \sqrt{\frac{\lambda d}{2\pi}} \tag{29}$$

and the beam waist (spot size) at each mirror located a distance $d/2$ from the minimum is

$$w = \sqrt{\frac{\lambda d}{\pi}} \tag{30}$$

Thus, for a confocal resonator, $w(d/2)$ at each of the mirrors is equal to $\sqrt{2}w_o$ and thus at that location, $z = z_o$. The distance between mirrors for such a cavity configuration is referred to as the *confocal parameter b* such that $b = 2z_o$. In a stable resonator, the curvature of the wavefront at the mirrors, according to Eqs. (25) and (28), exactly matches the curvature of the mirrors as shown in Fig. 20.

Each individual transverse mode of the beam is produced by traveling a specific path between the laser mirrors such that, as it passes from one mirror to the other and returns, the gain it receives from the amplifier is at least as great as the total losses of the mirror, as indicated from Eq. (17), plus the additional diffraction losses produced by either the finite lateral extent of the laser mirrors or the finite diameter of the laser amplifier or some other optical aperture placed in the system, whichever is smaller. Thus the TEM_{00} mode is produced by a beam passing straight down the axis of the resonator as indicated in Fig. 19.

Laser Resonator Configurations and Cavity Stability[4,14]

There are a variety of resonator configurations that can be used for lasers. The use of slightly curved mirrors leads to much lower diffraction losses of the transverse modes than do plane parallel mirrors, and they also have much less stringent alignment tolerances. Therefore, most lasers use curved mirrors for the optical cavity. For a cavity with two

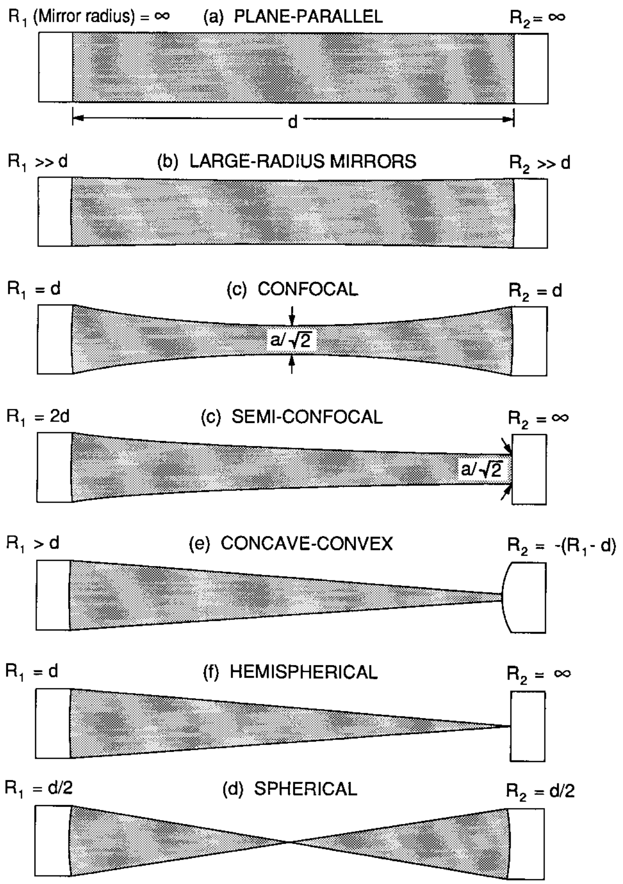

FIGURE 21 Possible two-mirror laser cavity configurations indicating the relationship of the radii of curvature of the mirrors with respect to the separation between mirrors.

mirrors of curvature R_1 and R_2, and a separation distance d, a number of possible cavity configurations are shown in Fig. 21.

A relationship between the radii of curvature and the separation between mirrors can be defined as

$$g_1 = 1 - \frac{d}{R_1} \quad \text{and} \quad g_2 = 1 - \frac{d}{R_2} \tag{31}$$

such that the condition for stable transverse modes is given by

$$0 < g_1 g_2 < 1 \tag{32}$$

A stable mode is a beam that can be maintained with a steady output and profile over a relatively long period of time. It results from a cavity configuration that concentrates the beam toward the resonator axis in a regular pattern as it traverses back and forth within the cavity, rather than allowing it to diverge and escape from the resonator. In considering the various possible combinations of curved mirror cavities, one must keep the relation

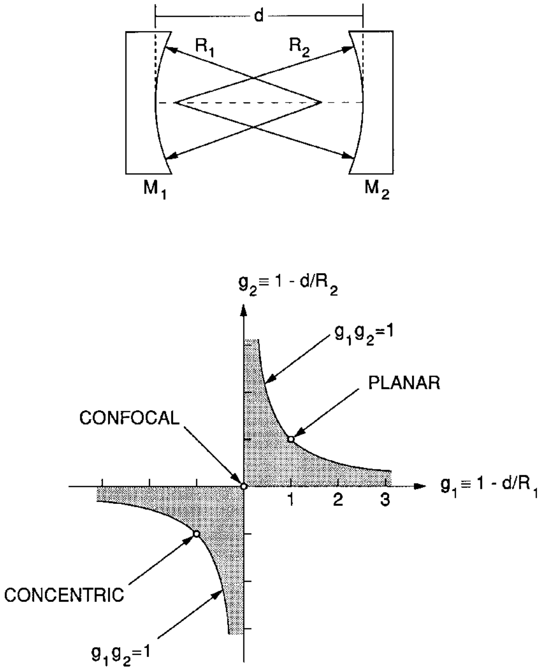

FIGURE 22 Stability diagram for two-mirror laser cavities indicating the shaded regions where stable cavities exist.

between the curvatures and mirror separation *d* within the stable regions of the graph, as shown in Fig. 22, in order to produce stable modes. Thus it can be seen from Fig. 22 that not all configurations shown in Fig. 21 are stable. For example, the planar, confocal, and concentric arrangements are just on the edge of stability according to Fig. 22.

There may be several transverse modes oscillating simultaneously "within" a single longitudinal mode. Each transverse mode can have the same value of *n* [Eq. (20)] but will have a slightly different value of *d* as it travels a different optical path between the resonator mirrors, thereby generating a slight frequency shift from that of an adjacent transverse mode. For most optical cavities, the mode that operates most easily is the TEM_{00} mode, since it travels a direct path along the axis of the gain medium.

11.5 SPECIAL LASER CAVITIES

Unstable Resonators[14]

A laser that is operating in a TEM_{00} mode, as outlined above, typically has a beam within the laser cavity that is relatively narrow in width compared to the cavity length. Thus, if a laser with a relatively wide gain region is used, to obtain more energy in the output beam, it is not possible to extract the energy from that entire region from a typically very narrow low-order gaussian mode. A class of resonators has been developed that can extract the energy from such wide laser volumes and also produce a beam with a nearly gaussian

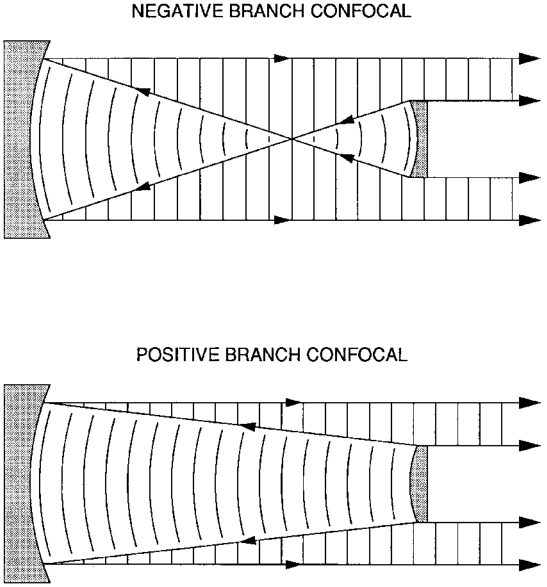

FIGURE 23 Unstable resonator cavity configurations showing both the negative and positive branch confocal cavities.

profile that makes it easily focusable. These resonators do not meet the criteria for stability, as outlined above, but still provide a good beam quality for some types of lasers. This class of resonators is referred to as *unstable resonators.*

Unstable resonators are typically used with high-gain laser media under conditions such that only a few passes through the amplifier will allow the beam to reach the saturation intensity and thus extract useful energy. A diagram of two unstable resonator cavity configurations is shown in Fig. 23. Figure 23*b* is the positive branch confocal geometry and is one of the most common unstable resonator configurations. In this arrangement, the small mirror has a convex shape and the large mirror a concave shape with a separation of length d such that $R_2 - R_1 = 2d$. With this configuration, any ray traveling parallel to the axis from left to right that intercepts the small convex mirror will diverge toward the large convex mirror as though it came from the focus of that mirror. The beam then reflects off of the larger mirror and continues to the right as a beam parallel to the axis. It emerges as a reasonably well-collimated beam with a hole in the center (due to the obscuration of the small mirror). The beam is designed to reach the saturation intensity when it arrives at the large mirror and will therefore proceed to extract energy as it makes its final pass through the amplifier. In the far field, the beam is near gaussian in shape, which allows it to be propagated and focused according to the equations described in the previous section. A number of different unstable resonator configurations can be found in the literature for specialized applications.

Q-Switching[15]

A typical laser, after the pumping or excitation is first applied, will reach the saturation intensity in a time period ranging from approximately 10 nsec to 1 μsec, depending upon the value of the gain in the medium. For lasers such as solid-state lasers the upper-laser-level lifetime is considerably longer than this time (typically 50–200 μ sec). It is possible to store and accumulate energy in the form of population in the upper laser level for a time duration of the order of that upper-level lifetime. If the laser cavity could be obscured during this pumping time and then suddenly switched into the system at a time order of the upper-laser-level lifetime, it would be possible for the gain, as well as the laser energy, to reach a much larger value than it normally would under steady-state conditions. This would produce a ‘‘giant’’ laser pulse of energy from the system.

Such a technique can in fact be realized and is referred to as *Q-switching* to suggest that the cavity Q is changed or switched into place. The cavity is switched on by using either a rapidly rotating mirror or an electro-optic shutter such as a Pockel cell or a Kerr cell. Nd:YAG and Nd:glass lasers are the most common Q-switched lasers. A diagram of the sequence of events involved in Q-switching is shown in Fig. 24.

Another technique that is similar to Q-switching is referred to as *cavity dumping.* With this technique, the intense laser beam inside of a normal laser cavity is rapidly switched out of the cavity by a device such as an acousto-optic modulator. Such a device is inserted at Brewster’s angle inside the cavity and is normally transparent to the laser beam. When the device is activated, it rapidly inserts a high-reflecting surface into the cavity and reflects the beam out of the cavity. Since the beam can be as much as two orders of magnitude higher in intensity within the cavity than that which leaks through an output mirror, it is possible to extract high power on a pulsed basis with such a technique.

Mode-Locking[14]

In the discussion of longitudinal modes it was indicated that such modes of intense laser output occur at regularly spaced frequency intervals of $\Delta\nu = c/2\eta d$ over the gain bandwidth of the laser medium. For laser cavity lengths of the order of 10–100 cm these frequency intervals range from approximately 10^8 to 10^9 Hz. Under normal laser operation, specific modes with the highest gain tend to dominate and quench other modes (especially if the gain medium is homogeneously broadened). However, under certain conditions it is possible to obtain all of the longitudinal modes lasing simultaneously, as shown in Fig. 25*a.* If this occurs, and the modes are all phased together so that they can act in concert by constructively and destructively interfering with each other, it is possible to produce a series of giant pulses separated in a time Δt of

$$\Delta t = 2\eta d/c \tag{33}$$

or approximately 1–10 nsec for the cavity lengths mentioned above (see Fig. 25*b*). The pulse duration is approximately the reciprocal of the separation between the two extreme longitudinal laser modes or

$$\Delta t_p = \frac{1}{n\,\Delta\nu} \tag{34}$$

as can also be seen in Fig. 25*b.* This pulse duration is approximately the reciprocal of the laser gain bandwidth. However, if the index of refraction varies significantly over the gain bandwidth, then all of the frequencies are not equally spaced and the mode-locked pulse duration will occur only within the frequency width over which the frequency separations are approximately the same.

The narrowest pulses are produced from lasers having the largest gain bandwidth such as organic dye lasers, and solid-state lasers including Ti:Al_2O_3, Cr:Al_2O_3, and Cr:LiSAlF. The shortest pulses to date, of the order of 6×10^{-15} sec, are produced in

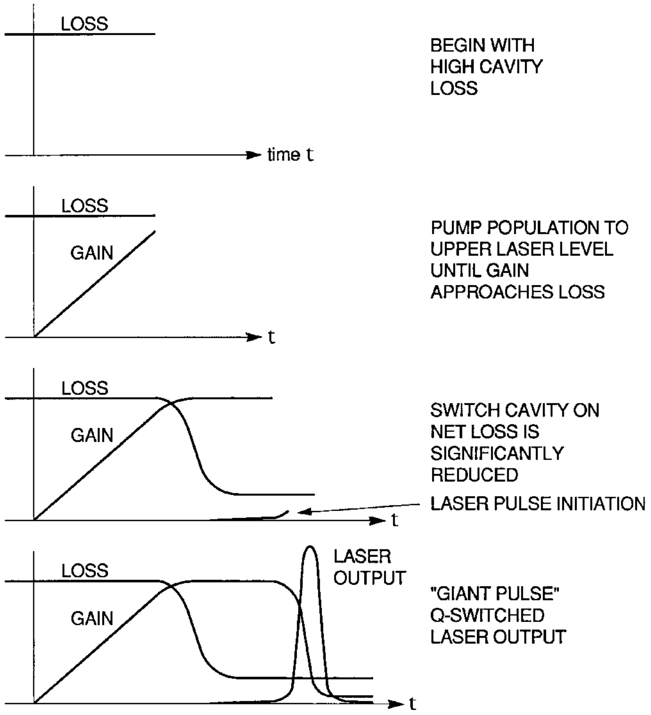

FIGURE 24 Schematic diagram of a Q-switched laser indicating how the loss is switched out of the cavity and a gaint laser pulse is produced as the gain builds up.

organic dyes where the gain bandwidth is approximately 50 nm at a center wavelength of 600 nm.

Such short-pulse operation is referred to as *mode-locking* and is achieved by inserting a very fast shutter within the cavity which is opened and closed at the intervals of the round-trip time of the short laser pulse within the cavity. This shutter coordinates the time at which all of the modes arrive at the mirror and thus brings them all into phase at that location. Electro-optic shutters, short duration gain pumping by another mode-locked laser, or passive saturable absorbers are techniques that can serve as the fast shutter. The second technique, short-duration gain pumping, is referred to as *synchronous pumping.* Three fast saturable absorber shutter techniques for solid-state lasers include colliding pulse mode-locking,[16] additive pulse mode-locking,[17] and Kerr lens mode-locking.[18]

Distributed Feedback Lasers[19]

The typical method of obtaining feedback into the laser gain medium is to have the mirrors located at the ends of the amplifier as discussed previously. It is also possible, however, to provide the reflectivity within the amplifying medium in the form of a periodic variation of either the gain or the index of refraction throughout the medium. This process is referred to as *distributed feedback* or DFB. Such feedback methods are particularly effective in

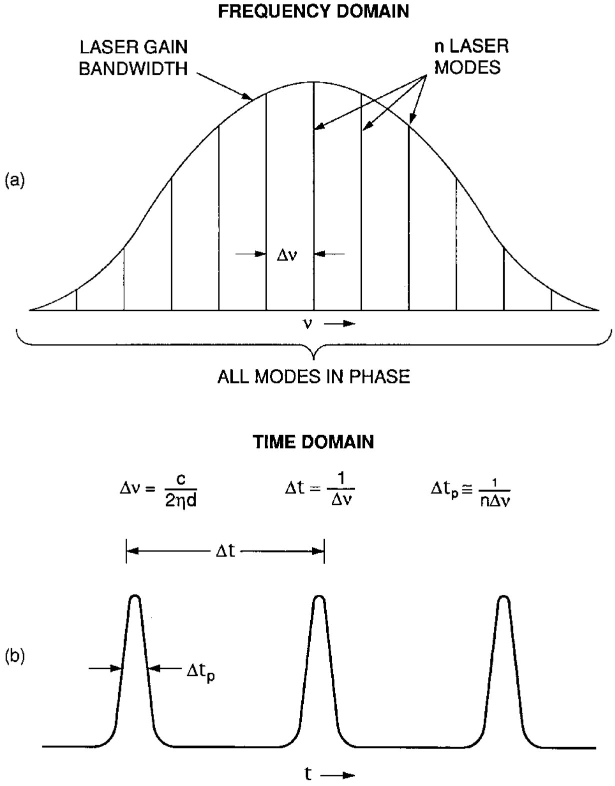

FIGURE 25 Diagrams in both the frequency and time domains of how mode-locking is produced by phasing *n* longitudinal modes together to produce an ultrashort laser pulse.

semiconductor lasers in which the gain is high and the fabrication of periodic variations is not difficult. The reader is referred to the reference section at the end of this chapter for further information concerning this type of feedback.

Ring Lasers[14]

Ring lasers are lasers that have an optical path within the cavity that involves the beam circulating in a loop rather than passing back and forth over the same path. This requires optical cavities that have more than two mirrors. The laser beam within the cavity consists of two waves traveling in opposite directions with separate and independent resonances within the cavity. In some instances an optical device is placed within the cavity that provides a unidirectional loss. This loss suppresses one of the beams, allowing the beam propagating in the other direction to become dominant. The laser output then consists of a traveling wave instead of a standing wave and therefore there are no longitudinal modes. Such an arrangement also eliminates the variation of the gain due to the standing waves in the cavity (spatial hole burning), and thus the beam tends to be more homogeneous than that of a normal standing-wave cavity. Ring lasers are useful for producing ultrashort mode-locked pulses and also for use in laser gyroscopes as stable reference sources.

11.6 SPECIFIC TYPES OF LASERS

Lasers can be categorized in several different ways including wavelength, material type, and applications. In this section we will summarize them by material type such as gas, liquid, solid-state, and semiconductor lasers. We will include only lasers that are available commercially since such lasers now provide a very wide range of available wavelengths and powers without having to consider special laboratory lasers.

Gaseous Laser Gain Media

Helium-Neon Laser.[10] The helium-neon laser was the first gas laser. The most widely used laser output wavelength is a red beam at 632.8 nm with a cw output ranging from 1 to 100 mW and sizes ranging from 10 to 100 cm in length. It can also be operated at a wavelength of 543.5 nm for some specialized applications. The gain medium is produced by passing a relatively low electrical current (10 mA) through a low pressure gaseous discharge tube containing a mixture of helium and neon. In this mixture, helium metastable atoms are first excited by electron collisions as shown in Fig. 10. The energy is then collisionally transferred to neon atom excited states which serve as upper laser levels.

Argon Ion Laser.[10] The argon ion laser and the similar krypton ion laser operate over a wide range of wavelengths in the visible and near-ultraviolet regions of the spectrum. The wavelengths in argon that have the highest power are at 488.0 and 514.5 nm. Power outputs on these laser transitions are available up to 20 W cw in sizes ranging from 50–200 cm in length. The gain medium is produced by running a high electric current (many amperes) through a very low pressure argon or krypton gas. The argon atoms must be ionized to the second and third ionization stages (Fig. 9) in order to produce the population inversions. As a result, these lasers are inherently inefficient devices.

Helium-Cadmium Laser.[10] The helium-cadmium laser operates cw in the blue at 441.6 nm, and in the ultraviolet at 353.6 and 325.0 nm with powers ranging from 20–200 mW in lasers ranging from 40–100 cm in length. The gain medium is produced by heating cadmium metal and evaporating it into a gaseous discharge of helium where the laser gain is produced. The excitation mechanisms include Penning ionization (helium metastables collide with cadmium atoms) and electron collisional ionization within the discharge as indicated in Fig. 10. The laser uses an effect known as *cataphoresis* to transport the cadmium through the discharge and provide the uniform gain medium.

Copper Vapor Laser.[10] This pulsed laser provides high-average powers of up to 100 W at wavelengths of 510.5 and 578.2 nm. The copper laser and other metal vapor lasers of this class, including gold and lead lasers, typically operate at a repetition rate of up to 20 kHz with a current pulse duration of 10–50 nsec and a laser output of 1–10 mJ/pulse. The copper lasers operate at temperatures in the range of 1600°C in 2–10-cm-diameter temperature-resistant tubes typically 100–150 cm in length. The lasers are self-heated such that all of the energy losses from the discharge current provide heat to bring the plasma tube to the required operating temperature. Excitation occurs by electron collisions with copper atoms vaporized in the plasma tube as indicated in Fig. 7.

Carbon-Dioxide Laser.[10] The CO_2 laser, operating primarily at a wavelength of 10.6 μm, is one of the most powerful lasers in the world, producing cw powers of over 100 kW and pulsed energies of up to 10 kJ. It is also available in small versions with powers of up to 100 W from a laser the size of a shoe box. CO_2 lasers typically operate in a mixture of carbon dioxide, nitrogen, and helium gases. Electron collisions excite the metastable levels in nitrogen molecules with subsequent transfer of that energy to carbon dioxide laser levels as shown in Fig. 11. The helium gas acts to keep the average electron energy high in the gas discharge region and to cool or depopulate the lower laser level. This laser is one of the most efficient lasers, with conversion from electrical energy to laser energy of up to 30 percent.

Excimer Laser.[20] The rare gas-halide excimer lasers operate with a pulsed output primarily in the ultraviolet spectral region at 351 nm in xenon fluoride, 308 nm in xenon chloride, 248 nm in krypton fluoride, and 193 nm in argon fluoride. The laser output, with pulse durations of 10–50 nsec, is typically of the order of 0.2–1.0 J/pulse at repetition rates up to several hundred Hz. The lasers are relatively efficient (1 to 5 percent) and are of a size that would fit on a desktop. The excitation occurs via electrons within the discharge colliding with and ionizing the rare gas molecules and at the same time disassociating the halogen molecules to form negative halogen ions. These two species then combine to form an excited molecular state of the rare gas-halogen molecule which serves as the upper laser state. The molecule then radiates at the laser transition and the lower level advantageously disassociates since it is unstable, as shown in Fig. 26, for the ArF excimer molecule. The excited laser state is an excited state dimer which is referred to as an *excimer state.*

X-Ray Laser.[24] Laser output in the soft-x-ray spectral region has been produced in plasmas of highly ionized ions of a number of atomic species. The highly ionized ions are

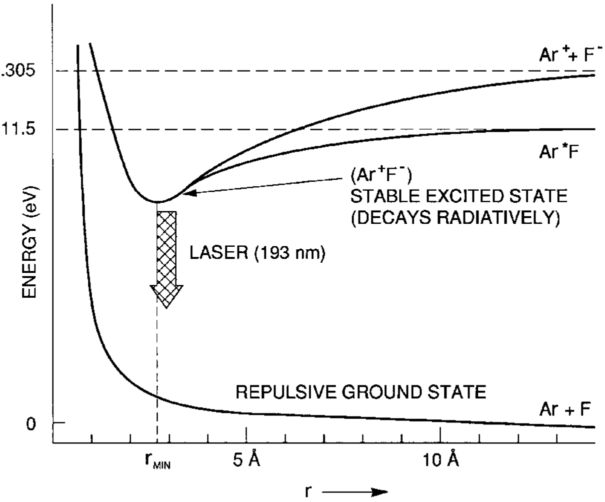

FIGURE 26 Energy-level diagram of an argon fluoride (ArF) excimer laser showing the stable excited state (upper laser level) and the unstable or repulsive ground state.

produced by the absorption of powerful solid-state lasers focused onto solid material of the desired atomic species. Since mirrors are not available for most of the soft-x-ray laser wavelengths (4–30 nm), the gain has to be high enough to obtain laser output in a single pass through the laser amplifier [Eq. (16)]. The lasers with the highest gain are the selenium laser (Se^{24+}) at 20.6 and 20.9 nm and the germanium laser (Ge^{22+}) at 23.2, 23.6, and 28.6 nm.

Liquid Laser Gain Media

Organic Dye Lasers.[8] A dye laser consists of a host or solvent material, such as alcohol or water, into which is mixed a laser species in the form of an organic dye molecule, typically in the proportion of one part in ten thousand. A large number of different dye molecules are used to make lasers covering a wavelength range of from 320 to 1500 nm with each dye having a laser bandwidth of the order of 30–50 nm. The wide, homogeneously broadened gain spectrum for each dye allows laser tunability over a wide spectrum in the ultraviolet, visible, and near-infrared. Combining the broad gain spectrum (Fig. 27) with a diffraction-grating or prism-tuning element allows tunable laser output to be obtained over the entire dye emission spectrum with a laser linewidth of 10 GHz or less. Dye lasers are available in either pulsed (up to 50–100 mJ/pulse) or continuous output (up to a few watts) in tabletop systems that are pumped by either flash lamps or by other lasers such as frequency doubled or tripled YAG lasers or argon ion lasers. Most dye lasers are arranged to have the dye mixture circulated by a pump into the gain region from a much larger reservoir since the dyes degrade at a slow rate during the excitation process.

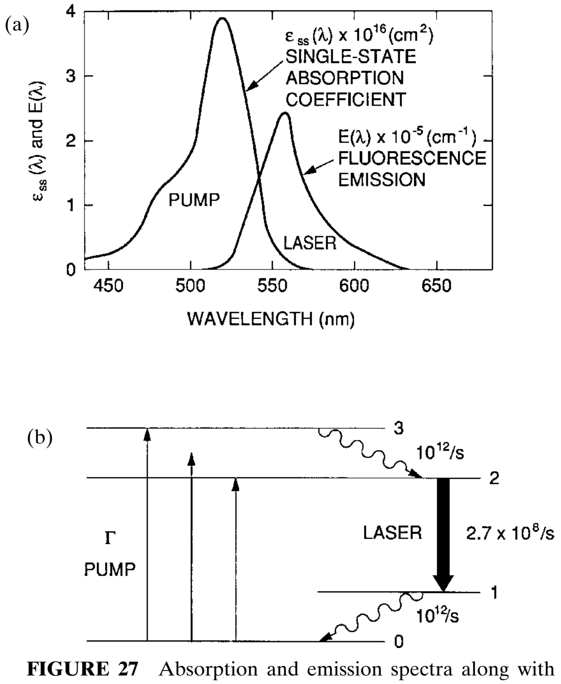

FIGURE 27 Absorption and emission spectra along with the energy-level diagram of an Rh6G organic dye laser showing both (*a*) the broad pump and emission bandwidths and (*b*) the fast decay of the lower laser level.

Dye lasers, with their broad gain spectrum, are particularly attractive for producing ultrashort mode-locked pulses. The shortest light pulses ever generated, of the order of 6×10^{-15} sec, were produced with mode-locked dye lasers. A mode-locked dye laser cavity is shown in Fig. 14 with a thin dye gain region located within an astigmatically compensated laser cavity.

Dielectric Solid-State Laser Gain Media

Ruby Laser.[5,7] The ruby laser, with an output at 694.3 nm, was the first laser ever developed. It consisted of a sapphire (Al_2O_3) host material into which was implanted a chromium laser species in the form of Cr^{3+} ions at a concentration of 0.05 percent as the amplifying medium. The ruby laser involves a three-level optical pumping scheme, with the excitation provided by flash lamps, and operates either in a pulsed or cw mode. The three-level scheme for the ruby laser (Fig. 6) requires a large fraction of the population to be pumped out of the ground state before an inversion occurs. Therefore, the ruby laser is not as efficient as other solid-state lasers such as the Nd:YAG laser which employs a four-level pumping scheme (Fig. 8). It is therefore no longer used as much as it was in the early days.

Nd:YAG and Nd:Glass Lasers.[7] Neodymium atoms, in the form of Nd^{3+} ions, are doped into host materials, including crystals such as yttrium-aluminum-garnet (YAG) and various forms of glass, in concentrations of approximately one part per hundred. The pumping scheme is a four-level system as shown in Fig. 8. When implanted in YAG crystals to produce what is referred to as an Nd:YAG laser, the laser emits primarily at 1.06 μm with continuous powers of up to 250 W and with pulsed powers as high as several MW. Difficulties in growing Nd:YAG crystals limit the size of commonly used laser rods to a maximum of 1 cm in diameter and 10 cm in length. Although this size limitation is somewhat restrictive, a YAG crystal has the advantage of high thermal conductivity allowing the rapid removal of wasted heat due to inefficient excitation. Slab geometries have recently been developed to compensate for focusing due to thermal gradients and gradient-induced stresses within the amplifier medium, thereby allowing higher average powers to be achieved. Efficient GaAs laser diodes are also being used to pump Nd:YAG amplifiers (see Fig. 15) since the diode pump wavelength matches a very strong pump absorption wavelength for the Nd^{3+} ion. This absorption wavelength is near the threshold pump energy, thereby minimizing the generation of wasted heat. Also, the diode pump laser can be made to more efficiently match the Nd laser mode volume than can a flash lamp.

Under long-pulse, flash-lamp-pumped operation, Nd:YAG lasers can produce 5 J/pulse at 100 Hz from a single rod. The pulses are trains of relaxation oscillation spikes lasting 3–4 msec which is obtained by powerful, long-pulse flash-lamp pumping. Q-switched Nd:YAG lasers, using a single Nd:YAG laser rod, can provide pulse energies of up to 1.5 J/pulse at repetition rates up to 50 Hz (75 W of average power).

Nd:glass lasers have several advantages over Nd:YAG lasers. They can be made in much larger sizes, allowing the construction of very large amplifiers. Nd:glass has a wider gain bandwidth which makes possible the production of shorter mode-locked pulses and a lower stimulated emission cross section. The latter property allows a larger population inversion to be created and thus more energy to be stored before energy is extracted from the laser. Nd:glass amplifiers operate at a wavelength near that of Nd:YAG, at 1.054 μm, for example, with phosphate glass, with a gain bandwidth 10–15 times broader than that of Nd:YAG. This larger gain bandwidth lowers the stimulated emission cross section compared to that of Nd:YAG, which allows increased energy storage when used as an amplifier, as mentioned above.

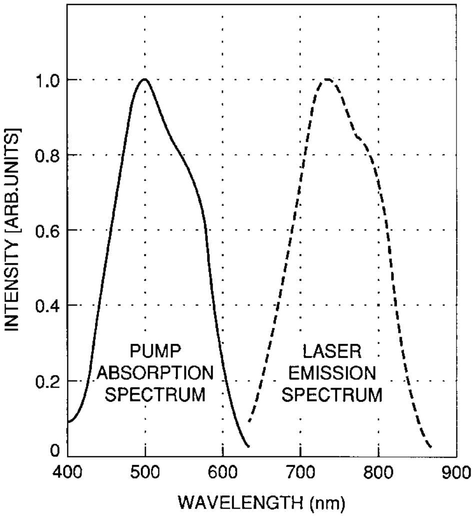

FIGURE 28 Absorption and emission spectra of a Ti:Al_2O_3 laser crystal showing the extremely broad emission (gain) spectrum for this material.

The large Nd:glass lasers system at Lawrence Livermore National Laboratory, referred to as NOVA, has produced a pulse energy of 100 KJ at the fundamental frequency and 40 KJ at the third harmonic frequency at 351 nm. This system was developed for studies associated with the inertial confinement laser fusion program.

Ti:Al_2O_3 Laser and Other Broad Bandwidth Solid-State Lasers.[7]

Another class of solid-state lasers provides emission and gain over a bandwidth of the order of 100–400 nm in the near-infrared, as indicated in Fig. 28. The pump absorption band is in the visible spectrum, thus allowing such pump sources as flash lamps and other lasers. The Ti:AL_2O_3 laser is perhaps the most well-known laser of this category in that it has the widest bandwidth, covering a wavelength range from 0.67 μm to greater than 1.07 μm. Other lasers of this type include alexandrite (Cr:$BeAl_2O_4$), lasing from 0.7 to 0.8 μm, and Cr:LiSAF which lases from 0.8 to 1.05 μm. These lasers are used in applications where either wide tunability or short-pulse production are desired. Pulses as short as 40 fsec have been produced with mode-locked versions of these lasers. Ti:Al_2O_3 lasers, although offering very wide gain bandwidth, have relatively short upper-laser-level lifetimes (3 μsec), thereby making them less efficient when pumping with conventional flash lamps. Cr:LiSAF lasers have longer upper-level lifetimes (67 μsec), closer to that of Nd:YAG or Nd:glass and have demonstrated efficient laser operation with pumping technologies developed for Nd:YAG lasers.

Color-Center Laser.[21] Color-center laser gain media are produced by a different form of impurity species than most solid-state lasers. Special defect centers (F-centers) are produced within alkali-halide crystals at a density of 1 part in 10,000 by irradiation with x rays. These defect centers have absorbing regions in the visible portion of the spectrum and emission (and gain) in the near-infrared. A variety of crystals are used to span the laser wavelength spectrum from 0.8 to 4.0 μm. Disadvantages of color-center lasers include operation at temperatures well below room temperature and the necessity to re-form the color centers at intervals of weeks or months in most cases.

Semiconductor Laser Gain Media

Semiconductor Lasers.[22] Semiconductor or diode lasers, typically about the size of a grain of salt, are the smallest lasers yet devised. They consist of a *p*-*n* junction formed in semiconductor crystal such as GaAs or InP in which the *p*-type material has an excess of holes (vacancies due to missing electrons) and the *n*-type material has an excess of electrons. When these two types of materials are brought together to form a junction, and an electric field in the form of a voltage is applied across the junction in the appropriate direction, the electrons and holes are brought together and recombine to produce recombination radiation at or near the wavelength associated with the bandgap energy of the material. The population of electrons and holes within the junction provides the upper-laser-level population, and the recombination radiation spectrum is the gain bandwidth $\Delta\nu$ of the laser, typically of the order of 0.5 to 1.0 nm.

The extended gain length required for these lasers is generally provided by partially reflecting cleaved parallel faces at the ends of the crystals which serve as an optical cavity. Because the cavity is so short, the longitudinal modes are spaced far apart in frequency ($\Delta\nu \cong 1\text{–}5 \times 10^{11}$ Hz or several tenths of a nanometer), and thus it is possible to obtain single longitudinal mode operation in such lasers. They require a few volts to operate with milliamperes of current.

Heterostructure semiconductor lasers include additional layers of different materials of similar electronic configurations, such as aluminum, indium, and phosphorous, grown adjacent to the junction to help confine the electron current to the junction region in order to minimize current and heat dissipation requirements (see Fig. 29). The laser mode in the transverse direction is either controlled by gain guiding, in which the gain is produced over a specific narrow lateral extent determined by fabrication techniques, or by index guiding, in which the index of refraction in the transverse direction is varied to provide total internal reflection of a guided mode. Quantum-well lasers have a smaller gain region (cross section), which confines the excitation current and thus the laser mode to an even smaller lateral region, thereby significantly reducing the threshold current and also the heat

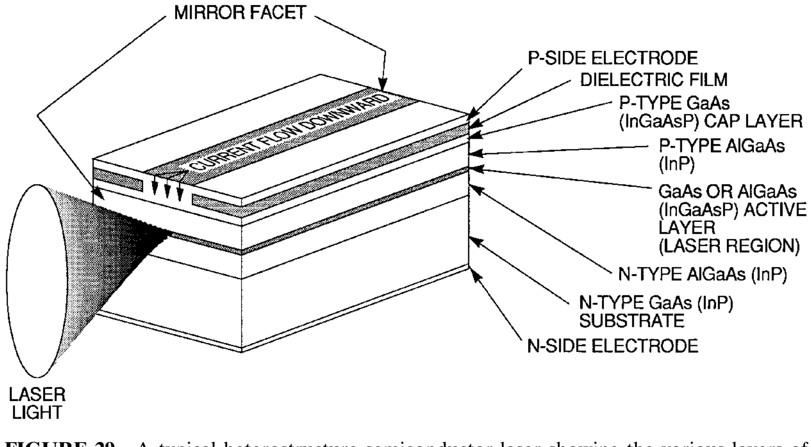

FIGURE 29 A typical heterostructure semiconductor laser showing the various layers of differential materials and the narrow region where current flows to produce the gain region in the active layer.

dissipation requirements. Because of these low threshold requirements, quantum-well semiconductor lasers are used almost exclusively for most semiconductor laser applications.

Multiple semiconductor lasers fabricated within the same bulk structure, known as *semiconductor arrays,* can be operated simultaneously to produce combined cw power outputs of up to 10 W from a laser crystal of dimensions of the order of 1 mm or less. Semiconductor lasers have also been fabricated in multiple arrays mounted vertically on a chip with the mirrors in the plane of the chip. They are known as *vertical cavity semiconductor lasers.* Each of the individual lasers has dimensions of the order of 5 μm and can be separately accessed and excited.

Semiconductor lasers operate over wavelengths ranging from 0.63 to 1.65 μm by using special doping materials to provide the expanded or contracted bandgap energies that provide the varied wavelengths. Also, new semiconductor lasers in the blue-green spectral region in crystals of ZnSe have recently been developed, but presently operate only at temperatures well below room temperature.

Laser Gain Media in Vacuum

Free Electron Laser.[23] Free-electron lasers are significantly different than any other type of laser in that the laser output does not result from transitions between discrete energy levels in specific materials. Instead, a high-energy beam of electrons, such as that produced by a synchrotron, traveling in a vacuum with kinetic energies of the order of 1 MeV, are directed to pass through a spatially varying magnetic field produced by two regular arrays of alternating magnet poles located on opposite sides of the beam as shown in Fig. 30. The alternating magnetic field causes the electrons to oscillate back and forth in a direction transverse to the beam direction. The frequency of oscillation is determined by the electron beam energy, the longitudinal spacing of the alternating poles (the magnet period), and the separation between the magnet arrays on opposite sides of the beam. The transverse oscillation of the electrons causes them to radiate at the oscillation frequency and to stimulate other electrons to oscillate and thereby radiate at the same frequency, in phase with the originally oscillating electrons. The result is an intense tunable beam of light emerging from the end of the device. Mirrors can be placed at the ends of the radiated beam to produce feedback and extra amplification.

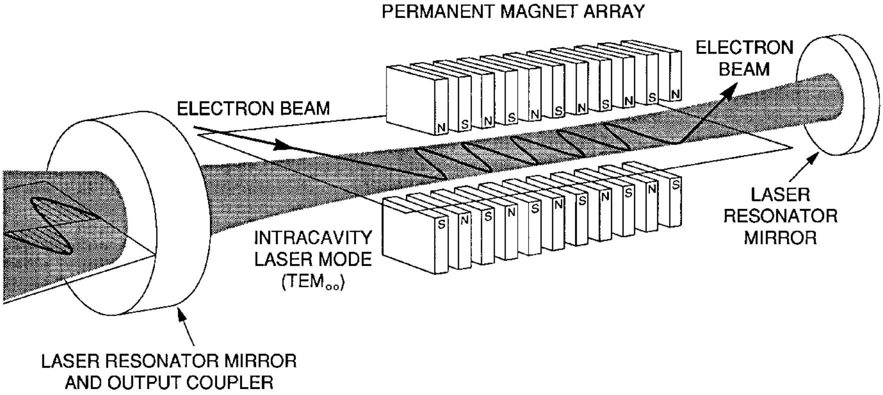

FIGURE 30 A general diagram of a free-electron laser showing how the electron beam is introduced into the cavity and how the alternating magnets cause the beam to oscillate to produce laser radiation.

Free-electron lasers have operated at wavelengths ranging from the near-ultraviolet (0.25 μm) to the far-infrared (6 mm) spectral regions. They are efficient devices and also offer the potential of very high average output powers.

12.1 GLOSSARY

c	velocity of light
E_g	semiconductor energy bandgap
h	Planck's constant
I_T	total LED current
J	LED current density
k	Boltzmann's constant
M	magnification
n_0	low index of refraction medium
n_1	high index of refraction medium
q	electron charge
T	temperature
V	applied voltage
η_i	internal quantum efficiency
θ_c	critical angle
λ	emission wavelength
τ	total minority carrier lifetime
τ_n	nonradiative minority carrier lifetime
τ_r	radiative minority carrier lifetime

12.2 INTRODUCTION

Over the past 25 years the light-emitting diode (LED) has grown from a laboratory curiosity to a broadly used light source for signaling applications. In 1992 LED production reached a level of approximately 25 billion chips, and $2.5 billion worth of LED-based components were shipped to original equipment manufacturers.

This article covers light-emitting diodes from the basic light-generation processes to descriptions of LED products. First, we will deal with light-generation mechanisms and light extraction. Four major types of device structures—from simple grown or diffused homojunctions to complex double heterojunction devices are discussed next, followed by a description of the commercially important semiconductors used for LEDs, from the pioneering GaAsP system to the AlGaInP system that is currently revolutionizing LED technology. Then processes used to fabricate LED chips are explained—the growth of GaAs and GaP substrates; the major techniques used for growing the epitixal material in which the light-generation processes occur; and the steps required to create LED chips up to the point of assembly. Next the important topics of quality and reliability—in particular, chip degradation and package-related failure mechanisms—will be addressed. Finally, LED-based products, such as indicator lamps, numeric and alphanumeric displays, optocouplers, fiber-optic transmitters, and sensors, are described.

This article covers the mainstream structures, materials, processes, and applications in use today. It does not cover certain advanced structures, such as quantum well or strained layer devices, a discussion of which can be found in Chap. 13, "Semiconductor Lasers." The reader is also referred to Chap. 13 for current information on edge-emitting LEDs, whose fabrication and use are similar to lasers.

For further information on the physics of light generation, the reader should consult Refs. 1–11. Semiconductor material systems for LEDs are discussed in Refs. 13–24. Crystal growth, epitaxial, and wafer fabrication processes are discussed in detail in Refs. 25–29.

12.3 LIGHT-GENERATION PROCESSES

When a *p*-*n* junction is biased in the forward direction, the resulting current flow across the boundary layer between the *p* and *n* regions has two components: holes are injected from the *p* region into the *n* region and electrons are injected from the *n* region into the *p* region. This so-called minority-carrier injection disturbs the carrier distribution from its equilibrium condition. The injected minority carriers recombine with majority carriers until thermal equilibrium is reestablished. As long as the current continues to flow, minority-carrier injection continues. On both sides of the junction, a new steady-state carrier distribution is established such that the recombination rate equals the injection rate.[1,2]

Minority-carrier recombination is not instantaneous. The injected minority carriers have to find proper conditions before the recombination process can take place. Both energy and momentum conservation have to be met. Energy conservation can be readily met since a photon can take up the energy of the electron-hole pair, but the photon doesn't contribute much to the conservation of momentum. Therefore, an electron can only combine with a hole of practically identical and opposite momentum. Such proper conditions are not readily met, resulting in a delay. In other words, the injected minority carrier has a finite lifetime τ_r before it combines radiatively through the emission of a photon.[2] This average time to recombine radiatively through the emission of light can be visualized as the average time it takes an injected minority carrier to find a majority carrier with the right momentum to allow radiative recombination without violating momentum conservation.

Unfortunately, radiative recombination is not the only recombination path. There are also crystalline defects, such as impurities, dislocations, surfaces, etc., that can trap the injected minority carriers. This type of recombination process may or may not generate light. Energy and momentum conservation are met through the successive emission of phonons. Again, the recombination process is not instantaneous because the minority carrier first has to diffuse to a recombination site. This nonradiative recombination process is characterized by a lifetime τ_n.[2]

Of primary interest in design of light-emitting diodes is the maximization of the radiative recombination relative to the nonradiative recombination. In other words, it is of interest to develop conditions where radiative recombination occurs fairly rapidly compared with nonradiative recombination. The effectiveness of the light-generation process is described by the fraction of the injected minority carriers that recombine radiatively compared to the total injection. The internal quantum efficiency, η_i can be calculated from τ_r and τ_n. The combined recombination processes lead to a total minority-carrier lifetime τ given by Eq. (1):

$$\frac{1}{\tau}=\frac{1}{\tau_r}+\frac{1}{\tau_n} \tag{1}$$

η_i is simply computed from Eq. (1) as the fraction of carriers recombining radiatively:[2]

$$\eta_i=\frac{\tau_n}{\tau_r+\tau_n} \tag{2}$$

Of interest are two simple cases: in the case of excellent material quality (large τ_n) or efficient radiative recombination conditions (small τ_r), the internal quantum efficiency approaches 100 percent. For the opposite case ($\tau_n \ll \tau_r$), we find $\eta_i \approx \tau_n/\tau_r \ll 1$. As discussed under "Material Systems," there are several families of III-V compounds with internal quantum efficiencies approaching 100 percent. There are also other useful semiconductor materials with internal quantum efficiencies in the 1 to 10 percent range.

To find material systems for LEDs with a high quantum efficiency, one has to understand the band structure of semiconductors. The band structure describes the allowed distribution of energy and momentum states for electrons and holes (see Fig. 1

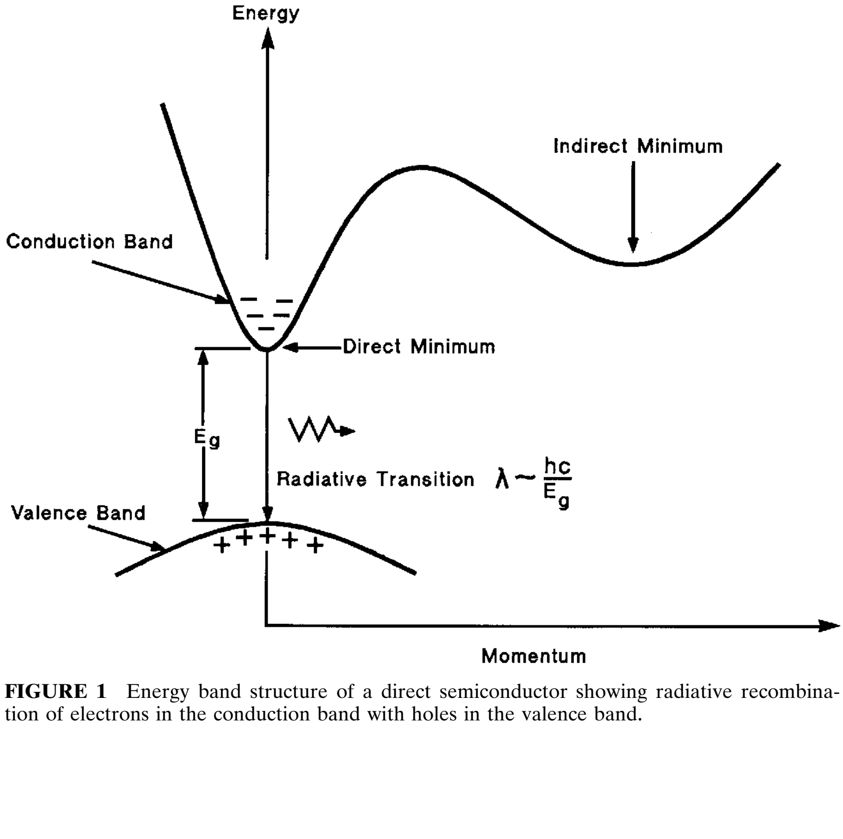

FIGURE 1 Energy band structure of a direct semiconductor showing radiative recombination of electrons in the conduction band with holes in the valence band.

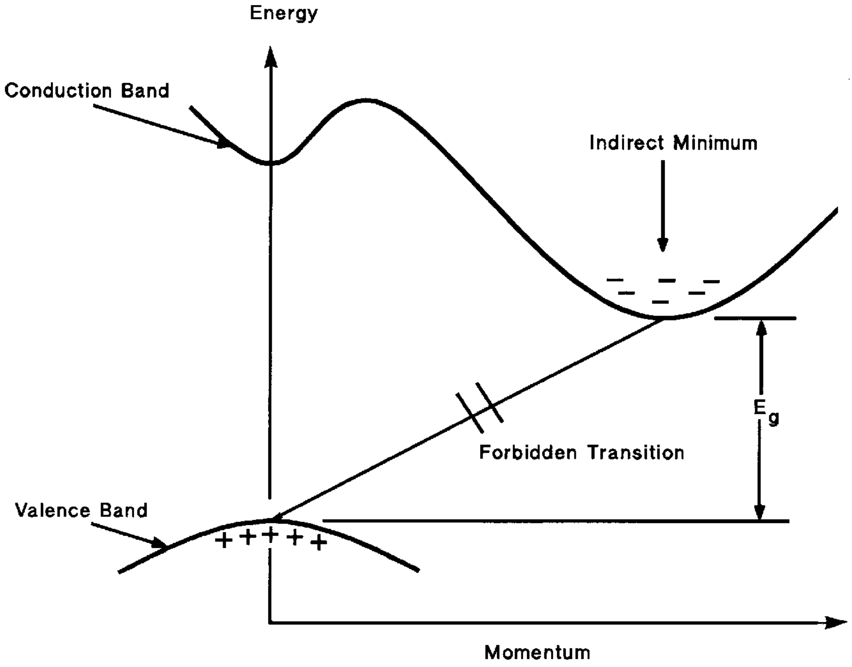

FIGURE 2 Energy band structure of an indirect semiconductor showing the conduction-band minima and valence-band maximum at different positions in momentum space. Radiative recombination of conduction-band electrons and valence-band holes is generally forbidden.

and Ref. 2). In practically all semiconductors the lower band, also known as the *valence band,* has a fairly simple structure, a paraboloid around the ⟨0, 0, 0⟩ crystalline direction. Holes will take up a position near the apex of the paraboloid and have very small momentum. The upper band, also known as the *conduction band,* is different for various semiconductor materials. All semiconductors have multiple valleys in the conduction band. Of practical interest are the valleys with the lowest energy. Semiconductor materials are classified as either *direct* or *indirect.*[1–3] In a direct semiconductor, the lowest valley in the conduction band is directly above the apex of the valence-band paraboloid. In an indirect semiconductor, the lowest valleys are not at ⟨0, 0, 0⟩, but at different positions in momentum/energy space (see Fig. 2). Majority or minority carriers mostly occupy the lowest energy states, i.e., holes near the top of the valence band paraboloid and electrons near the bottom of the lowest conduction-band valley.

In the case of a direct semiconductor the electrons are positioned directly above the holes at the same momentum coordinates. It is relatively easy to match up electrons and holes with proper momentum-conserving conditions. Thus, the resulting radiative lifetime τ_r is short. On the other hand, electrons in an indirect valley will find it practically impossible to find momentum-matching holes and the resulting radiative lifetime will be long. Injected carriers in indirect material generally recombine nonradiatively through defects.

In a direct semiconductor, such as GaAs, the radiative lifetime τ_r is in the range of 1–100 ns, depending on doping, temperature, and other factors. It is relatively easy to grow crystals with sufficiently low defect density such that τ_n is in the same range as τ_r.

For indirect semiconductors, such as germanium or silicon, the radiative recombination process is extremely unlikely, and τ_r is in the range of seconds.[1] In this case, $\tau_r \gg \tau_n$, and practically all injected carriers recombine nonradiatively.

The wavelength of the photons emitted in a radiative recombination event is determined by the energy difference between the recombining electron-hole pair. Since carriers relax quickly to an energy level near the top of the valence band (holes), or the bottom of the conduction band (electrons), we have the following approximation for the wavelength λ of the emitted photon (see Fig. 1):

$$\lambda \approx hc/E_g \tag{3}$$

where h = Planck's constant, c = velocity of light, and E_g = bandgap energy.

This relation is only an approximation since holes and electrons are thermally distributed at levels slightly below the valence-band maximum and above the conduction-band minimum, resulting in a finite linewidth in the energy or wavelength of the emitted light. Another modification results from a recombination between a free electron and a hole trapped in a deep acceptor state. See Ref. 2 for a discussion of various recombination processes.

To change the wavelength or energy of the emitted light, one has to change the bandgap of the semiconductor material. For example, GaAs with a bandgap of 1.4 eV has an infrared emission wavelength of 900 nm. To achieve emission in the visible red region, the bandgap has to be raised to around 1.9 eV. This increase in E_g can be achieved by mixing GaAs with another material with a wider bandgap, for instance GaP with $E_g = 2.3$ eV. By adjusting the ratio of arsenic to phosphorous the bandgap of the resulting ternary compound, GaAsP, can be tailored to any value between 1.4 and 2.3 eV.[3]

The resulting band structure with varying As to P ratio is illustrated in Fig. 3. Note, the

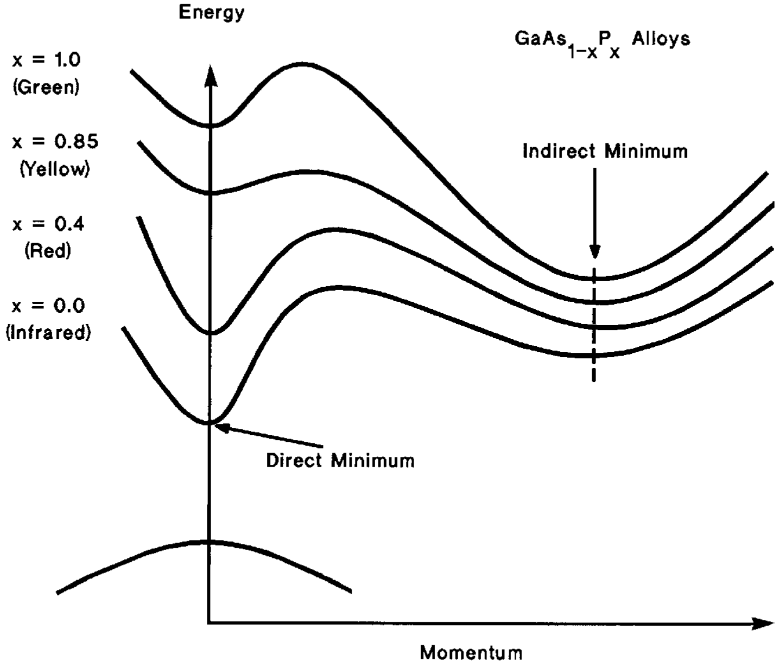

FIGURE 3 Energy band diagram for various alloys of the $GaAs_{1-x}P_x$ material system showing the direct and indirect conduction-band minima for various alloy compositions.

two conduction-band valleys do not move upward in energy space at the same rate. The direct valley moves up faster than the indirect valley with increasing phosphorous composition. At a composition of around 40 percent GaP and 60 percent GaAs, the direct and indirect valleys are about equal in energy. When the valleys are approximately equal in energy, electrons in the conduction band can scatter from the direct valley into the indirect valley. While the direct valley electrons still undergo rapid radiative recombination, the indirect valley electrons have a long radiative lifetime and either have to be scattered back to the direct valley or they will recombine nonradiatively. In other words, near this crossover between direct and indirect valleys, the radiative efficiency drops off dramatically, and for compositions with greater than 40 percent phosphorous the direct radiative recombination is practically nonexistent.[3,4]

The above discussion indicates that indirect semiconductors are not suitable for efficient generation of light through minority-carrier recombination. Fortunately, the introduction of so-called isoelectronic impurities can circumvent this limitation and introduces a new radiative recombination process.[5] A commonly used isoelectronic trap is generated by substituting a nitrogen atom for phosphorous in the GaAsP system[6–11] (see Fig. 4). Since N and P both have five electrons in their outer shell, the trap is electrically neutral. However, the stronger electronegativity of N relative to P can result in capture of an electron from the conduction band. Since the electron is very tightly bound to the impurity atom, its wave function in momentum space is spread out and has reasonable magnitude at $\langle k = 0\rangle$ in momentum space.[10] The negatively charged defect can attract a free hole to form a loosely bound electron-hole pair or "exciton." This electron-hole pair has a high probability to recombine radiatively. The energy of the emitted light is less than E_g. Another isoelectronic trap in GaP is formed by ZnO pairs (Zn on a Ga site and O on a P

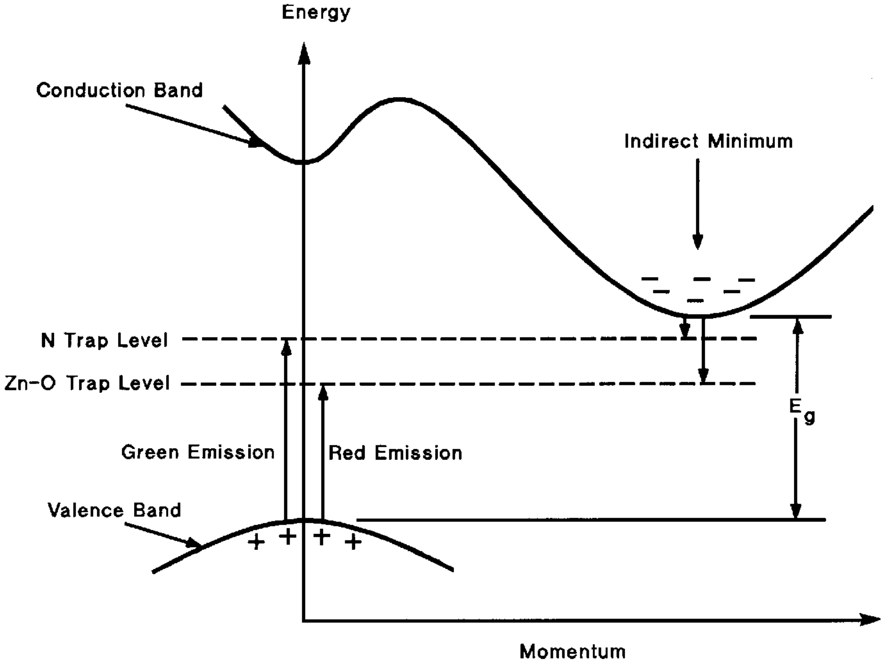

FIGURE 4 Formation of excitons (electron-hole pairs) by the addition of isoelectronic dopants N and ZnO to an indirect semiconductor. The excitons have a high probability to recombine radiatively.

site) (see Fig. 4). The ZnO trap is deeper than the N trap, resulting in longer wavelength emission in the red region of the spectrum.[1]

The recombination process for exciton recombination is quite complex. For a detailed analysis, the reader is referred to Ref. 10. One result of this analysis is the recognition that the bound exciton has a relatively long lifetime in the range of 100–1000 ns. Light emission by exciton recombination is generally slower than emission due to direct band-to-band recombination.

12.4 LIGHT EXTRACTION

Generating light efficiently within a semiconductor material is only one part of the problem to build an efficient light source. The next challenge is the extraction of light from within the LED chip to the outside. The designer must consider total internal reflection.[1] According to Snell's law, light can escape from a medium of high index of refraction n_1 into a medium of low index refraction n_0 only if it intersects the surface between the two media at an angle from normal less than the critical angle θ_c with θ_c being defined by Eq. (4):

$$\theta_c = \arcsin n_0/n_1 \tag{4}$$

Most semiconductor LEDs have an isotropic emission pattern as seen from within the light-generating material. Assuming a cubic shape for the LED chip, because of internal reflections, only a small fraction of the isotropically emitted light can escape any of the six surfaces. As a case in point, let us calculate the emission through the top surface. For typical light-emitting semiconductors, n_1 is in the range of 2.9 to 3.6. If $n_1 = 3.3$ and $n_0 = 1.0$ (air), we find $\theta_c = 17.6°$. The emission from an isotropic source into a cone with a half angle of θ_c is given by $(1 - \cos\theta_c)/2$. After correcting for Fresnel reflections, only 1.6 percent of the light generated escapes through the LED top surface into air. Depending on chip and *p-n* junction geometry, virtually all of the remaining light (98.4 percent) is reflected and absorbed within the LED chip.

The fraction of light coupled from chip to air is a function of the number of surfaces through which the chip can transmit light effectively. Most LED chips are called "absorbing substrate" (AS) chips. In such a chip, the starting substrate material (discussed later under "Substrate Technology") has a narrow bandgap and absorbs all the light with energy greater than the bandgap of the substrate. Consider the case of a GaAsP LED grown on a GaAs substrate. The emitted light ($E_g > 1.9$ eV) is absorbed by the GaAs substrate ($E_g = 1.4$ eV). Thus, a GaAsP-emitting layer on a GaAs substrate can transmit only through its top surface. Light transmitted toward the side surfaces or downward is absorbed.

To increase light extraction, the substrate or part of the epitaxial layers near the top of the chip has to be made of a material transparent to the emitted light. The "transparent substrate" (TS) chip is designed such that light transmitted towards the side surfaces within θ_c half-angle cones can escape. Assuming that there is negligible absorption between the point of light generation and the side walls, this increases the extraction efficiency by a factor of five (five instead of one escape cones).

In a TS chip, additional light can be extracted if the side walls are nonplanar, i.e., if light from outside an escape cone can be scattered into an escape cone. This process increases the optical path within the chip and is very dependent on residual absorption. In a chip with low absorption and randomizing side surfaces, most of the light should escape. Unfortunately, in practical LED structures, there are several absorption mechanisms left such as front and back contacts, crystal defects, and absorption in areas where secondary radiative recombination is inefficient.

TABLE 1 Extraction Efficiency into Air or Plastic for Three Types of Commonly Used LED Chips

		Typical extraction efficiency	
Chip type	No. cones	Air, %	Plastic, %
AS	1	1.5	4
Thick window	3	4.5	12
TS	5	7.5	18

A common approach is to use a hybrid chip with properties between AS and TS chips. These chips utilize a thick, transparent window layer above the light-emitting layer. If this layer is sufficiently thick, then most of the light in the top half of the cones transmitted toward the side surfaces will reach the side of the chip before hitting the substrate. In this case of hybrid chips, the efficiency is between that of AS and TS chips as shown in Table 1.

Another important way to increase extraction efficiency is derived from a stepwise reduction in the index of refraction from chip to air. If the chip is first imbedded in a material with an intermediate index, i.e., plastic with $n_2 = 1.5$, then the critical angle θ_c between chip and plastic is increased to 27°. The extraction efficiency relative to air increases by the ratio of $(n_2/n_0)^2$ plus some additional correction for Fresnel-reflection losses. The gain from plastic encapsulation is usually around 2.7× compared to air. Chips with multipath internal reflection will result in lower gains. It is important to note that this gain can be achieved only if the plastic/air interface can accommodate the increased angular distribution through proper lenslike surface shaping or efficient scattering optics. Table 1 illustrates the approximate extraction efficiencies achieved by the three dominant chip structures in air and in plastic. The numbers assume only first-pass extraction, limited absorption, and no multiple reflections within the chip.

12.5 DEVICE STRUCTURES

LED devices come in a broad range of structures. Each material system (see following section) requires a different optimization. The only common feature for all LED structures is the placement of the *p-n* junction where the light is generated. The *p-n* junction is practically never placed in the bulk-grown substrate material for the following reasons:

- The bulk-grown materials such as GaAs, GaP, and InP usually do not have the right energy gap for the desired wavelength of the emitted light.
- The light-generating region requires moderately low doping that is inconsistent with the need for a low series resistance.
- Bulk-grown material often has a relatively high defect density, making it difficult to achieve high efficiency.

Because of these reasons, practically all commercially important LED structures utilize a secondary growth step on top of a single-crystal bulk-grown substrate material. The secondary growth step consists of a single-crystal layer lattice matched to the substrate.

This growth process is known as *epitaxial growth* and is described in a later section of this chapter.

The commonly used epitaxial structures can be classified into the following categories:

- Homojunctions
  - grown
  - diffused
- Heterojunctions
  - single confinement
  - double confinement

Grown Homojunctions

Figure 5 illustrates one of the simplest design approaches to an LED chip. An *n*-type GaAs layer with low to moderate doping density is grown on top of a highly doped *n*-type substrate by a vapor or liquid-phase epitaxial process (see "Epitaxial Technology"). After a growth of 5–10 μm, the doping is changed to *p*-type for another 5–10 μm. A critical dimension is the thickness of the epitaxial *p*-layer. The thickness should be larger than the diffusion length of electrons. In other words, the electrons should recombine radiatively in the epitaxially grown *p* layer before reaching the surface. The *p*-layer should be of sufficiently high quality to meet the condition for efficient recombination, i.e., $\tau_n \gg \tau_r$. In addition, the side surfaces may have to be etched to remove damage. Damage and other defects where the *p*-*n* junction intercepts the chip surface can lead to a substantial leakage current that reduces efficiency, especially at low drive levels.

The structure of Fig. 5 was used in some of the earliest infrared emitters (wavelength 900 nm). Efficiency was low, typically 1 percent. Modern infrared emitters use Si-doped

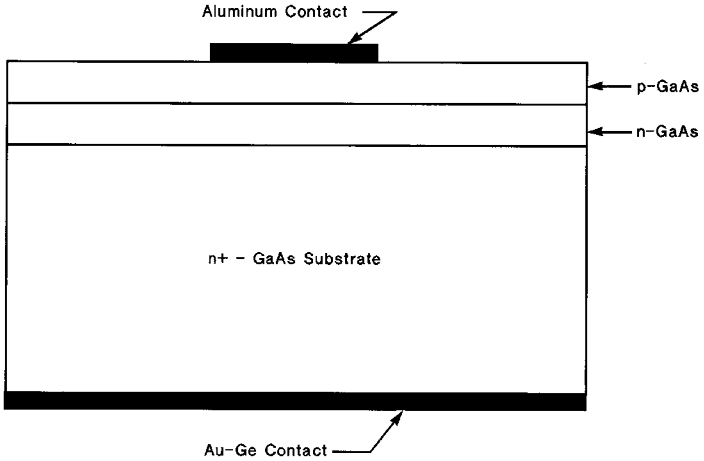

FIGURE 5 Cross section of an infrared LED chip. A *p*-*n* junction is formed by epitaxially growing *n*- and *p*-doped GaAs onto an *n*+-doped GaAs substrate.

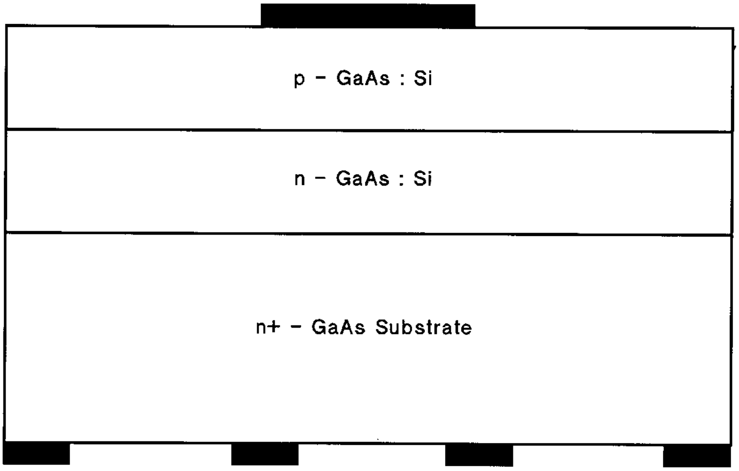

FIGURE 6 A high-efficiency IR LED made by LPE growth of GaAs that is doped with silicon on both the *p* and *n* sides of the junction. To increase external quantum efficiency, a partly reflective back contact is employed.

GaAs (see Fig. 6). The detailed recombination mechanism in GaAs:Si even today is quite controversial and goes beyond the scope of this publication. The recombination process has two important characteristics: (1) the radiative lifetime τ_r is relatively slow, i.e., in the range of 1 μs; and (2) the wavelength is shifted to 940 nm. At this wavelength the GaAs substrate is partly transparent, making this device a quasi-TS structure with efficiencies into plastic of 5 to 10 percent.

Diffused Homojunction

The chip structure of Fig. 5 can also be produced by a zinc (Zn) diffusion into a thick *n*-layer. The commercially most significant structure of this type is shown in Fig. 7. By replacing 40 percent of the As atoms with P atoms, the bandgap is increased to 1.92 eV to make a GaAsP LED that emits visible red light. In this case, the *p-n* junction is diffused selectively by using a deposited layer of silicon-nitride as a diffusion mask. This structure of Fig. 7 has several advantages over the structure of Fig. 5. Lateral diffusion of Zn moves the intersection of the junction with the chip surface underneath the protecting Si_3N_4 layer. This layer protects the junction from contamination and adds to the long-term stability of the device. In addition, it is important for applications requiring more than one clearly separated light-emitting area. For instance, seven-segment displays, such as those used in the early hand-held calculators, are made by diffusing seven long and narrow stripes into a single chip of GaAsP material. (See Fig. 8.) This chip consists of eight (seven segments plus decimal point) individually addressable *p*-regions (anodes) with a common *n*-type cathode. Such a chip is feasible only in an AS-type structure because the individual segments have to be optically isolated from each other. A TS-type structure results in unacceptable levels of crosstalk.

Figure 7 shows another feature of practical LED devices. The composition with 40 percent P and 60 percent As has a lattice constant (atomic spacing) that is different from the GaAs substrate. Such a lattice mismatch between adjacent layers would result in a very high density of dislocations. To reduce this problem to an acceptable level, one has to slowly increase the phosphorous composition from 0 percent at the GaAs interface to 40

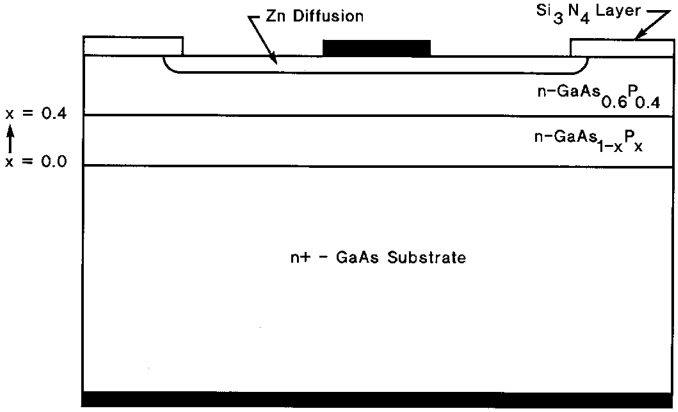

FIGURE 7 GaAsP LED which emits at 650 nm. On a GaAs substrate, a layer is grown whose composition varies linearly from GaAs to $GaAs_{0.6}P_{0.4}$, followed by a layer of constant composition. Zinc is selectively diffused using an Si_3N_4 mask to form the light-emitting junction.

percent over a 10–20-μm-thick buffer layer. Typically, the buffer layer is graded linearly. The phosphorous composition is increased linearly from bottom to top. The thicker the buffer layer, the lower is the resulting dislocation density. Cost constraints keep the layer in the 10–15-μm range. The layer of constant composition (40 percent P) has to be thick enough to accommodate the Zn diffusion plus the diffusion length of minority carriers. A thickness range of 5–10 μm is typical.

Another variation of a homojunction is shown in the TS-chip structure of Fig. 9. Instead of an absorbing GaAs substrate, one starts with a transparent GaP substrate. The graded layer has an inverse gradient relative to the chip shown in Fig. 7. The initial growth is 100 percent GaP phasing in As linearly over 10–15 μm. At 15 percent As, the emission is in the yellow range (585 nm), at 25 percent in the orange range (605 nm), and at 35 percent in the red range (635 nm). Figure 3 shows the approximate band structure of this material system. The composition range mentioned above has an indirect band structure. To obtain efficient light emission, the region of minority-carrier injection is doped with nitrogen forming an isoelectronic recombination center (see exciton recombination in the first section).

Figure 9 shows an important technique to increase extraction efficiency. In a TS-chip, the major light loss is due to free carrier absorption at the alloyed contacts. Rather than covering the entire bottom surface of the chip with contact metal, one can reduce the contact area either by depositing small contact islands (see Fig. 6) or by placing a dielectric mirror (deposited SiO_2) between the substrate and the unused areas of the back contact (Fig. 9). This dielectric mirror increases the efficiency by 20 to 50 percent at the expense of higher manufacturing cost.

Single Heterojunctions

Heterojunctions introduce a new variable: local variation of the energy bandgap resulting in carrier confinement. Figure 10 shows a popular structure for a red LED emitter chip. A *p*-type layer of GaAlAs with 38 percent Al is grown on a GaAs substrate. The GaAlAs alloy system can be lattice-matched to GaAs; therefore, no graded layer is required as in the GaAsP system of Fig. 7. Next, an *n*-type layer is grown with 75 percent Al. The variation of E_g from substrate to top is illustrated in Fig. 11. Holes accumulate in the

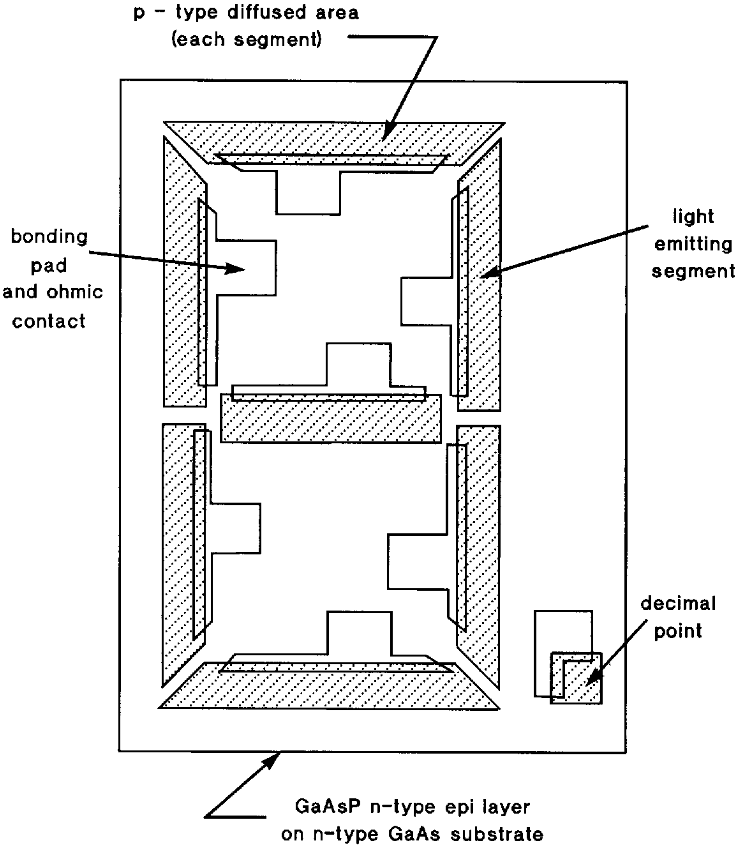

FIGURE 8 Monolithic seven-segment display chip with eight separate diffused regions (anodes) and a common cathode (the GaAs substrate).

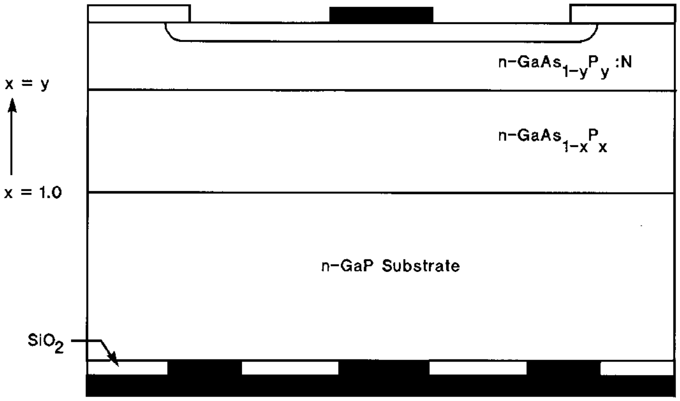
GaAlAs p-layer with the narrower bandgap. Electrons are injected from the n-layer into this p-layer. The holes have insufficient energy to climb the potential barrier into the wide-bandgap material. Holes are confined to the p layer. In the p layer, the radiative recombination time is very short because of the high concentration of holes. As a result, the internal quantum efficiency is quite high. A variation of this structure is a widely used infrared emitter that emits at 880 nm.

Double Heterostructures

The double heterostructure shown in Fig. 12 repeats the p-side confinement of Fig. 10 on the n side. An n-type buffer layer is grown on the GaAs substrate to create a high-quality surface onto which the first n-type GaAlAs confinement layer with 75 percent Al is grown. The active or light-generation layer is a 3-μm-thick p-type layer with 38 percent Al. The top p-type confinement layer again uses 75 percent Al. This structure with the energy-band diagram of Fig. 13 has two advantages: (1) There is no hole injection into the n-type layer with reduced efficiency and a slow hole recombination in the lowly doped n layer. (2) The high electron and hole density in the active layer reduces τ_r, thus increasing device speed



y = 0.85 (yellow), y = 0.75 (orange), y = 0.65 (red)

FIGURE 9 Cross section of a GaAs$_{1-x}$P$_x$ LED which, by changing the composition "x," produces red, orange, or yellow light. Also shown is a reflective back contact made by depositing the contact metallization on top of SiO$_2$.

and efficiency. The increased speed is quite important for LED sources in fiber-optic communication applications. (See "Fiber Optics" subsection later in this chapter.)

The double heterostructure of Fig. 12 represents a one-dimensional containment of injected carriers. Injection and light emission occurs across the entire lateral dimension of the chip. For fiber-optic applications, the light generated over such a large area cannot be effectively coupled into small-diameter fiber. A rule of thumb for fiber coupling requires that the light-emitting area be equal to or, preferably, smaller than the fiber core diameter. This rule requires lateral constraint of carrier injection. The localized diffusion of Fig. 7 is not applicable to grown structures such as those in Fig. 12. The preferred solution inserts

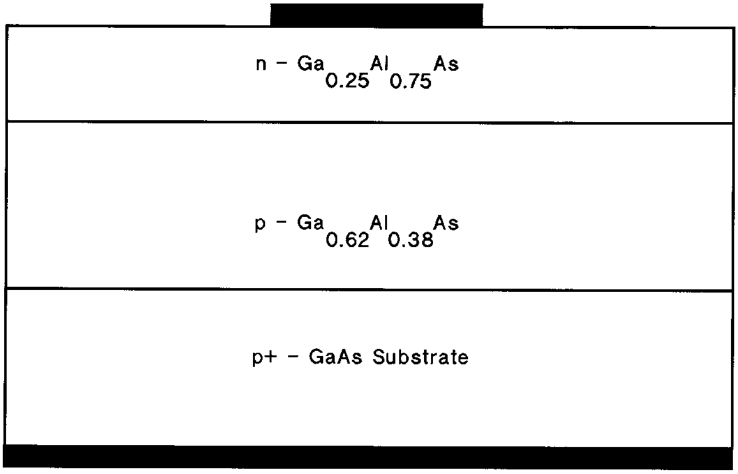


FIGURE 10 Cross section of a single heterostructure LED.

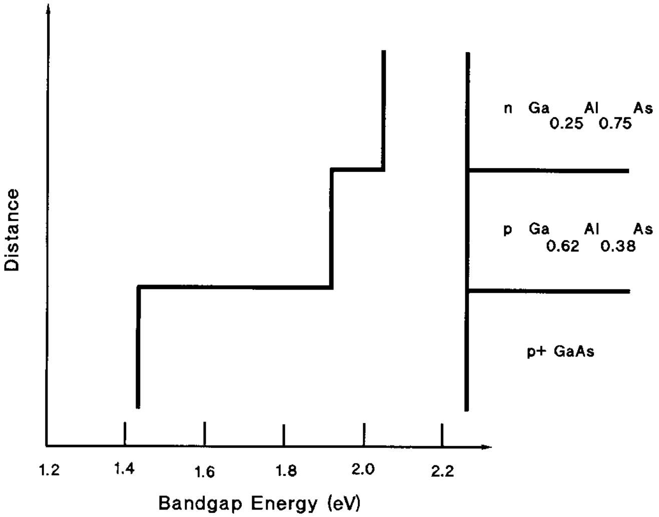

FIGURE 11 Variation in energy bandgap for the various layers in the GaAlAs LED shown in Fig. 10.

an *n* layer between buffer and lower confinement layer (see Fig. 14). A hole etched into the *n* layer allows current flow. Outside of this hole, the *p*-*n* junction between *n* layer and lower confinement layer is reverse-biased, thus blocking any current flow. The disadvantage of this approach is a complication of the growth process. In a first growth process, the *n* layer is grown. Then a hole is etched into the *n* layer using standard photolithographic etching techniques. Finally, a second epitaxial growth is used for the remaining layers.

Another technique to constrain current injection utilizes a small ohmic contact.[12] It is used frequently in conjunction with InP-based fiber-optic emitters (see Fig. 15). A SiO_2 layer limits contact to a small-diameter (typically 25 μm) hole that results in a relatively

small light-emitting area. The etched lens shown for this structure helps to collimate the light for more efficient coupling onto the fiber.[12]

12.6 MATERIALS SYSTEMS

The $GaAs_{1-x}P_x$ System

The most widely used alloy for LEDs is the ternary $GaAs_{1-x}P_x$ system, including its two binary components GaAs and GaP. This system is best described by the composition parameter "x" with $0 \le x \le 1$. For $x = 0$, we have GaAs and for $x = 1$ the composition is GaP. For $x \le 0.4$, the alloy has a direct bandgap. GaAs was developed in the early 1960s as an infrared emitter with a wavelength of 910 nm and an efficiency in the range of 1 percent. This emitter was soon followed by a Si-doped variety. As discussed earlier, this leads to an emission wavelength of 940 nm, a wavelength at which the GaAs substrate is partly transparent. The resulting efficiency is increased substantially and, depending on configuration, is in the 5 to 10 percent range. However, the recombination process is quite slow, resulting in rise and fall times in the 0.5–1.0 μs range (see Table 2). One other drawback is caused by the low absorption coefficient of Si detectors at 940 nm. To absorb 90 percent of the light requires a detector thickness of 60–70 μm. Conventional photo

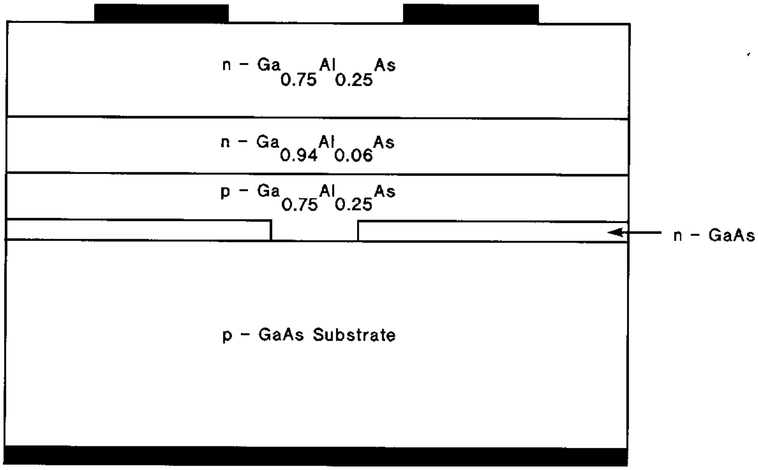

FIGURE 14 Cross section of an LED with three-dimensional carrier confinement. A DH structure is used to confine injected carriers in the $Ga_{0.94}Al_{0.06}As$ layer (direction perpendicular to the junction). The patterned, *n*-type GaAs layer is used to limit current flow in the lateral direction. The small emitting area and the 820–nm emission of this LED makes it ideal for fiber-optic applications.

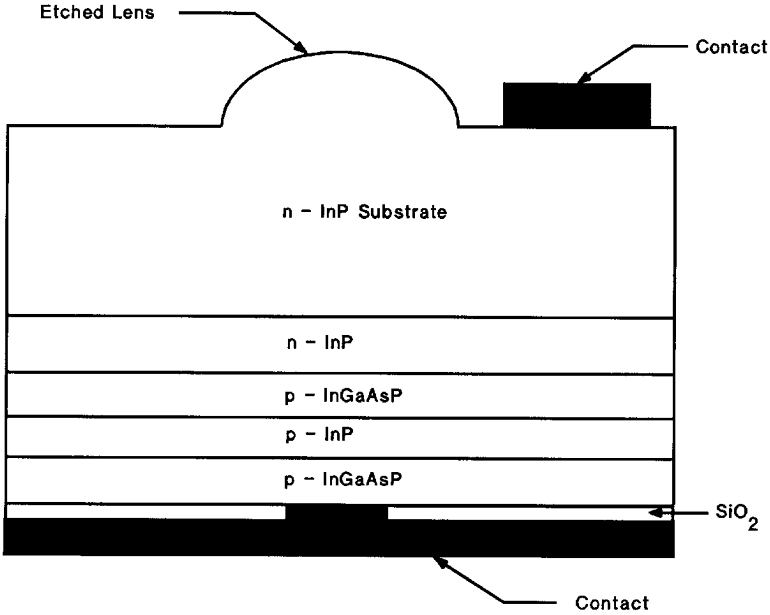

FIGURE 15 Structure of a 1300-nm LED used for optical fiber communications. The cross section shows the DH-layer configuration, limited area back contact for emission-size control, and an etched lens at the top of the chip which magnifies ($M = 2$) the source area and collimates the light for effective coupling into a fiber.

TABLE 2 Performance Summary of LED Chips in the $GaAs_{1-x}P_x$ System

x	Growth process*	Isoel. dopant	Substrate†	Dominant wavelength (nm)	Color‡	Luminous efficacy§ (lm/A)	Quantum efficiency§ (%)	Speed (ns)

transistors are quite suitable as detectors. Integrated photo ICs with their 5–7-μm-thick epitaxial layers are very inefficient as detectors at 940 nm.

To shift the wavelength toward the near-infrared or into the visible spectrum, one has to grow a ternary alloy, a mixture between GaAs and GaP. Of commercial interest are two alloys with $x = 0.3$ and $x = 0.4$ grown on a GaAs substrate (see Table 2). The $x = 0.4$ alloy was the first commercially produced material with a wavelength in the visible range of the spectrum. Grown on an absorbing substrate, it has a modest luminous efficacy of around 0.2 lm/A. [Luminous efficacy is the luminous (visible) flux output measured in lumens divided by the electrical current input.] The absorbing substrate allows the integration of multiple light sources into a single chip without crosstalk. Such monolithic seven-segment displays became the workhorse display technology for hand-held calculators from 1972 to 1976.[9,13] Today this alloy is used in LED arrays for printers.[14]

The $x = 0.3$ alloy with a wavelength of 700 nm became important in the mid 1970s as a light source in applications using integrated photodetectors. It has three to five times the quantum efficiency of the $x = 0.4$ alloy (see Table 2), but has a lower luminous efficacy because of the much-reduced eye sensitivity at 700 nm.

For $x > 0.4$, the GaAsP material system becomes indirect (see earlier under ‘‘Light-Generation Process’’ and Fig. 3). The quantum efficiency decreases faster than the increase in eye sensitivity.[4] The only way to achieve a meaningful efficiency is through the use of isoelectronic dopants as described earlier. The choices for isoelectronic dopants that have been successful are N for GaAsP[11] and N or ZnO for GaP. Nitrogen doping is used widely for alloys with $x = 0.65$ to $x = 1.0$.[6–10] The resulting light sources cover the wavelength range from 635 nm to approximately 565 nm (see Table 2). Since these alloys are either GaP or very close in composition to GaP, they are all grown on GaP substrates. The resulting transparent-substrate chip structure increases the luminous efficacy.

In the case of the binary GaP compound, the dominant wavelength depends on N concentration. With low concentrations, practically all N atoms are isolated in single sites. With increasing concentration, N atoms can arrange themselves as pairs or triplets. The resulting electron traps have lower energy states which shift the emitted light toward longer wavelength. Phonon coupling can also reduce the emission energy. Commercially significant are two compositions: (1) undoped GaP which emits at 565 nm (dominant wavelength) with a reasonably green appearance and a low efficiency of around 1 lm/A, and (2) GaP with a nitrogen concentration in the range of $10^{19}\,\text{cm}^{-3}$ with a substantially higher luminous efficiency of around 6 lm/A at 572 nm. At this wavelength, the color appearance is yellow-green, often described as chartreuse.

Three nitrogen-doped ternary alloys of GaAsP are commercially important for red, orange, and yellow. The red source with $x = 0.65$ has an efficiency in the range of 2–3 lm/A. With increasing bandgap or decreasing wavelength, the drop in quantum efficiency is compensated by an increase in eye sensitivity, resulting in a practically wavelength-independent luminous efficiency for the range of 635 to 585 nm.[8,15]

ZnO-doped GaP is an interesting material. The quantum efficiency of such chips is relatively high, around 3 percent. However, the linewidth is quite broad. The quantum efficiency peaks at 700 nm, but the luminous efficiency peaks at 640 nm (dominant wavelength). In other words, most of the photons are emitted at wavelengths with low eye sensitivity. Another problem of GaP:ZnO is saturation. The deep ZnO electron trap causes very slow exciton recombination. At high injection currents, all traps are saturated and most of the injected carriers recombine nonradiatively. At low injection levels ($\leq 1\,\text{A/cm}^2$), the efficacy is relatively high, 3–5 lm/A. At a more useful density of $10\text{–}30\,\text{A/cm}^2$, the emission saturates, resulting in an efficacy of around 1 lm/A.

The $\text{Al}_x\text{Ga}_{1-x}\text{As}$ System

The $\text{Al}_x\text{Ga}_{1-x}\text{As}$ material system has a direct bandgap for $0 \leq x \leq 0.38$. This system has one very significant advantage over the GaAsP system described above, the entire alloy range from $x = 0$ to $x = 1$ can be lattice-matched to GaAs. In other words, every alloy composition can be directly grown on any other alloy composition without the need for transition layers. This feature allows the growth of very abrupt heterojunctions, i.e., abrupt transition in composition and bandgap. These heterojunctions add one important property not available in the GaAsP system: carrier containment (see earlier under "Device Structures"). Carrier containment reduces the movement of injected carriers in a direction perpendicular to the junction. Thus, carrier density can be increased beyond the diffusion-limited levels. This results in increased internal quantum efficiency and higher speed. Another benefit is reduced absorption and improved extraction efficiency (under "Light Extraction").

Of practical significance are two compositions: $x = 0.06$ and $x = 0.38$ (see Table 3). Both compositions exist in single and double heterojunction variations (see under "Device Structures"). The double heterojunctions usually have a 1.5–2.0-times advantage in efficiency and speed. In all cases, the efficiency strongly depends on the thickness of the window layer and, to a lesser degree, on the thickness of the transparent layer between active layer and absorbing substrate (see Fig. 12). Chips with a transparent substrate have an additional efficiency improvement of 1.5–3.0 times again, depending on layer thickness

TABLE 3 Performance Summary of LED Chips in the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ System

x	λ (nm)	Substrate*	Structure†	Efficiency or efficacy	Speed (ns)
0.06	820	AS, TW	DH	8%	30
0.06	820	TS	DH	15%	30
0.38	650	AS, TW	SH	4 lm/A	
0.38	650	AS, TW	DH	8 lm/A	
0.38	650	TS	DH	16 lm/A	

* AS = absorbing substrate; TW = thick window layer; TS = transport substrate.
† DH = double heterostructure; SH = single heterostructure.

and contact area. The efficiency variation is best understood by counting exit cones as described in the text in conjunction with Table 1. For $x = 0.06$, the internal quantum efficiency of a double heterojunction approaches 100 percent. For $x = 0.38$, the direct and indirect valleys are practically at the same level and the internal quantum efficiency is reduced to the range of 50 percent, again dependent upon the quality of the manufacturing process.

The best compromise for efficiency and speed is the $x = 0.06$ alloy as a double heterostructure. Depending on layer thickness, substrate, and contact area, these devices have efficiencies of 5 to 20 percent and rise/fall times of 20–50 ns. This alloy is becoming the workhorse for all infrared applications demanding power and speed. A structural variation as shown in Fig. 14 is an important light source for fiber-optic communication.

The $x = 0.38$ alloy is optimized for applications in the visible spectrum. The highest product of quantum efficiency and eye response is achieved at $x = 0.38$ and $\lambda = 650$ nm. The single heterostructure on an absorbing substrate has an efficacy of around 4 lm/A. The equivalent double heterostructure is in the 6–8 lm/A range. On a transparent GaAlAs substrate, the efficacy is typically in the 15–20 lm/A range and results of as high as 30 lm/A have been reported in the literature.[16] The major application for these red LEDs is in light-flux-intensive applications, such as message panels and automotive stoplights. A variation optimized for speed is widely used for optical communication using plastic fiber.

The AlInGaP System

The AlInFaP system has most of the advantages of the AlGaAs system with the additional advantage that it has a higher-energy direct energy gap of 2.3 eV that corresponds to green emission at 540 nm. AlInGaP can be lattice-matched to GaAs substrates. Indium occupies about half of the Group III atomic sites. The ratio of aluminum to gallium can be changed without affecting the lattice match, just as it can in the AlGaAs material system, since AlP and GaP have nearly the same lattice spacing. This enables the growth of heterostructures that have the efficiency advantages described in the previous section.

Various AlInGaP device structures have been grown. A simple DH structure with an AlInGaP active layer surrounded by higher bandgap AlInGaP confining layers has been effective for injection lasers, but has not produced efficient surface-emitting LEDs.[17] The main problem has been that AlInGaP is relatively resistive and the top AlInGaP layer is not effective in distributing the current uniformly over the chip. This is not a problem with lasers since the top surface is covered with metal and the light is emitted from the edge of the chip.

The top layer must also be transparent to the light that is generated. Two window layers used are AlGaAs or GaP on top of the AlInGaP heterostructure.[18,19] AlGaAs has the advantage that it is lattice-matched and introduces a minimum number of defects at the interface, but it has the disadvantage that it is somewhat absorptive to the yellow and green light which is generated for high-aluminum compositions. The highest AlInGaP device efficiencies have been achieved using GaP window layers.[18,20] GaP has the advantage that it is transparent to shorter wavelengths than AlGaAs and that it is easy to grow thick GaP layers, using either VPE or LPE, on top of the AlInGaP DH that was grown by MOVPE. Both VPE and LPE have substantially higher growth rates than MOCVD. The various growth techniques are discussed later under "Epitaxial Technology."

AlInGaP devices with 45-μm-thick GaP window layers have achieved external quantum efficiencies exceeding 5 percent in the red and yellow regions of the emission spectrum.[21] This is more than twice as bright as devices that have thinner AlGaAs window layers.

Green-emitting AlInGaP devices have also been grown which are brighter than the conventional GaP and GaP:N green emitters.[18,20,21] Substantial further improvement in green is expected since the quantum efficiency is not as high as would be expected based on the energy position of the transition from a direct to an indirect semiconductor.

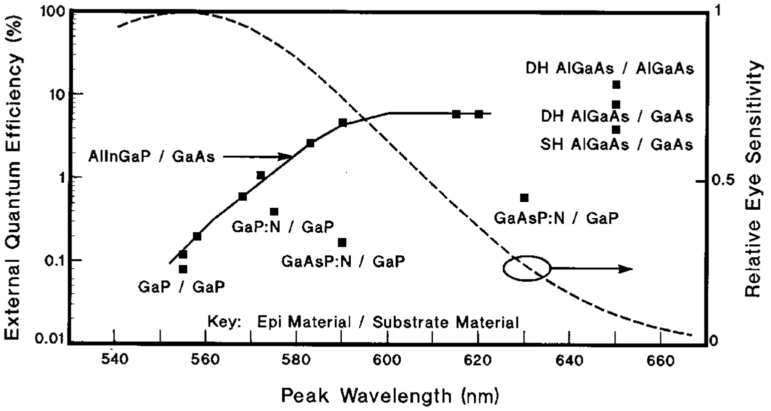

FIGURE 16 External quantum efficiency as a function of peak wavelength for various types of visible LEDs. Below 590 nm the efficiency of AlInGaP LEDs decreases due to the approaching transition from direct to indirect semiconductor. The human eye sensitivity curve is also shown. Since the eye response increases sharply from 660 to 540 nm, it partially makes up for the drop in AlInGaP LED efficiency. The resulting luminous performance is shown in Fig. 17.

The performance of AlInGaP LEDs compared to the most important other types of visible emitters is shown in Figs. 16 and 17. GaAsP on a GaAs substrate and GaP:ZnO are not shown since their luminous efficacy are off the chart at the bottom and the lower-right-hand corner, respectively. It is clear from Fig. 17 that the luminous efficacy of AlInGaP is substantially higher than the other technologies in all color regions except for red beyond 640 nm. Since forward voltage is typically about 2V, the lumen/watt value for a given device is about one-half the lumen/ampere value that is given in Tables 2 and 3. The quantum efficiency of AlInGaP is also better than all of the other technologies except for the highest-performance AlGaAs devices operating at about 650 nm. Because of the eye

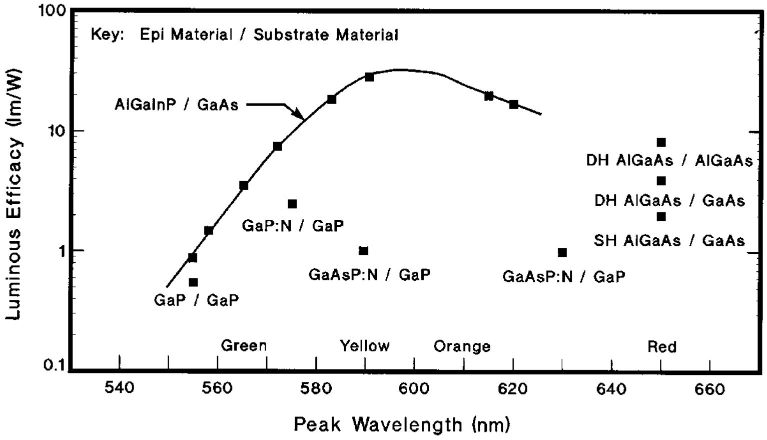

FIGURE 17 Luminous efficacy for AlInGaP LEDs versus wavelength compared to other LED technologies. AlInGaP LEDs are more than an order of magnitude brighter in the orange and yellow regions than other LEDs. AlInGaP LEDs compare favorably to the best AlGaAs red LEDs.

sensitivity variations (see C.I.E. curve in Fig. 16), the 620 nm (red/orange) AlInGaP devices have a higher luminous efficiacy than 650 nm AlGaAs LEDs (see Fig. 17).

Blue LED Technology

Blue emitters have been commercially available for more than a decade, but have only begun to have a significant impact on the market in the last few years. SiC is the leading technology for blue emitters with a quantum efficiency of about 0.02 percent and 0.04 lm/A luminous performance. SiC devices are not much used due to their high price and relatively low performance efficiency.

Other approaches for making blue LEDs are the use of II-VI compounds such as ZnSe or the nitride system GaN, AlGaN, or AlGaInN. It has been difficult to make good *p-n* junctions in these materials. Recently improved *p-n* junctions have been demonstrated in both ZnSe[22,23] and GaN.[24] Device performance is still in the 0.1 lm/A range and reliability is unproven. However, this recent progress is very encouraging for blue-emission technology and could lead to a high-performance device in the next few years. Both ZnSe and the nitride system have a major advantage over SiC because they are direct bandgap semiconductors, so a much higher internal quantum efficiency is possible. However, it is difficult to find suitable lattice-matched substrates for these materials.

12.7 SUBSTRATE TECHNOLOGY

Substrate Criteria

There are several requirements for substrates for LEDs. The substrate must be as conductive as possible both thermally and electrically to minimize power loss. In order to minimize defects it should match the epitaxial layers as closely as possible in atomic lattice spacing, and in the coefficient of thermal expansion. The substrate should also have a low defect density itself. Finally, the substrate should, if possible, be transparent to the light generated by the LED structure since this will enhance the external quantum efficiency.

Substrate Choices

The substrates used for nearly all visible LEDs are GaAs and GaP. GaAs or InP is used for infrared devices, depending upon the device structure required. Substrate parameters are summarized in Table 4, along with Si and Ge for comparison. GaAs is used for the AlGaAs and AlInGaP material systems since they can be lattice-matched to it. GaAs is

TABLE 4 Properties of Common Semiconductor Substrates

Substrate	Lattice parameter	Energy gap @ 300 K (eV)		Melting point (°C)
GaAs	5.653	1.428	Direct	1238
GaP	5.451	2.268	Indirect	1467
InP	5.868	1.34	Direct	1062
Si	5.431	1.11	Indirect	1415
Ge	5.646	0.664	Indirect	937

also used for the $GaAs_{1-x}P_x$ system for $x \leq 0.4$ because it is more nearly latticed-matched and, since it is absorbing, it is useful in multiple-junction devices where optical crosstalk must be minimized (see under "Diffused Homojunction" and Fig. 8). GaP is used for compositions of $x > 0.6$ due to its transparency and closer lattice match. However, neither GaP nor GaAs are well matched to GaAsP, and grading layers are required to grow epitaxial layers with decent quality. InP is the choice for long wavelength emitters made using the InGaAs or InGaAsP materials systems, due to the better lattice match.

Substrate Doping

Generally, substrates are *n*-type and are doped with Te, S, or Si, although sometimes Se and Sn are also used. In some cases, particularly for some AlGaAs LEDs and laser structures, *p*-type substrates are required and Zn is nearly always the dopant. The doping levels are typically in the 10^{18}-cm^{-3} range. Basically, the substrates are doped as heavily as possible to maximize conductivity. However, the doping must be below the solubility limit to eliminate precipitates and other defects. In the case of substrates that are transparent to the light which is generated, such as GaP, with a $GaAs_{1-x}P_x$ epitaxial layer, the doping should also remain below the level at which substantial free carrier absorption occurs.

Growth Techniques

Substrates can be grown by either the Bridgeman or Liquid Encapsulated Czochralski (LEC) technique. The LEC technique is the most widely used. Both techniques are described in detail elsewhere and will be only briefly summarized here.[25]

The LEC technique for GaAs consists of a crucible containing a molten GaAs solution, into which a single crystal "seed" is dipped. The temperature is carefully controlled so that the molten GaAs slowly freezes on the seed as the seed is rotated and raised out of the molten solution. By properly controlling the temperature, rotation rate, seed lift rate, etc., the seed can be grown into a single crystal weighing several kilograms and having a diameter of typically 2–4 inches for GaAs and for 2–2.5 inches for GaP. At the GaAs and GaP melting points As and P would rapidly evaporate from the growth crucible if they were not contained with a molten boric oxide layer covering the growth solution. This layer is the reason for the name "liquid encapsulated." The seed is dipped through the boric oxide to grow the crystal. The growth chamber must be pressurized to keep the phosphorus and arsenic from bubbling through the boric oxide. The growth pressure for GaP is 80 atm, and for GaAs is 20 atm or less, depending upon the approach for synthesis and growth. The LEC technique, used for GaAs, GaP, and InP, is similar to the Czochralski technique used for silicon, but the silicon process is much simpler since encapsulation is not required and the growth can be done at atmospheric pressure.

The Bridgeman and the gradient-freeze technique, which is a variation of the Bridgeman technique, can also be used to grow compound semiconductors. In this technique the growth solution and seed are contained in a sealed chamber so liquid encapsulation is not required. Growth is accomplished by having a temperature gradient in the solution, with the lowest temperature at the melting point in the vicinity of the seed. Growth can be accomplished by lowering the temperature of the entire chamber (gradient freeze), or by physically moving the growth chamber relative to the furnace (Bridgeman technique) to sweep the temperature gradient through the molten solution. The growing crystal can be in either a vertical or horizontal position.

GaAs for LEDs is commonly grown using either LEC or horizontal gradient freeze, also called "boat grown," but sometimes a vertical Bridgeman approach is used. GaP and InP are almost always grown using LEC but sometimes a vertical Bridgeman approach has also been used.

12.8 EPITAXIAL TECHNOLOGY

Growth Techniques Available

Epitaxial layers are grown using one of several techniques, depending upon the material system. The most common techniques are liquid phase epitaxy (LPE), which is primary used to grow GaAs, GaP, and AlGaAs; and vapor phase epitaxy (VPE), which is used to grow GaAsP. Metalorganic vapor phase epitaxy (MOCVD) is also used to grow AlGaAs, GaInAsP, and AlInGaP. Molecular beam epitaxy (MBE) is used for lasers and high-speed devices but is not used for high-volume commercial LEDs at this time. It has been used to grow blue ZnSe-based lasers and LEDs and could be important in the future. All of these epitaxial techniques have been discussed extensively elsewhere and will be only briefly described here.

LPE

LPE growth consists of a liquid growth solution, generally gallium, which is saturated with the compound to be grown.[26] The saturated solution is placed in contact with the substrate at the desired growth temperature, and cooled. As the solution cools, an epitaxial film is grown on the substrate. The technique has the advantage that it is relatively easy to grow high-quality epitaxial layers, and materials containing aluminum (such as AlGaAs) can be readily grown. The disadvantages are that composition control can be difficult. Also, the growth of epitaxial structures involving more than two or three layers, particularly thin layers, can be mechanically complicated since each layer requires a separate growth solution that must be carefully saturated and sequentially brought into contact with the substrate.

One important use of the LPE technique has been for the growth of GaP:ZnO and GaP:N for red and green LEDs, respectively. These devices each consist of two relatively thick layers: an *n*-type layer, followed by the growth of a *p*-type layer. While other growth techniques can be used to grow GaP LEDs, the best results have been obtained using LPE. As a result of a high-volume, low-cost production technology has evolved, which produces more visible LED chips than any other technique. Another major use of LPE is for the growth of GaAs:Si for infrared emitters. LPE is the only technique with which it has been possible to produce the recombination center that gives rise to the 940 nm emission characteristic of this material. The GaAs:Si structures are generally grown from a single growth solution. At high temperatures the silicon is incorporated on Ga sites and the layers are *n*-type. As the solution cools the silicon becomes preferentially incorporated on the As sites and the layer becomes *p*-type.

AlGaAs devices for both visible (red) and IR devices are also generally grown by LPE. AlGaAs devices can also be grown by MOCVD, but LPE has the advantage that thick layers can be more easily grown. This is important for high extraction efficiency (see under ''Device Structures'' and Fig. 12]. In the case of visible devices at 650 nm, the internal quantum efficiency is also higher using LPE than MOCVD. This is not understood, but the result is that virtually all of the visible AlGaAs LEDs are produced using LPE.

VPE

VPE is the other major commercial epitaxial technology for LEDs.[9,27] VPE consists of a quartz chamber containing the substrate wafers at the appropriate growth temperature. The reactants are transported to the substrates in gaseous form. The technique is mainly used for the growth of GaAsP which, along with GaP, dominates the high-volume visible LED market. In this case HCl is passed over Ga metal to form gallium chlorides, and AsH_3 and PH_3 are used to provide the As and P compounds. Appropriate dopant gases are added to achieve the n- and p-type doping. NH_3 is used to achieve nitrogen doping for the growth of GaAsP:N. The VPE technique has the advantages that it is relatively easy to scale up the growth chamber size so large quantities of material can be grown and layer composition and thickness can be easily controlled by adjusting the flow conditions. A limitation of VPE is that it has not been possible to grow high-quality compounds containing aluminum because the aluminum-bearing reactants attack the quartz chamber resulting in contaminated films. Thus, AlGaAs and AlInGaP, the emerging high-brightness technologies, cannot be grown using this technique.

MOCVD

MOCVD growth, like conventional VPE, uses gases to transpose the reactants to the substrates in a growth chamber.[28] However, in this case metallorganic compounds such as trimethylgallium (TMG) are used for one or more of the reactants. A major difference between VPE and MOCVD is that in the case of MOCVD the decomposition of the source gas (e.g., TMG) occurs as a reaction at or near the substrate surface, and the substrate is in the hottest area of the reactor such that the decomposition occurs on the substrate instead of the walls of the growth chamber. The walls of the growth chamber remain relatively cool. This is the key factor that makes MOCVD suitable for the growth of aluminum-bearing compounds which, unlike the VPE situation, do not react significantly with the cooler reactor walls. Thus AlGaAs and AlInGaP can be readily grown with MOCVD, and this technology is widely used for infrared AlGaAs LEDs and lasers, and for the emerging visible AlInGaP laser and LED technology.

MOCVD is also used for the growth of GaN and AlGaN that are candidates for blue emission, and for the growth of II–VI compounds, such as ZnSe, that is also a potential blue emitter. However, at this time the key limitation in obtaining blue ZnSe emitters is the growth of low-resistivity p-type ZnSe. For reasons that are not yet understood, low-resistivity p-type ZnSe has been grown using MBE only.

MBE

MBE is a high vacuum growth technique in which the reactants are essentially evaporated onto the substrates under very controlled conditions.[29] MBE, like MOCVD, can be used to deposit compounds containing aluminum. The growth rates using MBE are generally slower than the other epitaxial techniques, so MBE is most suitable for structures requiring thin layers and precise control of layer thickness. MBE equipment is somewhat more expensive than the equipment used for the other types of epitaxial growth, so it has not been suitable for the high-volume, low-cost production that is required for most types of LEDs. MBE has generally been utilized for lasers and high-speed devices where control of complicated epitaxial structures is critical and where relatively low volumes of devices are required. One advantage that MBE has over the other growth technologies is that the reactants utilized are generally less hazardous. Consequently, MBE equipment is often cheaper and easier to install since there are less safety issues and safety-code restrictions to deal with.

12.9 WAFER PROCESSING

Wafer Processing Overview

Wafer processing of compound semiconductors for LED applications has many of the same general steps used to process silicon integrated-circuit wafers, namely passivation, diffusion, metallization, testing, and die fabrication. The LED device structures are much simpler, so fewer steps are required; but, due to the materials involved, the individual steps are generally different and sometimes more complicated.

Compound semiconductor processing has been described in detail elsewhere, so only a brief summary is discussed here.[30] Some types of LED structures require all of the processing steps listed here, but in many cases fewer process steps are required. An example is a GaP or AlGaAs device with a grown *p-n* junction. For these devices no passivation or diffusion is required.

Passivation

Some types of LED structures, particularly multijunction structures, require a passivation layer prior to diffusion, as shown in Fig. 7. This layer must be deposited relatively free of pinholes, be patternable with standard photolithographic techniques, and must block the diffusing element, generally zinc. In the case of silicon, a native oxide is grown which is suitable for most diffusions. Unfortunately, the compound semiconductors do not form a coherent native oxide as readily as silicon. Silicon nitride (Si_3N_4) is the most widely used passivation layer for LEDs. Si_3N_4 is grown by reacting silane (SiH_4) and ammonia at high temperature in a furnace. S_3N_4 blocks zinc very effectively, and is easily grown, patterned, and removed. Sometimes an SiO_2 layer is used in conjunction with Si_3N_4 for applications such as protecting the surface of the compound semiconductor during high-temperature processing. Silicon oxynitride can also be used instead of or in addition to pure Si_3N_4. Silicon oxynitride is somewhat more complicated to deposit and control, but can have superior properties, such as a better match of coefficient of expansion, resulting in lower stress at the interface.

Diffusion

Generally, only *p*-type impurities, usually Zn, are diffused in compound semiconductors. *N*-type impurities have prohibitively small diffusion coefficients for most applications. Zn is commonly used because it diffuses rapidly in most materials and because it is nontoxic in contrast to Be, which also diffuses rapidly. Mg is another reasonable *p*-type dopant, but it diffuses more slowly than zinc. Diffusions are generally done in evacuated and sealed ampoules using metallic zinc as source material. A column V element such as As is also generally added to the ampoule to provide an overpressure that helps to prevent decomposition of the semiconductor surface during diffusion. Diffusion conditions typically range from 600–900°C for times ranging from minutes to days, depending upon the material and device involved. Junction depths can range from a fraction of a μm to a more than 10 μm.

Open-tube diffusions have also been employed but have generally been harder to control than the sealed ampoule approach, often because of surface decomposition problems. Open-tube diffusions have the advantage that one does not have to deal with the expense and hazard of sealing, breaking, and replacing quartz ampoules.

A third type of diffusion that has been used is a ''semisealed'' ampoule approach in which the ampoule can be opened and reused. The diffusion is carried out at atmospheric pressure and the pressure is controlled by having a one-way pressure relief valve on the ampoule.

Contacting

The contacts must make good ohmic contact to both the *p*- and *n*-type semiconductor, and the top surface of the top contact must be well suited for high-speed wire bonding. Generally, multilayer contacts are required to meet these conditions. Evaporation, sputtering, and e-beam deposition are all employed in LED fabrication. The *p*-type contact generally uses an alloy of either Zn or Be to make the ohmic contact. An Au-Zn alloy is the most common due to the toxicity of Be. The Au-Zn can be covered with a layer of Al or Au to enable high-yield wire bonding. A refractory metal barrier layer may be included between the Au-Zn and top Al or Au layer to prevent intermixing of the two layers and the out-diffusion of Ga, both of which can have a deleterious effect on the bondability of the Al or Au top layer. The *n*-type contact can be similar to the *p*-type contact except that an element which acts as an *n*-type dopant, commonly Ge, is used instead of Zn. An Au-Ge alloy is probably most frequently used to form the *n*-type ohmic contact since it has a suitably low melting point. If the *n*-type contact is the top, or bonded, contact it will be covered by one or more metallic layers to enhance bondability.

Testing

The key parameters that need to be tested are light output, optical rise and fall times, emission wavelength, forward voltage, and leakage current. The equipment used is similar to that used to test other semiconductor devices except that a detector must be added to measure light output. Rise and fall times and wavelength are generally measured on only a sample basis and not for each device on a wafer. In order to test the individual LEDs, the devices must be isolated on the wafer. This occurs automatically for LEDs that are masked and diffused, but if the LEDs are sheet diffused or have a grown junction the top layer must be processed to isolate individual junctions. This can be accomplished by etching or sawing with a dicing saw. Generally, sawing is used, followed by an etch to remove saw damage, because the layers are so thick that etching deep ($>10\ \mu m$) grooves is required. It is advisable to avoid deep groove etching because undercutting and lateral etching often occur and the process becomes hard to control. In many cases LED junctions are not 100 percent tested. This is particularly true of GaP and AlGaAs red-emitting devices in which the top layer may be 30 μm thick. Wafers of this type can be sampled by "coring" through the top layer of the wafer in one or more places with an ultrasonic tool in order to verify that the wafer is generally satisfactory. Later, when chips are fully processed, chips can be selected from several regions of the wafer and fully tested to determine if the wafer should be used or rejected.

Die Fab

Die fab is the process of separating the wafer into individual dice so they are ready for assembly. Generally, the wafer is first mounted on a piece of expandable tape. Next the wafer is either scribed or sawed to form individual dice. Mechanical diamond scribing or laser scribing were the preferred technologies in the past. Mechanical scribing has zero kerf loss, but the chips tend to have jagged edges and visual inspection is required. Laser scribing provides uniform chips but the molten waste material from between the chips damages neighboring chips, and in the case of full function chips the edges of the junction can be damaged by the laser. As a result of the limitations of scribing, sawing (using a dicing saw with a thin diamond impregnated blade) has become the technology of choice for most LEDs.

The kerf loss for sawing has been reduced to about 40 μm and the chip uniformity is excellent such that a minimum of inspection and testing is required. For most materials a "cleanup" etch is required after sawing to remove work damage at the edges of the chips which can both affect the electrical performance and absorb light. The wafer remains on the expandable tape during the sawing process. After sawing, the tape is expanded so that the chips are separated. The tape is clamped in a ring that keeps it expanded and the chips aligned. In this form the chips are easily individually picked off the tape by the die-attach machine that places the chips in the LED package.

12.10 LED QUALITY AND RELIABILITY

LEDs offer many advantages over other types of light sources. They have long operating life, they operate over a wide temperature range, and they are unaffected by many adverse environmental conditions. LED devices also are mechanically robust, making them suitable for applications where there is high vibration, shock, or acceleration. Excellent quality and reliability are obtainable when an LED product is properly designed, fabricated, packaged, tested, and operated.

Product quality is defined as ‘‘fitness for use’’ in a customer’s application. Quality is measured in units of the average number of defective parts per million shipped (i.e., ppm), and is inferred from product sampling and testing. LED product quality is assured by: (1) robust chip and product design, (2) high-quality piece parts, (3) well-controlled fabrication processes, (4) use of statistical process control during manufacturing, (5) careful product testing, and (6) proper handling and storage. Most III-V LEDS are comparable in quality to the best silicon devices manufactured today. Well-designed LED products have total defect levels well below 100 ppm.

Reliability measures the probability that a product will perform its intended function under defined use conditions over the useful life of the product. Probability of survival is characterized by a failure rate, which is calculated by dividing the number of failures by the total number of operating hours (number of products tested per x hours operated). Common measures for reliability are percent failures per 1000 hours (percent/khr) and number failures per 10^9 hours (FITS). LED failure rates typically are better than 0.01 percent per khr at 50°C.

The reliability of an LED product is dependent on the reliability of the LED semiconductor chip and on the robustness of the package into which the chip is placed. Interactions between the chip and package can affect product reliability as well. Aspects of LED packaging and LED chip reliability are discussed in the following paragraphs.

LED Package Reliability

The package into which the LED chip is assembled should provide mechanical stability, electrical connection, and environmental protection. To evaluate package integrity, stress tests such as temperature cycling, thermal and mechanical shock, moisture resistance, and vibration are used to establish the worst-case conditions under which a product can survive. Generally, product data sheets contain relevant information about safe conditions for product application and operation.

Plastic materials are commonly used to package LEDs (see under ‘‘LED-Based Products’’). Thermal fatigue is a limiting factor in plastic-packaged LEDs. Take the case of the plastic LED lamp shown later in Fig. 21. Because of the different materials used (epoxy plastic, copper lead frame, gold wire, III-V LED, etc.) and the different coefficients of expansion of these materials, temperature changes cause internal stresses. If the package is not well designed and properly assembled, thermal changes can cause cracking, chip-attach failure, or failure of the wire bond (open circuits). Careful design can reduce these problems to negligible levels over wide temperature ranges. Today’s high-quality plastic lamps are capable of being cycled from −55 to +100°C for 100 cycles without failure.

Long-term exposure to water vapor can lead to moisture penetration through the plastic, subjecting the chips to humidity. High humidity can cause chip corrosion, plastic delamination, or surface leakage problems. Plastic-packaged LEDs are typically not harmed when used under normal use conditions. Accelerated moisture resistance testing can be used to test the limits of LED packages. Plastic materials have been improved to the point that LED products can withstand 1000 hr of environmental testing at elevated temperatures and high humidity (i.e., 85°C and 85 percent RH).

The thermal stability of plastic packaging materials is another important parameter. Over normal service conditions, the expansion coefficient of plastic is relatively constant. Above the so-called glass transition temperature *Tg* the coefficient increases rapidly. Reliable operation of plastic-packaged LEDs generally requires operation at ambient temperatures below *Tg*. Failures associated with improper soldering operations, such as too high a soldering temperature or for too long a time can cause the package to fail. Excessive storage temperatures also should be avoided. When an LED product is operated, internal ohmic heating occurs; hence, the safe operating maximum temperature is generally somewhat lower than the safe storage temperature.

LED Chip Reliability

The reliability characteristics of the LED chip determine the safe limits of operation of the product. When operated at a given temperature and drive current there is some probability that the LED will fail. In general, LED failure rates can be separated into three time periods: (1) infantile failure, (2) useful life, and (3) the wearout period (see Fig. 18). During the infant mortality period, failures occur due to weak or substandard units. Typically, the failure rate decreases during the infantile period until no weak units remain. During the "useful life" period, the failure rate is relatively low and constant. The number of failures that do occur are random in nature and cannot be eliminated by more testing. The useful life of an LED is a function of the operating temperature and drive conditions. Under normal use conditions, LEDs have useful lives exceeding 100,000 hours. The wearout period is characterized by a rapidly rising failure rate. Generally, wearout for LEDs is not a concern, as the useful life far exceeds the useful life of the product that the LEDs are designed into.

The principle failure mode for LED chips is light-output degradation. In the case of a

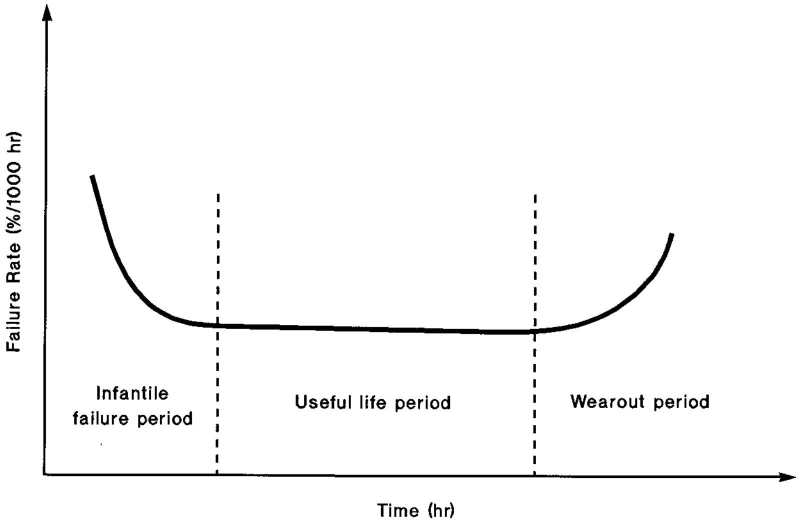

FIGURE 18 Plot of LED failure rate versus time, showing the infantile failure period (decreasing rate), the useful life period (constant, low rate) and the wear-out period (rapidly rising rate).

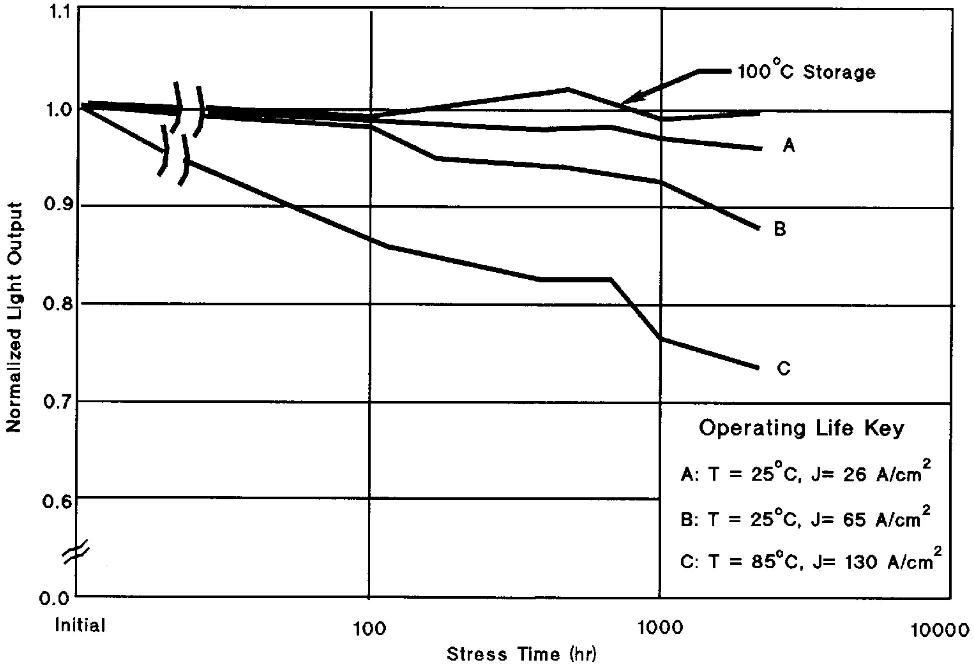

FIGURE 19 Curves of light output versus time for GaAsP indicator lamps stressed under various conditions. Light output is normalized to the initial value. Each curve shows the average degradation of 20 lamps.

visible lamp or display, failure is typically defined as a 50 percent decrease in light output from its initial value, since that is the level where the human eye begins to observe a noticeable change. For infrared emitters or visible LEDs where flux is sensed by a semiconductor detector, failure is commonly defined as a 20 to 30 percent decrease in flux output.

Figure 19 shows degradation curves for a direct bandgap GaAsP LED packaged in a 5-mm plastic lamp.[31] Current must flow for degradation to occur, as negligible change is observed after 1 khr of 100°C storage. Degradation is a function of the temperature at the *p*-*n* junction and the junction current density. As shown in Fig. 19, a larger decline in light output is observed as junction current density and/or temperature at the junction increases. The dependence of degradation on current density J is superlinear, varying as J^x with $1.5 < x < 2.5$. Hence, accelerated-aging tests typically use high currents and temperatures to shorten the time needed to observe LED degradation. The maximum stress level shown in Fig. 19 is 200 percent of the maximum allowable drive current specified in the data sheet.

Light-output degradation in GaAsP LEDs is due to an increase in the nonradiative space-charge recombination current. Total current flowing through the LED is made up of the sum of diffusion current and space-charge recombination current, as shown in the following equations:

$$I_T(V, t) = A(t)e^{qV/kT} + B(t)e^{qV/2kT} \tag{5}$$

where q is electron charge, k is Boltzmann's constant, and T is temperature.[32] The first term is diffusion current that produces light output, while the second term is space-charge

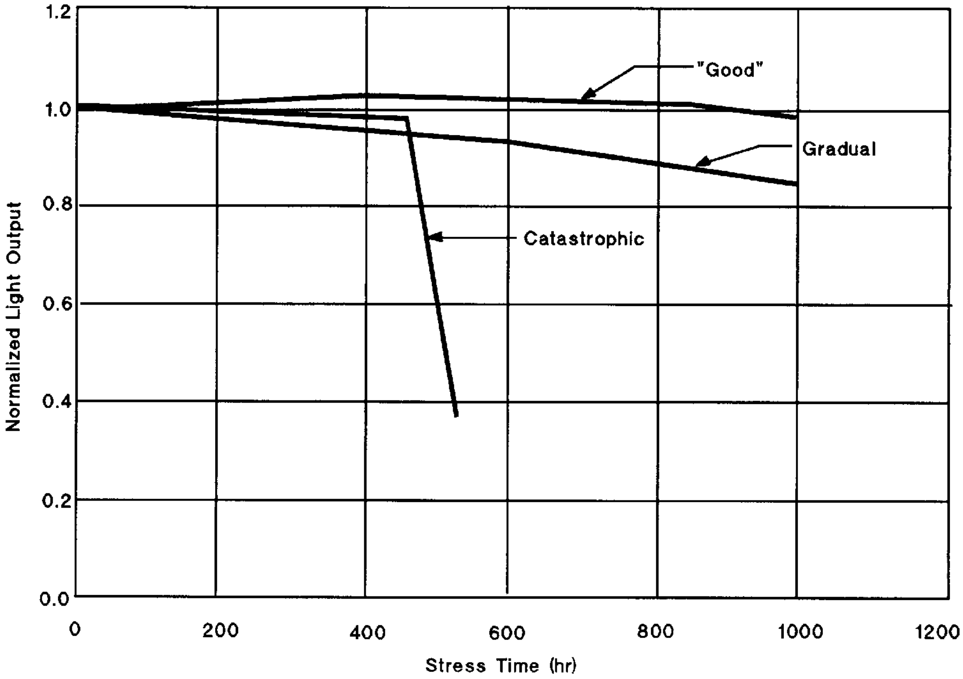

FIGURE 20 Light output degradation of AlGaAs LEDs. Three modes are shown: "good" devices with negligible light-output decrease over time, devices which degrade gradually over time, and "catastrophic" degradation devices where the flux rapidly decreases over a short time period.

recombination that is nonradiative. At fixed I_T, if $B(t)$ increases, then the diffusion term must decrease and, hence, the light output decreases. The reason for the increase in space-charge recombination in GaAsP LEDs is not fully understood.

The degradation characteristics of GaAlAs LEDs differ from those of GaAsP LEDs. Typical curves of normalized light output versus time for GaAlAs LEDs are shown in Fig. 20. "Good" units show negligible decrease in light output when operated under normal service conditions. Gradual degradation may occur, but it is relatively uncommon. The predominate failure mode in GaAlAs LEDs is catastrophic degradation. The light emission decreases very rapidly over a period of less than 100 hr and simultaneously nonradiative regions ("dark-spot" or "dark-line defects") are observed to form. The catastrophic degradation mechanism is described in detail in Refs. 33 and 34. In brief, the dark regions are caused by nonradiative recombination at dislocation networks that grow rapidly from a crystal dislocation located in the light-emitting region of the LED. Network formation depends on carrier recombination, both nonradiative, which creates mobile point defects, and radiative recombination, which enhances the movement of the point defects to the growing network.

Formation of dark-line defects is enhanced by mechanical stress either present in the LED chip or occurring during assembly. Properly designed products reduce such stress by minimizing bending caused by the different coefficients of expansion in the LED, and by stress-free die attach, wire bond, and encapsulation of the LED during assembly.

Failures due to dark-spot or dark-line defects can be effectively screened out by operating the LED at high current and temperature. Units with defects typically fail within the first few hundred hours. GaAlAs LEDs with dark-spot or dark-line defects are screened out by means of visual inspection and/or by eliminating units with large decreases in light output. GaAlAs LEDs used for fiber-optic applications have small emitting areas (see under "Fiber Optics" discussion and Fig. 14). Due to the high current densities present in such devices, high temperature and current burn-in is used extensively for these types of LEDs.

Another degradation mode in LEDs is change in the reverse breakdown characteristics over time. The reverse characteristics become soft and the breakdown voltage may decrease to a very low value. Several mechanisms have been observed in LEDs. One cause is localized avalanche breakdown due to microplasma formation at points where electric fields are high. Microplasmas have been observed in GaAs and GaAsP LEDs.

Damage or contamination of the edges of an LED chip can cause increased surface leakage and reduced reverse breakdown. Incomplete removal of damage during die separation operations and damage induced during handling and assembly are known to cause reverse breakdown changes. Die-attach materials also can unintentionally contaminate the edges of LEDs. Copper, frequently found in LED packaging materials, can diffuse into the exposed surfaces of the LED, causing excess leakage and, in some cases, light-output degradation.[35] Chips whose *p-n* junction extends to the edges (i.e., Fig. 6) are very susceptible to damage and/or contamination.

12.11 LED BASED PRODUCTS

Indicator Lamps

The simplest LED product is an indicator lamp or its infrared equivalent. The most frequently used lamp is shown in Fig. 21. A LED chip with a typical dimension of

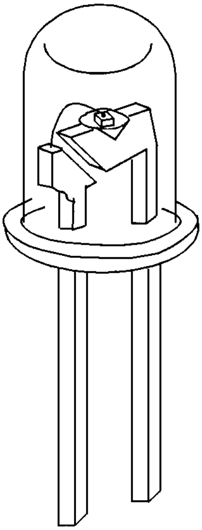

FIGURE 21 Plastic indicator lamp. The LED chip is placed in a reflector coined into the end of one electrode lead. The top of the chip is connected with a gold wire to the second electrode. The electrodes are encapsulated in plastic to form a mechanically robust package.

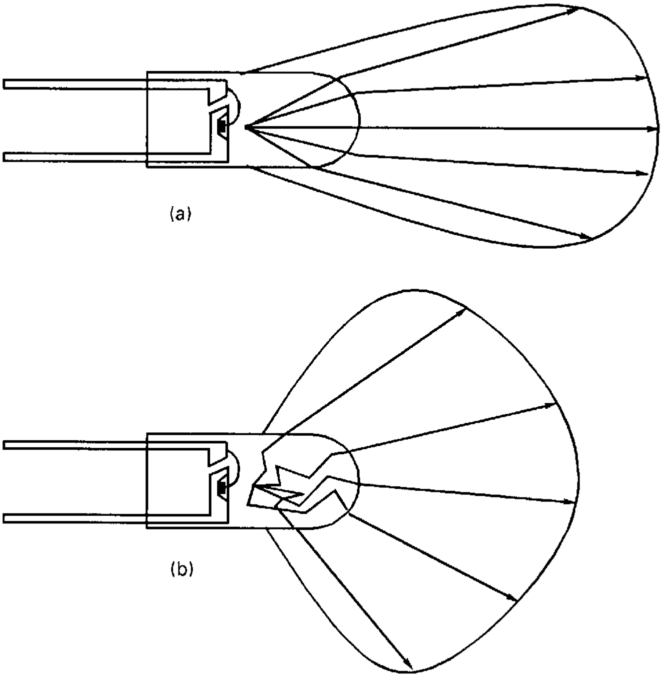

FIGURE 22 Radiation pattern of two types of LED indicator lamps: (*a*) lamp with clear plastic package with a narrow beam; (*b*) lamp with a diffusing plastic package (glass powder added) with a broader radiation pattern.

250 × 250 μm is attached with conductive silver-loaded epoxy into a reflective cavity coined into the end of a silver-plated copper or steel lead frame. The top of the LED chip is connected with a thin 25-μm gold wire to the second terminal of the lead frame. The lead frame subassembly is then embedded in epoxy. The epoxy serves several functions: (1) it holds the assembly together and protects the delicate chip and bond wire; (2) it increases the light extraction from the chip (see under ''Light Extraction,'' discussed earlier); and (3) it determines the spatial light distribution.

There are a large number of variations of the lamp shown in Fig. 21. Besides the obvious variation of source wavelength, there are variations of size, shape, radiation pattern, etc. The cross section of the plastic body ranges from 2–10 mm. The radiation pattern is affected by three factors: the shape of the dome, the relative position of the chip/reflector combination, and by the presence of a diffusant in the epoxy. Figure 22*a* shows the radiation pattern of a lamp using clear plastic as an encapsulant. The rays emanating from chip and reflector are collimated into a narrow beam. For many indicator lamps a broader viewing angle is desired such as that shown in the radiation pattern of Fig. 22*b*. This effect is achieved by adding a diffusant, such as glass powder, to the clear plastic. Another variation is shape. Common shapes are round, square, rectangular, or triangular.

Another variation is achieved by placing two different chips into the reflector cup. For instance, a lamp with green and red chips connected to the second post in an antiparallel fashon can operate as a red indicator if the reflector post is biased positive, and as a green indicator if it is biased negative. Rapidly switching between the two polarities one can achieve any color between the two basic colors, i.e., yellow or orange, depending on current and duty cycle.

A number of chips can be combined in a single package to illuminate a rectangular area. These so-called annunciator assemblies range in size from one to several cm. They typically use 4 chips per cm^2. By placing an aperture-limiting symbol or telltale in front of the lit area, these structures are cost-effective means to display a fixed message, such as warning lights in an automotive dashboard.

Numeric Displays

Numeric displays are usually made up of a nearly rectangular arrangement of seven elongated segments in a figure-eight pattern. Selectively switching these segments generates all ten digits from 0–9. Often decimal point, colon, comma, and other symbols are added.

There are two main types of LED numeric displays: (1) monolithic displays and (2) stretched segment displays. All monolithic displays are based on GaAs-GaAsP technology. Seven elongated p-doped regions and a decimal point are diffused into an n-type epitaxial layer of a single or monolithic chip (see Fig. 8). Electrically, this is a structure with eight anodes and one common cathode. This monolithic approach is relatively expensive. For arms-length viewing, a character height of 3–5 mm is required. Adding space for bonding pads, decimal point, and edge separation, such a display consumes around 10 mm^2 of expensive semiconductor material per digit. One way to reduce material and power consumption is optical magnification. Viewing-angle limitation and distortion limit the magnification M to $M \leq 2.0$. Power consumption is reduced by M^2—an important feature for battery-powered applications.

For digits >5 mm, a stretched segment display is most cost effective. The design of Fig. 23 utilizes a $250 \times 250\ \mu$m chip to generate a segment with dimensions of up to 8×2 mm for a 20-mm digit height. This corresponds to a real magnification of $M^2 = 256$, or an equivalent linear magnification of $M = 16$. This magnification is achieved without a reduction in viewing angle by using scattering optics. An LED chip is placed at the bottom

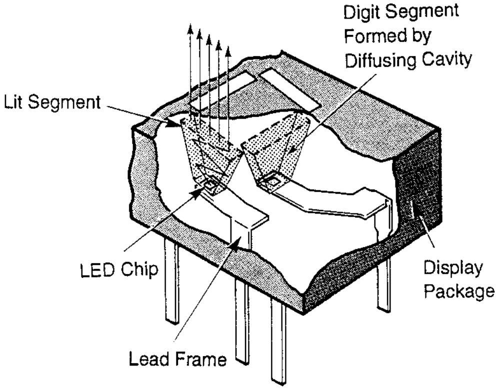

FIGURE 23 Cutaway of a seven-segment numeric LED display, showing how light from a small LED chip is stretched to a large character segment using a diffusing cavity. Characters 0–9 are created by turning on appropriate combinations of segments.

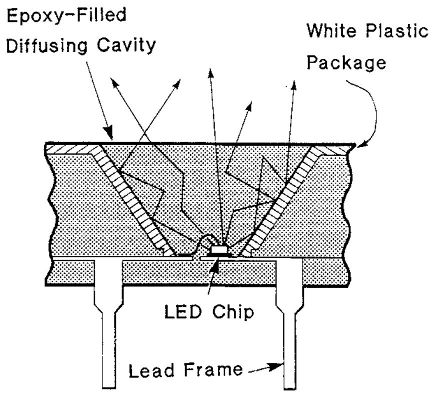

FIGURE 24 Cross section through one segment of the seven-segment numeric display shown in Fig. 23. A LED chip is placed at the bottom of a highly reflective, white plastic cavity which is filled with clear plastic containing a diffusant. Light is scattered within the cavity to produce uniform emission at the segment surface.

of a cavity having the desired rectangular exit shape and the cavity is filled with a diffusing plastic material (see Fig. 24). The side and bottom surfaces of the cavity are made as reflective as possible. Highly reflective white surfaces are typically used. A good white plastic surface measured in air may have a reflectivity of 94 percent compared with 98 percent for Ag and 91 percent for Al. Ag and Al achieve this reflectivity only if evaporated on a specularly smooth surface. Measured in plastic, the reflectivity of the white surface increases from 94 to 98 percent, the Ag surface remains at 98 percent, while the Al surface decreases to 86 percent. Both metallic surfaces have substantially lower reflectivities if they are evaporated onto a nonspecular surface, or if they are deposited by plating. Practically all numeric LED displays above 5-mm character heights are made using white cavity walls and diffusing epoxy within the cavity.

This case of magification by scattering does not result in a power saving as in the case of magnification of monolithic displays. Since there is practically no reduction in emission angle, the law of energy conservation requires an increased light flux from the chip that equals the area magnification plus reflection losses in the cavity.

Alphanumeric Displays

There are two ways LEDs are used to display alphanumeric information: either by using more than seven elongated segments, i.e., 14, 16, or 24; or by using an array of LED chips in a 5×7 dot matrix format. The multiple segment products are similar in design to the monolithic or stretched segment numeric displays described above.

In the case of small monolithic characters, the number of input terminals quickly exceeds conventional pin spacing. These products are usually clusters of 4 to 16 characters combined with a decoder/driver integrated circuit within the same package. To reduce cost and power, some modest optical magnification is usually used. The segmented displays are usually larger, i.e., 12–25 mm and limited to 14 segments per character. At this size, there is no pin density constraint and the decoder is usually placed outside the package.

The most frequently used alphanumeric LED display is based on a 5×7 matrix per character. For small characters in the range of 5–8 mm, the LED chips are directly viewed and pin density limitations require an on-board decoder/driver IC. Products are offered as end-stackable clusters of 4, 8, and 16 characters.

For larger displays, the LED chip is magnified by the same optical scattering technique described above for numerics. Exit apertures per pixel have a diameter of 2–5 mm. Products are offered as 5 × 7 single characters or end-stackable 20 × 20 tiles for large message- or graphics-display panels. At this size, pin density is not a limitation.

Optocouplers

An optocoupler is a device where signal input and signal output have no galvanic connection. It is mainly used in applications as the interface between the line voltage side of a system and the low-voltage circuit functions, or in systems where the separate ground connection of interconnected subsystems causes magnetic coupling in the galvanic loop between signal and ground connections. By interrupting the galvanic loop with an optical signal path, many sources of signal interference are eliminated.

The oldest optocouplers consist of an IR LED and a photodetector facing each other in an insulating tube. The second generation utilized the so-called dual-in-line package widely used by logic ICs. In this package an IR emitter and a phototransistor are mounted face-to-face on two separate lead frames. The center of the package between emitter and detector is filled with a clear insulating material. The subassembly is then molded in opaque plastic to shield external light and to mechanically stabilize the assembly (Fig 25). The second generation optocouplers have limited speed performance for two reasons: (1) the slow response time of the GaAs:Si LED and (2) the slow response of the phototransistor detector because of the high collector-base capacitance.

The third generation of optocouplers overcomes the speed limitation. It uses an integrated photodetector and a decoupled gain element. Integration limits the thickness of the effective detection region in silicon to 5–7 μm. This thickness range forces a shift of the source to wavelengths shorter than the 940 nm sources used in the second-generation couplers. Third-generation couplers use GaAsP (700 nm) or AlGaAs emitters (880 nm).

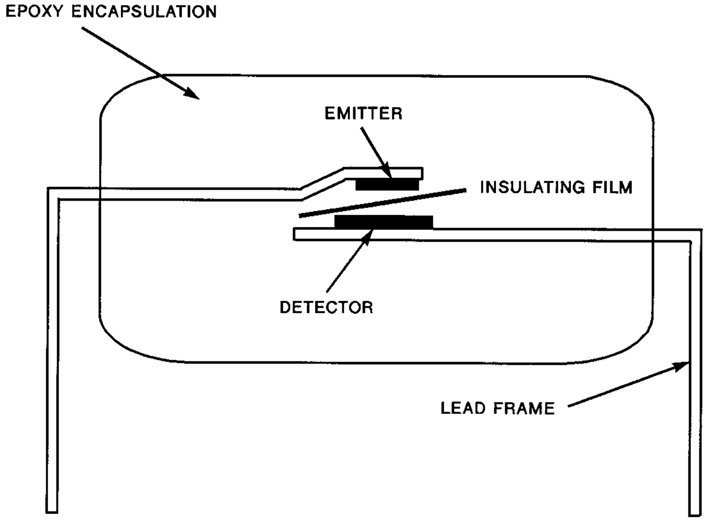

FIGURE 25 Optocoupler consisting of face-to-face emitter and detector chips. An insulating film is placed between the chips to increase the ability of the optocoupler to withstand high voltages between input and output electrodes.

Within the last decade, the optocoupler product family has seen further proliferation by adding features on the input or output side of the coupler. One proliferation resulted in couplers behaving like logic gates. Another variation used MOS FET devices on the output side, eliminating the offset voltages of bipolar devices. These couplers are comparable to the performance of conventional relays and are classified as solid-state relays. Other types use a CMOS input driver and CMOS output circuitry to achieve data transfer rates of 50 Mb/s and CMOS interface compatibility.

Fiber Optics

LEDs are the primary light source used in fiber-optic links for speeds up to 200 Mb/s and distances up to 2 km. For higher-speed and longer distances, diode lasers are the preferred source.

For fiber-optic applications, LEDs have to meet a number of requirements that go well beyond the requirements for lamps and displays. The major issues are: minimum and maximum flux coupled into the fiber, optical rise and fall times, source diameter, and wavelength. Analysis of flux budget, speed, fiber dispersion, wavelength, and maximum distance is quite complex and goes far beyond the scope of this work. A simplified discussion for the popular standard, Fiber Distributed Data Interface (FDDI) will highlight the issues. For a detailed discussion, the reader is referred to Ref. 36.

Flux budget. The minimum flux that has to be coupled into the fiber is determined by receiver sensitivity (−31 dBm), fiber attenuation over the 2-km maximum distance (3 dB), connector and coupler losses (5 dB), and miscellaneous penalties for detector response variations, bandwidth limitations, jitter, etc. (3 dB). With this flux budget of 11 dB, the minimum coupled power has to be −20 dBm. Another flux constraint arises from the fact that the receiver can only handle a maximum level of power before saturation (−14 dBm). These two specifications bracket the power level coupled into the fiber at a minimum of −20 dBm (maximum fiber and connector losses) and at a maximum of −14 dBm (no fiber or connector losses for the case of very short fiber).

Speed. The transmitter speed or baud rate directly translates into a maximum rise and fall time of the LED. The 125 Mdb FDDI specifications call for a maximum rise and fall time of 3.5 ns. As a rule of thumb, the sum of rise and fall time should be a little shorter than the inverse baud period (8 ns for 125 Mbd).

Source Diameter and Fiber Alignment. Efficient coupling of the LED to the fiber requires a source diameter that is equal to or preferably smaller than the diameter of the fiber core. For sources smaller than the core diameter, a lens between source and fiber can magnify the source to a diameter equal to or larger than the core diameter. The magnification has two benefits: (1) It increases the coupling efficiency between source and fiber. The improvement is limited to the ratio of source area to core cross-sectional area. (2) It increases the apparent spot size to a diameter larger than the fiber core. This effect relaxes the alignment tolerance between source and core and results in substantially reduced assembly and connector costs.

Wavelength. The LEDs used in fiber-optic applications operate at three narrowly defined wavelength bands 650, 820–870, and 1300 nm, as determined by optical fiber transmission characteristics.

650 nm. This band is defined by an absorption window in acrylic plastic fiber. It is a very narrow window between two C-H resonances of the polymer material. The bottom of the window has an absorption of approximately 0.17 dB/m. However, the effective absorption is in the 0.3–0.4 dB/m range because the LED linewidth is comparable to the width of the absorption window and the LED wavelength changes with temperature. The 650-nm LEDs use either $GaAs_{1-x}P_x$ with $x = 0.4$ or $GaAl_xAs_{1-x}$ with $x = 0.38$. Quantum efficiencies are at 0.2 and 1.5 percent, respectively. Maximum link length is in the range of 20–100 m, depending on source efficiency, detector sensitivity, speed, and temperature range.

820–870 nm. This window was chosen for several reasons. GaAlAs emitters (see Fig. 14) and Si detectors are readily available at this wavelength. Early fibers had an absorption peak from water contamination at approximately 870 nm. As fiber technology improved, the absorption peak was eliminated and the wavelength of choice moved from 820- to the 850–870-nm range. Fiber attenuation at 850 nm is typically 3 dB/km. Maximum link length in the 500–2000 m range, depending on data rate. In the 850–870-nm window the maximum link length is limited by chromatic dispersion. GaAlAs emitters have a half-power linewidth of approximately 35 nm. The velocity of light in the fiber is determined by the index of refraction of the fiber core. The index is wavelength-dependent resulting in dispersion of the light pulse. This dispersion grows with distance. The compounded effect of LED linewidth and fiber dispersion is a constant distance-speed product. For a typical multimode fiber and GaAlAs LED combination, this product is in the range of 100 Mbd-km.[36]

1300 nm. At this wavelength, the index of refraction as a function of wavelength reaches a minimum. At this minimum, the velocity of light is practically independent of wavelength, and chromatic dispersion is nearly eliminated. The distance-speed limitation is caused by modal dispersion. Modal dispersion can be envisioned as a different path length for rays of different entrance angles into the fiber. A ray going down the middle of the core will have a shorter path than a ray entering the fiber at the maximum acceptance angle undergoing many bends as it travels down the fiber. The resulting modal dispersion limits multimode fibers to distance bandwidth products of approximately 500 Mbd-km. LED sources used at this wavelength are GaInAsP emitters, as shown in Fig. 15. At this wavelength, fiber attenuation is typically <1.0 dB/km and maximum link length is in the range of 500–5000 m, depending on data rate and flux budget.

Sensors

LED/detector combinations are used in a wide range of sensor applications. They can be grouped into three classes: transmissive, reflective, and scattering sensors.

Transmissive Sensors. The most widely used transmissive sensor is the slot interrupter. A U-shaped plastic holder aligns an emitter and detector face-to-face. It is used widely for such applications as sensing the presence or absence of paper in printers, end-of-tape in tape-recorders, erase/overwrite protection on floppy disks and many other applications where the presence or absence of an opaque obstruction in the light path determines a system response.

A widely used slot interrupter is a two- or three-channel optical encoder. A pattern of opaque and transmissive sections moves in front of a fixed pattern with the same spatial frequency. Two optical channels positioned such that they are 90° out-of-phase to each other with regard to the pattern allow the measurement of both distance (number of transmissive/opaque sequences) and direction (phase of channel A with regard to channel B). Such encoders are widely used in industrial control applications, paper motion in printers, pen movement in plotters, scales, motor rotation, etc. A third channel is often used to detect an index pulse per revolution to obtain a quasi-absolute reference.

Reflective Sensors. In a reflective sensor an LED, detector, and associated optical elements are positioned such that the detector senses a reflection when a reflective surface (specular or diffuse) is positioned within a narrow sensing range. A black surface or nonaligned specular surface or the absence of any reflective surface can be discriminated from a white surface or properly aligned specular surface. Applications include bar-code reading (black or white surface), object-counting on a conveyer belt (presence or no presence of a reflecting surface), and many others. Many transmissive sensor applications can be replaced by using reflective sensors and visa versa. The choice is usually determined by the optical properties of the sensing media or by cost. An emerging application for reflective sensors is blood gas analysis. The concentration of O_2 or CO_2 in blood can be determined by absorption at two different LED wavelengths, i.e., red and infrared.

Scattering Sensors. One design of smoke detectors is based on light scattering. The LED light beam and the detector path are crossed. In the absence of smoke, no light from the LED can reach the detector. In the presence of smoke, light is scattered into the detector.

13.1 GLOSSARY

A	Constant approximating the slope of gain versus current or carrier density
C	Capacitance
c	Speed of light
D	Density of states for a transition
D_c	Density of states for the conduction band
D_v	Density of states for the valence band
d	Active layer thickness
d_{eff}	Effective beam width in the transverse direction
d_G	Guide layer thickness
dg/dN	Differential gain
E	Energy of a transition
E_c	Total energy of an electron in the conduction band
E_g	Bandgap energy
E_n	The nth quantized energy level in a quantum well
E_n^c	The nth quantized energy level in the conduction band
E_n^v	The nth quantized energy level in the valence band
E_v	Total energy of a hole in a valence band
e	Electronic charge
F_c	Quasi-Fermi level in the conduction band
F_v	Quasi-Fermi level in the valence band
f_c	Fermi occupation function for the conduction band
f_d	Damping frequency
f_o	Resonant frequency of an LRC circuit
f_p	Peak frequency

f_r	Resonance frequency
f_v	Fermi occupation function for the valence band
g	Model gain per unit length
g_{th}	Threshold modal gain per unit length
H	Heavyside function
h	Refers to heavy holes
$\hbar$	Plank's constant divided by 2π
I	Current
I_{off}	DC bias current before a modulation pulse
I_{on}	Bias current during a modulation pulse
I_{th}	Threshold current
J	Current density
J_o	Transparency current density
J_{th}	Threshold current density
K	Constant dependent on the distribution of spectral output function
$\mathbf{k}$	Wavevector
k	Boltzmann constant
L	Inductance
L	Laser cavity length
L_c	Coherence length
L_z	Quantum well thickness
l	Refers to light holes
$\|M\|^2$	Matrix element for a transition
m	Effective mass of a particle
m_c	Conduction band mass
m_r	Effective mass of a transition
m_v	Valence band mass
N	Carrier density
N_0	Transparency carrier density
n_{eff}	Effective index of refraction
n_r	Index of refraction
n_{sp}	Spontaneous emission factor
P	Photon density
P_{off}	Photon density before a modulation pulse
P_{on}	Photon density during a modulation pulse
R	Resistance
R_F	Front facet reflectivity
R_R	Rear facet reflectivity
T	Temperature

w	Laser stripe width
α	Absorption coefficient
α	Linewidth enhancement factor
α_i	Internal loss per unit length
β	Spontaneous emission factor
Γ	Optical confinement factor
$\Delta f_{1/2}$	Frequency spectral linewidth
$\Delta\lambda_L$	Longitudinal mode spacing
$\Delta\lambda_{1/2}$	Half-width of the spectral emission in terms of wavelength
λ	Wavelength
λ_o	Wavelength of the stimulated emission peak
τ_d	Turn-on time delay
τ_p	Photon lifetime
τ_s	Carrier lifetime

13.2 INTRODUCTION

This chapter is devoted to the performance characteristics of semiconductor lasers. In addition, some discussion is provided on fabrication and applications. In the first section we describe some of the applications being considered for semiconductor lasers. The following several sections describe the basic physics, fabrication, and operation of a variety of semiconductor laser types, including quantum well and strained layer lasers. Then we describe the operation of high-power laser diodes, including single element and arrays. A number of tables are presented which summarize the characteristics of a variety of lasers. Next we discuss the high-speed operation and provide the latest results, after which we summarize the important characteristics dealing with the spectral properties of semiconductor lasers. Finally, we discuss the properties of surface emitting lasers and summarize the latest results in this rapidly evolving field.

More than 260 references are provided for the interested reader who requires more information. In this *Handbook,* Chap. 12 (LEDs) also contains related information. For further in-depth reviews of semiconductor lasers we refer the reader to the several excellent books which have been written on the subject.[1–5]

13.3 APPLICATIONS FOR SEMICONDUCTOR LASERS

The best-known application of diode lasers is in optical communication systems. However, there are many other potential applications. In particular, semiconductor lasers are being considered for high-speed optical recording,[6] high-speed printing,[7] single- and multimode database distribution systems,[8] long-distance transmission,[9] submarine cable transmission,[10] free-space communications,[11] local area networks,[12] Doppler optical radar,[13] optical signal processing,[14] high-speed optical microwave sources,[15] pump sources for other solid-state lasers,[16] fiber amplifiers,[17] and medical applications.[18]

For very high speed optical recording systems (>100 MB/s), laser diodes operating at relatively short wavelengths ($\lambda < 0.75\ \mu\text{m}$) are required. In the past few years, much progress has been made in developing short-wavelength semiconductor lasers, although the output powers are not yet as high as those of more standard semiconductor lasers.

One of the major applications for lasers with higher power and wide temperature of operation is in local area networks. Such networks will be widely used in high-speed computer networks, avionic systems, satellite networks, and high-definition TV. These systems have a large number of couplers, switches, and other lossy interfaces that determine the total system loss. In order to maximize the number of terminals, a higher-power laser diode will be required.

Wide temperature operation and high reliability are required for aerospace applications in flight control and avionics. One such application involves the use of fiber optics to directly link the flight control computer to the flight control surfaces, and is referred to as fly-by-light (FBL). A second application involves the use of a fiber-optic data network for distributing sensor and video information.

Finally, with the advent of efficient high-power laser diodes, it has become practical to replace flash lamps for the pumping of solid-state lasers such as Nd:YAG. Such an approach has the advantages of compactness and high efficiency. In addition, the use of strained quantum well lasers operating at 0.98 μm has opened significant applications for high-gain fiber amplifiers for communications operating in the 1.55-μm wavelength region.

13.4 BASIC OPERATION

Lasing in a semiconductor laser, as in all lasers, is made possible by the existence of a gain mechanism plus a resonant cavity. In a semiconductor laser the gain mechanism is provided by light generation from the recombination of holes and electrons (see Fig. 1). The wavelength of the light is determined by the energy bandgap of the lasing material. The recombining holes and electrons are injected, respectively, from the *p* and *n* sides of a *p-n* junction. The recombining carriers can be generated by optical pumping or, more commonly, by electrical pumping, i.e. forward-biasing the *p-n* junction. In order for the light generation to be efficient enough to result in lasing, the active region of a semiconductor laser, where the carrier recombination occurs, must be a direct bandgap semiconductor. The surrounding carrier injection layers, which are called *cladding layers,*

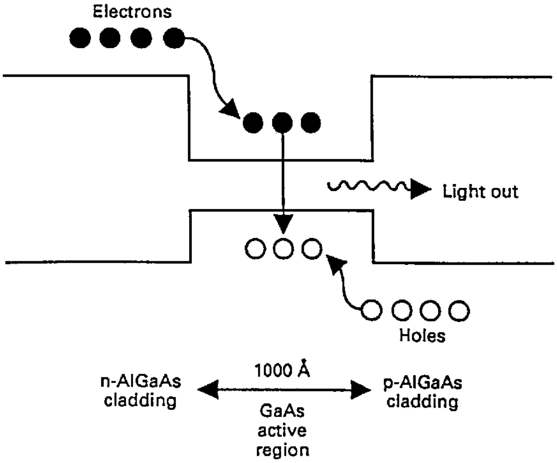

FIGURE 1 Schematic diagram of the recombination of electrons and holes in a semiconductor laser.

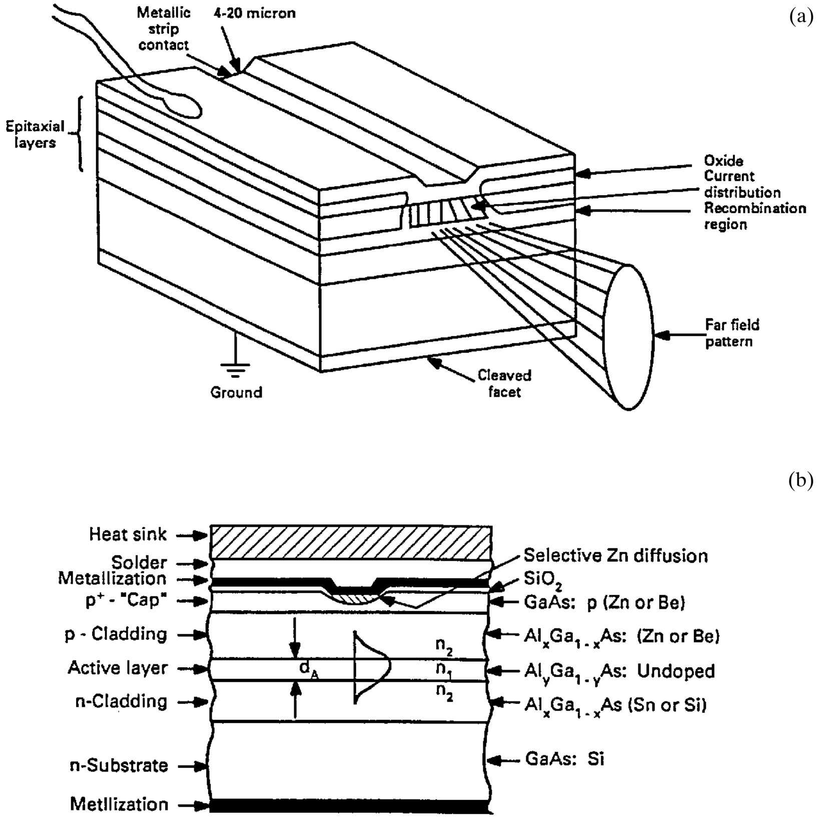

FIGURE 2 (*a*) Schematic diagram of a simple double heterostructure laser; (*b*) cross-sectional view showing the various epitaxial layers. (*After Ref. 20.*)

can be indirect bandgap semiconductors. For a discussion of semiconductor band levels see any solid-state physics textbook such as that by Kittel.[19] For a more detailed discussion of carrier recombination see Chap. 12 in this *Handbook.*

For a practical laser, the cladding layers have a wider bandgap and a lower index of refraction than the active region. This type of semiconductor laser is called a *double heterostructure* (DH) laser, since both cladding layers are made of a different material than the active region (see Fig. 2). The first semiconductor lasers were homojunction lasers,[21–24] which did not operate at room temperature; it is much easier to achieve lasing in semiconductors at low temperatures. Today, however, all semiconductor lasers contain heterojunctions. The narrower bandgap of the active region confines carrier recombination to a narrow optical gain region. The sandwich of the larger refractive index active region surrounded by cladding layers forms a waveguide, which concentrates the optical modes generated by lasing in the active region. For efficient carrier recombination the active region must be fairly thin, typically on the order of 1000 Å, so a significant fraction of the optical mode spreads into the cladding layers. In order to completely confine the optical mode in the semiconductor structure, the cladding layers must be fairly thick, usually about 1 μm.

The resonant cavity of a simple semiconductor laser is formed by cleaving the ends of the structure. Lasers are fabricated with their lasing cavity oriented perpendicular to a natural cleavage plane. For typical semiconductor materials this results in mirror reflectivities of about 30 percent. If necessary, the reflectivities of the end facets can be modified by applying dielectric coatings to them.[25] For applications where it is not possible to cleave the laser facets, it is also possible to etch them,[26–28] although this is much more difficult and usually does not work as well. Laser cavity lengths can be anywhere from about 50 to 2000 μm, although commercially available lasers are typically 200 to 1000 μm long.

Unpumped semiconductor material absorbs light of energy greater than or equal to its bandgap. When the semiconductor material is pumped optically or electrically, it reaches a point at which it stops being absorbing. This point is called *transparency.* If it is pumped beyond this point it will have optical gain, which is the opposite of absorption. A semiconductor laser is subject to both internal and external losses. For lasing to begin, i.e., to reach threshold, the gain must be equal to these optical losses. The threshold gain per unit length is given by:

$$g_{th} = \alpha_i + \frac{1}{2L} \ln \left(\frac{1}{R_F R_R} \right) \tag{1}$$

where α_i is the internal loss per unit length, L is the laser cavity length, and R_F and R_R are the front and rear facet reflectivities. (For semiconductor lasers, gain is normally quoted as gain per unit length in cm^{-1}. This turns out to be very convenient, but unfortunately is confusing for people in other fields, who are used to gain being unitless.)

The internal loss is a material parameter determined by the quality of the semiconductor layers. Mechanisms such as free-carrier absorption and scattering contribute to α_i.[1] The second term in Eq. (1) is the end loss. A long laser cavity will have reduced end loss, since the laser light reaches the cavity ends less frequently. Similarly, high facet reflectivities also decrease the end loss, since less light leaves the laser through them.

For biases below threshold, a semiconductor laser emits a small amount of incoherent light spontaneously (see Fig. 3). This is the same type of light emitted by an LED (see Chap. 12). Above threshold, stimulated emission results in lasing. The relationship between lasing emission and the bias current of a healthy semiconductor laser is linear. To

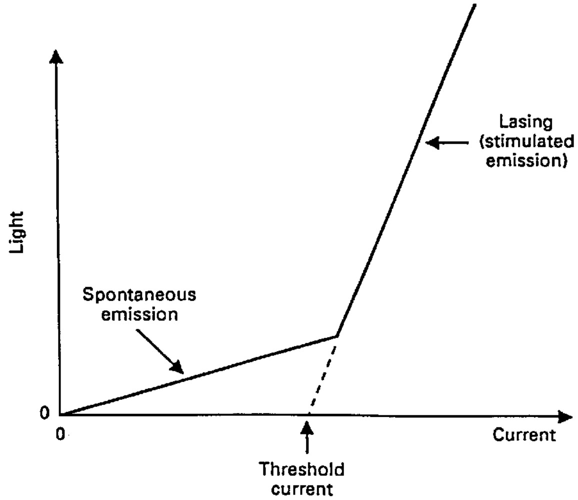

FIGURE 3 An example of the light-versus-current relationship of a semiconductor laser, illustrating the definition of threshold current.

find the threshold current of a laser this line is extrapolated to the point at which the stimulated emission is zero (see Fig. 3).

For further discussion of optical gain in semiconductors, see under ‘‘Quantum Well Lasers’’ later in this chapter. For more detail, see one of the books that has been written about semiconductor lasers.[1–5]

13.5 FABRICATION AND CONFIGURATIONS

In order to fabricate a heterostructure laser, thin semiconductor layers of varying composition must be grown on a semiconductor substrate (normally GaAs or InP). There are three primary epitaxial methods for growing these layers: liquid phase epitaxy (LPE), molecular beam epitaxy (MBE), and metalorganic chemical vapor deposition (MOCVD), which is also called organometallic vapor phase deposition (OMVPE).

Most of the laser diode structures which have been developed were first grown by LPE.[29] For a description of LPE see Chap. 12. Most commerically available lasers are grown by LPE; however, it is not well suited for growing thin structures such as quantum well lasers, because of lack of control and uniformity, especially over large substrates.[30] MBE and MOCVD are better suited for growths of thin, uniform structures.

MOCVD[31,32] is basically a specialized form of chemical vapor deposition. In MOCVD, gases reacting over the surface of a substrate form epitaxial layers; some of the gases are metalorganics. MOCVD is well suited for production environments, since epitaxial layers can be grown simultaneously on multiple large-area substrates and quickly, compared to MBE. It is expected that more commercial laser diodes will be grown by MOCVD in the future.

In the simplest terms, MBE[30,33,34,35] is a form of vacuum evaporation. In MBE growth occurs through the thermal reaction of thermal beams of atoms and molecules with the substrate, which is held at an appropriate temperature in an ultrahigh vacuum. MBE is different from simple vacuum evaporation for several reasons: the growth is single crystalline; the growth is much more controlled; and the vacuum system, evaporation materials, and substrate are cleaner.

With MOCVD the sources are gases, while with MBE they are solids. There are advantages and disadvantages to both types of sources. With gaseous sources the operator must work with arsine and/or phosphine, which are extremely hazardous gases. Solid-source phosphorus, however, is very flammable. Also, with MBE balancing the ratios of arsenic and phosphorus is extremely difficult; therefore, MOCVD is the preferred method for growth of GaInAsP and InP. MBE is a slower growth process (on the order of 1–2 μm per hour) than MOCVD. MBE therefore has the control necessary to grow very thin structures (10 Å), but MOCVD is more efficient for production. MBE has a cleaner background environment, which tends to make it better suited for growths at which background impurities must be kept at a minimum. Newer growth techniques,[36,37] which combine some of the advantages of both MBE and MOCVD, are gas source MBE, metalorganic MBE (MOMBE), and chemical beam epitaxy (CBE). In these growth techniques the background environment is that of MBE, but some or all of the sources are gases, which makes them more practical for growth of phosphorus-based materials.

Double heterostructure (DH) semiconductor lasers can be fabricated from a variety of lattice-matched semiconductor materials. The two material systems most frequently used are GaAs/$\mathrm{Al}_x\mathrm{Ga}_{1-x}\mathrm{As}$ and $\mathrm{In}_{1-x}\mathrm{Ga}_x\mathrm{As}_y\mathrm{P}_{1-y}$/InP. All of these semiconductors are III-V alloys. The GaAs/$\mathrm{Al}_x\mathrm{Ga}_{1-x}\mathrm{As}$ material system has the advantage that all compositions of $\mathrm{Al}_x\mathrm{Ga}_{1-x}\mathrm{As}$ are closely lattice-matched to GaAs, which is the substrate. For GaAs-based lasers, the active region is usually GaAs or low Al concentration $\mathrm{Al}_x\mathrm{Ga}_{1-x}\mathrm{As}$ ($x < 0.15$), which results in lasing wavelengths of 0.78–0.87 μm. $\mathrm{Al}_x\mathrm{Ga}_{1-x}\mathrm{As}$ quantum well lasers with wavelengths as low as 0.68 μm have been fabricated,[38] but the performance is reduced.

In the $In_{1-x}Ga_xAs_yP_{1-y}$/InP material system, the active region is $In_{1-x}Ga_xAs_yP_{1-y}$ and the cladding layers and substrate are InP. Not all compositions of $In_{1-x}Ga_xAs_yP_{1-y}$ are lattice-matched to InP; x and y must be chosen appropriately to achieve both lattice match and the desired lasing wavelength.[4] The lasing wavelength range of InP-based lasers, 1.1–1.65 μm, includes the wavelengths at which optical fibers have the lowest loss (1.55 μm) and material dispersion (1.3 μm). (For more information on fibers see Vol. II, Chap. 10) This match with fiber characteristics makes $In_{1-x}Ga_xAs_yP_{1-y}$/InP lasers the preferred laser for long-distance communication applications. InP-based lasers can also include lattice-matched $In_{1\text{-}x\text{-}y}Al_xGa_yAs$ layers,[39–42] but the performance is reduced.

There is a great deal of interest in developing true visible lasers for optical data storage applications. $(Al_xGa_{1-x})_{0.5}In_{0.5}P$ lasers[43–46] lattice-matched to GaAs have proven superior to very short wavelength GaAs/$Al_xGa_{1-x}As$ lasers. Higher Al concentration layers are cladding layers and a low Al concentration layer or $Ga_{0.5}In_{0.5}P$ is the active region. In this material, system lasers with a lasing wavelength as low as 0.63 μm which operate continuously at room temperature have been fabricated.[46]

In order to fabricate a blue semiconductor laser, other material systems will be required. Recently, lasing at 0.49 μm at a temperature of 77 K was demonstrated in a ZnSe- (II-VI semiconductor) based laser.[47]

Very long wavelength (>2 μm) semiconductor lasers are of interest for optical communication and molecular spectroscopy. The most promising results so far have been achieved with GaInAsSb/AlGaAsSb lattice-matched to a GaSb substrate. These lasers have been demonstrated to operate continuously at 30°C with a wavelength of 2.2 μm.[48]

Lead salt lasers ($Pb_{1-x}Eu_xSe_yTe_{1-y}$, $Pb_{1-x}Sn_xSe$, $PbS_{1-x}Se_x$, $Pb_{1-x}Sn_xTe$, $Pb_{1-x}Sr_xS$) can be fabricated for operation at even longer wavelengths,[4,49–52] but they have not been demonstrated at room temperature. Progress has been made, however, increasing the operating temperature; currently $Pb_{1-x}Eu_xSe_yTe_{1-y}$/PbTe lasers operating continuously at 203 K with a lasing wavelength of 4.2 μm have been demonstrated.[53] Other very long wavelength lasers are possible; recently, HgCdTe lasers with pulsed operation at 90 K and a lasing wavelength of 3.4 μm have been fabricated.[54]

Laser Stripe Structures

We have discussed the optical and electrical confinement provided by a double heterostructure parallel to the direction of epitaxial growth; practical laser structures also require a confinement structure in the direction parallel to the substrate.

The simplest semiconductor laser stripe structure is called an *oxide stripe laser* (see Fig. 4*a*). The metallic contact on the *n*-doped side of a semiconductor laser is normally applied with no definition for current confinement; current confinement is introduced on the *p* side of the device. For a wide-stripe laser, a dielectric coating (usually SiO_2 or Si_3N_4) is evaporated on the *p* side of the laser. Contact openings in the dielectric are made through photolithography combined with etching of the dielectric. The *p* metallic contact is then applied across the whole device, but makes electrical contact only at the dielectric openings. A contact stripe works very well for wide stripes, but in narrow stripes current spreading is a very significant drawback, because there is no mechanism to prevent current spreading after the current is injected. Also, since the active region extends outside of the stripe, there is no mechanism to prevent optical leakage in a contact-stripe laser. Lasers like this, which provide electrical confinement, but no optical confinement are called *gain-guided lasers.*

Another type of gain-guide laser is an ion bombardment stripe (see Fig. 4*b*). The material outside the stripe is made highly resistive by ion bombardment or implantation which produces lattice defects.[55] Implantation causes optical damage,[56] so implantation should not be heavy enough to reach the active region.

A more complicated stripe structure with electrical and optical confinement is required

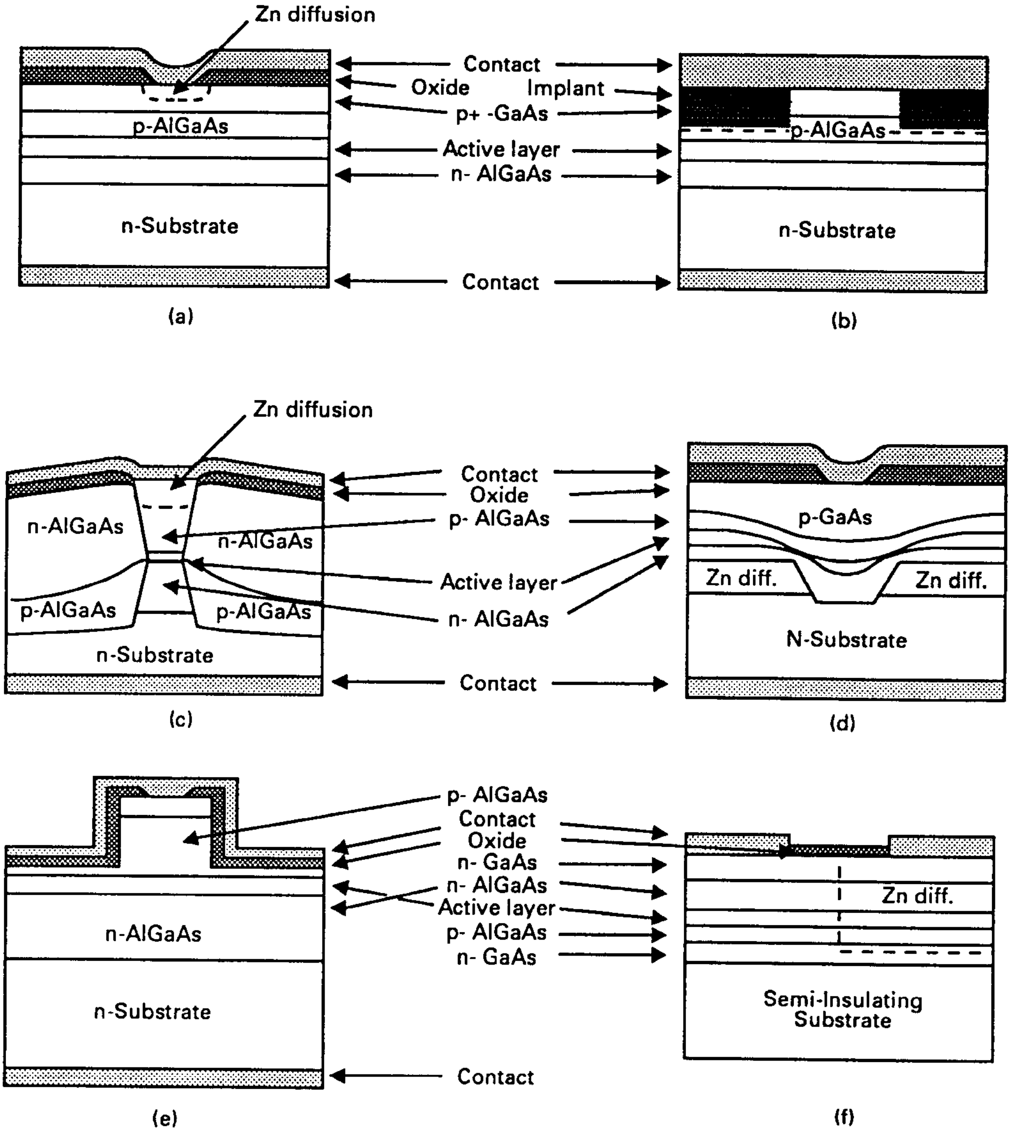

FIGURE 4 Schematic diagrams of GaAs/AlGaAs stripe laser structures. (*a*) Oxide stripe laser; (*b*) ion bombardment laser, (*c*) buried heterostructure (BH) laser; (*d*) variation on buried heterostructure laser; (*e*) ridge waveguide (RWG) laser; and (*f*) transverse junction stripe (TJS) laser.

for an efficient narrow-stripe laser. A number of structures which accomplish the necessary confinement have been developed. These structures are called *index-guided lasers,* since optical confinement is achieved through a change in refractive index.

The buried heterostructure laser (BH) was first developed by Tsukada.[57] To form a BH stripe, a planar laser structure is first grown. Stripe mesas of the laser structure are formed by photolithography combined with etching. For a GaAs-based BH laser, AlGaAs is then regrown around the lasing stripe. Figure 4*c* is a schematic diagram of a buried heterostructure. Since the active region is completely surrounded by AlGaAs, a BH has tight optical confinement. If the regrown layers are doped to produce a reverse-biased junction or are semi-insulating, a BH laser can also provide good current confinement. There are many variations on the BH structure. In some cases the active region is grown in the second growth step (see Fig. 4*d*). The tight optical confinement of BH lasers allows practical fabrication of very narrow stripes, on the order of 1 to 2 μm.

There are many other stripe structures that provide weaker optical confinement than a buried heterostructure. One of the simplest and most widely used of these is the ridge waveguide laser (RWG) (Fig. 4*e*). After epitaxial growth, most of the *p*-cladding layer is etched away, leaving a mesa where the lasing stripe will be. Only this mesa is contacted, which provides electrical confinement. The change in surrounding refractive index produces an effective change in refractive index in the active region beyond the mesa and provides optical confinement. Other stripe structures are described later in this chapter under "High-Power Semiconductor Lasers."

Another type of laser stripe is one in which confinement is provided by the *p*-*n* junction. The best-known laser of this type is the transverse junction stripe[58,59,60] (see Fig. 4*f*). In order to fabricate a TJS laser, both cladding layers are grown as *n*-AlGaAs. Zn diffusion is then used to create a *p*-*n* junction and contacts are applied on either side of the junction. In this laser the current flows parallel to the substrate rather than perpendicular to it. In a TJS laser the active region is limited to the small region of GaAs in which the Zn diffusion front ends.

The examples of laser stripe structures described here are GaAs/AlGaAs lasers. Long-wavelength laser structures (InP-based) are very similar,[4] but the active region is InGaAsP and the cladding layers are InP. With an *n*-InP substrate the substrate can be used as the *n*-type cladding, which allows greater flexibility in designing structures such as that illustrated in Fig. 4*d*. For a more detailed discussion of GaAs-based laser stripe structures see Casey and Panish[2] or Thompson.[3]

13.6 QUANTUM WELL LASERS

The active region in a conventional DH semiconductor laser is wide enough (~1000 Å) that it acts as bulk material and no quantum effects are apparent. In such a laser the conduction band and valence band are continuous (Fig. 5*a*). In bulk material the density of states, $D(E)$, for a transition energy E per unit volume per unit energy is:[26]

$$D(E) = \sum_{i=l,h} \frac{m_r^i}{\pi^2 \hbar^3} \sqrt{2m_r^i(E - E_g)} \qquad E > E_g \tag{2}$$

where E_g is the bandgap energy, $\hbar$ is Plank's constant divided by 2π, l and h refer to light and heavy holes, and m_r is the effective mass of the transition which is defined as:

$$\frac{1}{m_r} = \frac{1}{m_c} + \frac{1}{m_v} \tag{3}$$

where m_c is the conduction band mass and m_v is the valence band mass. (The split-off hole band and the indirect conduction bands are neglected here and have a negligible effect on most semiconductor laser calculations.)

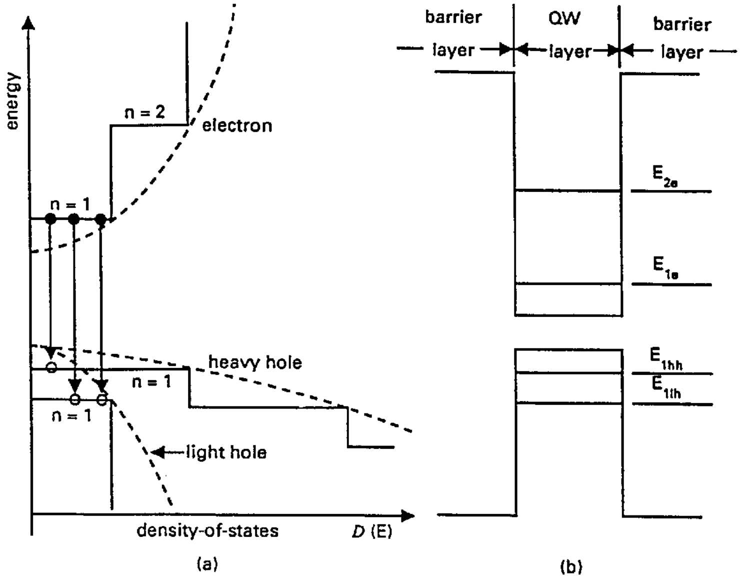

FIGURE 5 Schematic diagrams of (*a*) the density of states for a quantum well (solid line) and for a bulk DH (dotted line) and (*b*) quantized energy levels in a quantum well for $n = 1$ and 2 for the conduction band and for the light and heavy hole bands. (*After Ref. 63*.)

If the active region of a semiconductor laser is very thin (on the order of the DeBroglie wavelength of an electron) quantum effects become important. When the active region is this narrow (less than ~200 Å) the structure is called a *quantum well* (QW). (For a review of QWs see Dingle,[61] Holonyak et al.,[62] Okamoto,[63] or the book edited by P. Zory.[64]) Since the quantum effects in a QW are occurring in only one dimension they can be described by the elementary quantum mechanical problem of a particle in a one-dimensional quantum box.[65] In such a well, solution of Schrödinger's equation shows that a series of discrete energy levels (Fig. 5*b*) are formed instead of the continuous energy bands of the bulk material. With the approximation that the well is infinitely deep, the allowed energy levels are given by:

$$E_n = \frac{(n\pi\hbar)^2}{2mL_z^2} \tag{4}$$

where $n = 1, 2, 3, \ldots, m$ is the effective mass of the particle in the well, and L_z is the quantum well thickness. Setting the energy at the top of the valence band equal to zero, the allowed energies for an electron in the conduction band of a semiconductor QW become $E = E_g + E_n^c$, where E_n^c is E_n with m equal to m_c. The allowed energies for a hole in the valence band are then $E = -E_n^v$, where E_n^v is E_n with m equal to m_v. The allowed transition energies E, are limited to:

$$E = E_g + E_n^c + E_n^v + \frac{\hbar^2\mathbf{k}^2}{2m_r} \tag{5}$$

where $\mathbf{k}$ is the wavevector, rigorous $\mathbf{k}$-selection is assumed, and transitions are limited to those with $\Delta n = 0$.

This quantization of energy levels will, of course, change the density of states. For a QW the density of states is given by:

$$D(E) = \sum_{i=l,h} \sum_{n=1}^{\infty} \frac{m_r^i}{L_z \pi \hbar^2} H(E - E_g - E_n^c - E_{n,i}^v) \tag{6}$$

where H is the Heavyside function. The difference in the density of states directly affects the modal optical gain generated by the injection of carriers. The modal gain is proportional to the stimulated emission rate:[1,66,67]

$$g(E, N) \alpha \frac{\Gamma D(E)\, |M|^2 (f_c(E, N) - f_v(E, N))}{E} \tag{7}$$

where Γ is the optical confinement factor, $|M|^2$ is the matrix element for the transition, N is the carrier density of either electrons or holes (the active region is undoped so they have equal densities), and $f_c(E, N)$ and $f_v(E, N)$ are the Fermi occupation factors for the conduction and valence bands. (For a detailed review of gain in semiconductor lasers see Ref. 67.)

The optical confinement factor Γ is defined as the ratio of the light intensity of the lasing mode within the active region to the total intensity over all space. Since a QW is very thin, Γ_{QW} will be much smaller than Γ_{DH}. Γ_{DH} is typically around 0.5 whereas for a single QW, Γ_{QW} is around 0.03.

The Fermi occupation functions describe the probability that the carriers necessary for stimulated emission have been excited to the states required. They are given by:[1,19]

$$f_c(E_c, N) = \frac{1}{1 + \exp\left((E_g + E_c - F_c)/kT\right)} \tag{8}$$

and

$$f_v(E_v, N) = \frac{1}{1 + \exp\left(-(E_v + F_v)/kT\right)} \tag{9}$$

where k is the Boltzmann constant, T is temperature, E_c is the energy level of the electron in the conduction band relative to the bottom of the band (including both the quantized energy level and kinetic energy), E_v is the absolute value of the energy level of the hole in a valence band, and F_c and F_v are the quasi-Fermi levels in the conduction and valence bands. Note that E_c and E_v are dependent on E, so f_c and f_v are functions of E. f_c and f_v are also functions of N through F_c and F_v. F_c and F_v are obtained by evaluating the expressions for the electron and hole densities:

$$N = \int D_c(E_c) f_c(E_c)\, dE_c \tag{10}$$

and

$$N = \int D_v(E_v) f_v(E_v)\, dE_v \tag{11}$$

where $D_c(E_c)$ and $D_v(E_v)$ are the densities of states for the conduction and valence bands and follow the same form as $D(E)$ for a transition.

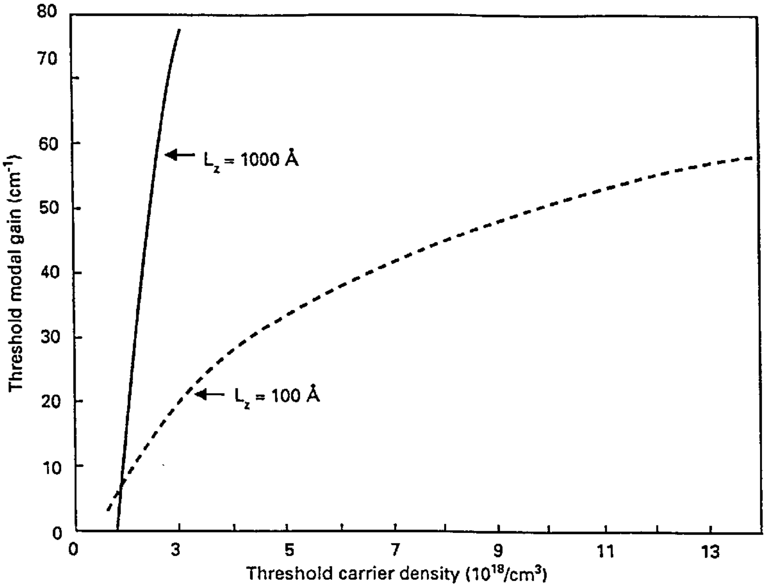

FIGURE 6 Threshold modal gain as a function of threshold carrier density for a conventional (Al, Ga)As double heterostructure with an active region thickness of 1000 Å and for a 100-Å single quantum well. (*From Ref. 68.*)

In Fig. 6, the results of a detailed calculation[68] based on Eq. (7) for the threshold modal gain as a function of threshold carrier density are plotted for a 100-Å single QW. The corresponding curve for a DH laser with an active region thickness of 1000 Å is also shown. The gain curves for the QWs are very nonlinear because of saturation of the first quantized state as the carrier density increases. The transparency carrier density N_o is the carrier density at which the gain is zero. From Fig. 6 it is clear that the transparency carrier densities for QW and DH lasers are very similar and are on the order of 2×10^{18} cm^{-3}.

The advantage of a QW over a DH laser is not immediately apparent. Consider, however, the transparency current density J_o. At transparency[28]

$$J_o = \frac{N_o L_z e}{\tau_s} \qquad (12)$$

where L_z is the active layer thickness, e is the charge of an electron and τ_s is the carrier lifetime near transparency. τ_s is approximately 2 to 4 ns for either a QW or a DH laser. Since N_o is about the same for either structure, any difference in J_o will be directly proportional to L_z. But L_z is approximately ten times smaller for a QW; therefore, J_o will be approximately ten times lower for a QW than for a conventional DH laser. (A lower J_o will result in a lower threshold current density since the threshold current density is equal to J_o plus a term proportional to the threshold gain.) Note that this result is not determined by the quantization of energy levels; it occurs because fewer carriers are needed to reach the same carrier density in a QW as in a DH laser. In other words, this result is achieved because the QW is thin!

In this discussion we are considering current density instead of current. The threshold current density (current divided by the length and width of the stripe) is a more meaningful measure of the relative quality of the lasing material than is current. Current depends very strongly on the geometry and stripe fabrication of the device. In order to

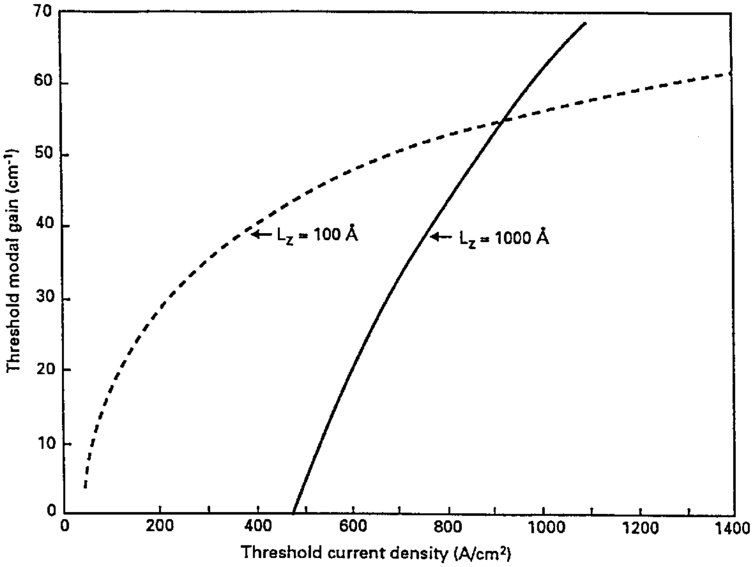

FIGURE 7 Threshold modal gain as a function of threshold current density for a conventional (Al, Ga)As double heterostructure with an active region thickness of 1000 Å and for a 100-Å single quantum well. (*From Ref. 68.*)

eliminate geometry-induced variations, current density is normally measured on broad-area (50–150 μm wide) oxide stripe lasers (see earlier under "Fabrication and Configurations"). With a narrow stripe the current spreads beyond the intended stripe width, so it is difficult to accurately measure the current density.

Figure 7 shows the results of a detailed calculation[68] of the threshold modal gain versus the threshold current density for a DH laser with an active region thickness of 1000 Å and for a 100-Å single QW. The potential for lower threshold current densities for QW lasers is clear for threshold gains less than that where the curve for the DH laser intercepts those of the QWs. With low losses, the threshold current of a QW laser will be substantially lower than that of a DH laser, since the threshold gain will be below the interception point.

To get an appreciation for how the threshold current density of a single QW will compare to that of a DH laser, consider that near transparency, the modal gain is approximately linearly dependent on the current density:

$$g(J) = A(J - J_o) \tag{13}$$

where A is a constant which should have a similar value for either a QW or a DH laser (this can be seen visually on Fig. 7). Taking Eq. (13) at threshold we can equate it to Eq. (1) and solve for J_{th} (the threshold current density):

$$J_{th} = J_o + \frac{\alpha_i}{A} + \frac{1}{2AL} \ln\left(\frac{1}{R_F R_R}\right) \tag{14}$$

α_i is related primarily to losses occurring through the interaction of the optical mode with the active region. In a QW, the optical confinement is lower, which means that the optical mode interacts less with the active region and α_i tends to be smaller. Let's substitute in the numbers in order to get an idea for the difference between a QW and a DH laser. Reasonable values are:[69] $A_{\text{QW}} \sim 0.7\ \text{A}^{-1}\,\text{cm}$, $A_{\text{DH}} \sim 0.4\ \text{A}^{-1}\,\text{cm}$, $J_o^{\text{QW}} \sim 50\ \text{A/cm}^2$, $J_o^{\text{DH}} \sim 500\ \text{A/cm}^2$, $\alpha_i^{\text{QW}} \sim 2\ \text{cm}^{-1}$, $\alpha_i^{\text{DH}} \sim 15\ \text{cm}^{-1}$, $L \sim 400\ \mu\text{m}$, and for uncoated facets $R_F = R_R = 0.32$. Substituting in we get: $J_{th}^{\text{QW}} \sim 95\ \text{A/cm}^2$ and $J_{th}^{\text{DH}} \sim 610\ \text{A/cm}^2$.

It is clear that changes in the losses will have a more noticeable effect on threshold current for a QW than for a DH laser since losses are responsible for a more significant portion of the threshold current of a QW laser. The gain curve of a QW laser saturates due to the filling of the first quantized energy level, so operating with low losses is even more important for a QW than is illustrated by the above calculation. When the gain saturates, the simple approximation of Eq. (13) is invalid. Operating with low end losses is also important for a QW, since they are a large fraction of the total losses. This explains why threshold current density results for QW lasers are typcially quoted for long laser cavity lengths (greater than 400 μm), while DH lasers are normally cleaved to lengths on the order of 250 μm. High-quality broad-area single QW lasers (without strain) have threshold current densities lower than 200 A/cm^2 (threshold current densities as low as 93 A/cm^2 have been achieved[69–71]), while the very best DH lasers have threshold current densities around 600 A/cm^2.[72] The end loss can also be reduced by the use of high-reflectivity coatings.[25] The combination of a single QW active region with a narrow stripe and high-reflectivity coatings has allowed the realization of submilliampere threshold current semiconductor lasers.[68,69,73] and high-temperature operation.[74,75,76]

A disadvantage of QW lasers compared to DH lasers is the loss of optical confinement. One of the advantages of a DH laser is that the active region acts as a waveguide, but in a QW the active region is too thin to make a reasonable waveguide. Guiding layers are needed between the QW and the (Al, Ga)As cladding layers. As the bandgap diagram of Fig. 8 illustrates, a graded layer of intermediate aluminum content can be inserted between the QW and each cladding layer. The advantage of this structure, which is called a *graded-index separate-confinement heterostructure* (GRIN SCH),[77,78] is separate optical and electrical confinement. The carriers are confined in the QW, but the optical mode is confined in the surrounding layers. The grading can be either parabolic (as illustrated in Fig. 8) or linear. Experimentally it has been found that the optimum AlAs mole fraction x for layers around a GaAs QW is approximately 0.2.[79] Typically, each additional layer is on the order of 2000 Å thick. In order to confine the optical model, the cladding layers need a low index of refraction compared to that of an $x = 0.2$ layer. In a simple DH laser, the cladding layers typically have x between 0.3 and 0.4, but for good confinement in an

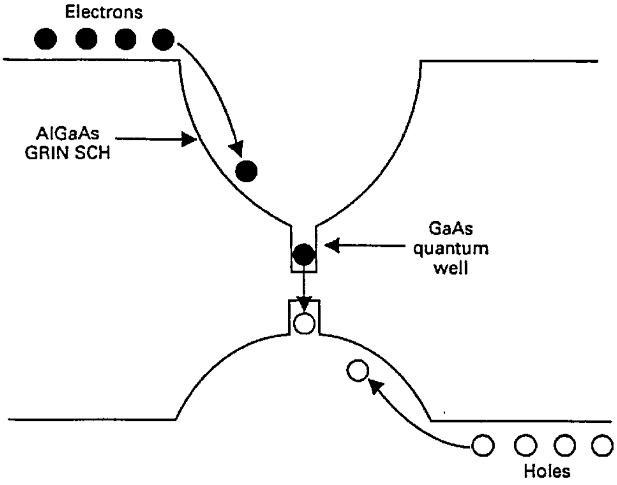

FIGURE 8 Schematic energy-band diagram for a GRIN SCH single QW.

$x = 0.2$ layer, more aluminum should be incorporated into the cladding layers; x should be between 0.5 and 0.7.

In the discussion so far we have considered only single QWs. Structures in which several quantum wells are separated by thin AlGaAs barriers are called *multiquantum wells* (MQWs) and also have useful properties. For a given carrier density, a MQW with n QWs of equal thickness, L_z has gain which is approximately n times the gain for a single QW of the same thickness L_z, but the current density is also approximately increased by a factor of n.[80] The transparency current density will be larger for the MQW than for the single QW since the total active region thickness is larger. Figure 9 shows that, as a function of current density, the gain in the single QW will start out higher than that in the MQW because of the lower transparency current, but the gain in the MQW increases more quickly so the MQW gain curve crosses that of the single QW at some point.[81]

Which QW structure has a lower threshold current will depend on how large the losses are for a particular device structure and on where the gain curves cross. The best structure for low threshold current in a GaAs-based laser is normally a single QW, but for some applications involving very large losses and requiring high gain a MQW is superior. For applications in which high output power is more important than low current a MQW is appropriate. A MQW is also preferred for high modulation bandwidth (see ''Spectral Properties'' later in this chapter).

An advantage of a QW structure over a bulk DH laser is that the lasing wavelength, which is determined by the bulk bandgap plus the first quantized energy levels, can be changed by changing the quantum well thickness [see Eq. (4)]. A bulk GaAs laser has a lasing wavelength of about 0.87 μm, while a GaAs QW laser of normal thickness (60–120 Å) has a lasing wavelength of 0.83–0.86 μm. Further bandgap engineering can be introduced with a strained QW.[67,81,82]

Strained Quantum Well Lasers

Normally, if a semiconductor layer of significantly different lattice constant is grown in an epitaxial structure, it will maintain its own lattice constant and generate misfit dislocations. If this layer is very thin, below a certain critical thickness,[81,83–85] it will be distorted to match the lattice constant (perpendicular to the substrate) of the surrounding layers and will not generate misfit locations. A layer with thickness above the critical thickness is called ''relaxed,'' one below is called ''strained.''

Straining a semiconductor layer changes the valence-band structure. Figure 10*a* shows the band structure of an unstrained III-V semiconductor, while Fig. 10*b* and *c* show the band structure under biaxial tension and compression, respectively.[81,82] For the unstrained semiconductor, the light and heavy hole bands are degenerate at $\mathbf{k} = 0$ (Γ). Strain lifts this degeneracy and changes the effective masses of the light and heavy holes. In the direction parallel to the substrate the heavy hole band becomes light and the light hole band becomes heavy. Under biaxial tension (Fig. 10*b*) the bandgap decreases and the ''heavy'' hole band lies below the ''light'' hole band. Under biaxial compression the bandgap increases and the ''heavy'' hole band lies above the ''light'' hole band.

Figure 10 is a simplification of the true band structure.[81,82] The bands are not really exactly parabolic, especially the hole bands, and strain increases the nonparabolicity of the hole bands. The details of the band structure can be derived using $\mathbf{k} \cdot \mathbf{p}$ theory.[86–90]

For a GaAs based QW, strain can be introduced by adding In to the QW. Since InAs has a larger lattice constant than GaAs, this is a compressively strained QW. In the direction of quantum confinement the highest quantized hole level is the first heavy hole level. This hole level will, therefore, have the largest influence on the density of states and on the optical gain. The effective mass of holes in this level confined in the QW is that parallel to the substrate and is reduced by strain. The reduction of the hole mass within the QW results in a reduced density of hole states [see Eq. (6)].

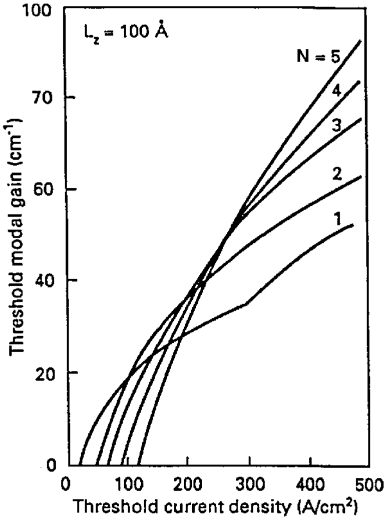

FIGURE 9 Threshold modal gain as a function of threshold current density for (Al, Ga)As single QW and MQWs with 2, 3, 4, and 5 QWs. Each QW has a thickness of 100 Å. (*From Ref. 80.*)

The reduction in density of hole states is a significant improvement. In order for a semiconductor laser to have optical gain (and lase), $f_c(E, N) - f_v(E, N)$ must be greater than zero [see Eq. (7)]. In an unstrained semiconductor the electrons have a much lighter mass than the heavy holes; the holes therefore have a higher density of states than the electrons. F_c and $f_c(E, N)$ change much more quickly with the injection of carriers than F_v and $f_v(E, N)$. Since approximately equal numbers of holes and electrons are injected into the undoped active layer, reducing the mass of the holes by introducing compressive strain reduces the carrier density required to reach transparency and therefore reduces the threshold current of a semiconductor laser.[91]

This theoretical prediction is well supported by experimental results. Strained InGaAs

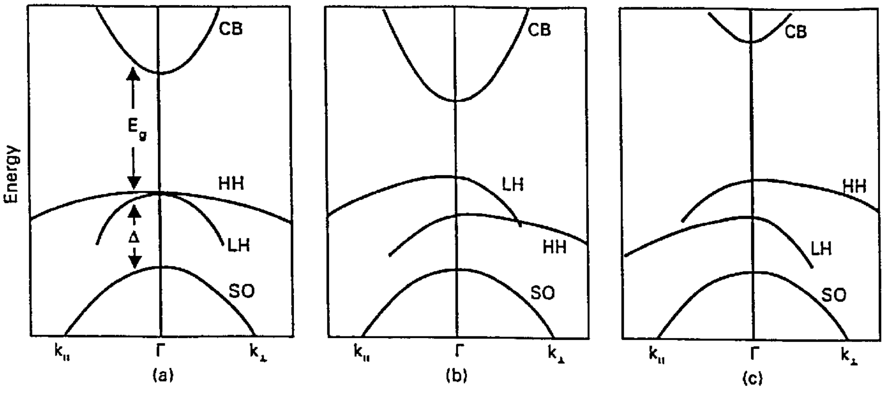

FIGURE 10 Schematic diagrams of the band structure of a III-V semiconductor: (*a*) unstrained; (*b*) under tensile strain; and (*c*) compressively strained. (*After Ref. 81.*)

single-QW lasers with record-low threshold current densities of 45 to 65 A/cm^2 have been demonstrated.[92–95] These very high quality strained QW lasers typically have lasing wavelengths from 0.98 to 1.02 μm, QW widths of 60 to 70 Å, and In concentrations of 20 to 25 percent. InGaAs QWs with wavelengths as long as 1.1 μm have been successfully fabricated,[96,97] but staying below the critical thickness of the InGaAs layers becomes a problem since the wavelength is increased by increasing the In concentration. (With higher In concentration the amount of strain is increased and the critical thickness is reduced.)

Strained InGaAs QWs have another advantage over GaAs QWs. Strained QW lasers are more reliable than GaAs lasers, i.e., they have longer lifetimes. Even at high temperatures (70–100°C), they are very reliable.[75,76] The reasons for this are not well understood, but it has been suggested that the strain inhibits the growth of defects in the active region.[98–100] Improving the reliability of GaAs-based lasers is of great practical significance since GaAs lasers are generally less reliable than InP-based lasers.[4,101,102]

Up to this point our discussion of QW lasers has been limited to GaAs-based QW lasers. QW lasers can also be fabricated in other material systems. GaInP/AlGaInP visible lasers have been improved significantly with the use of a single strained QW active region.[103–105] These are also compressively strained QWs formed by adding excess In to the active region. This is a much less developed material system than GaAs, so recent results such as 215 A/cm^2 for a single strained $Ga_{0.43}In_{0.57}P$ QW[103] are very impressive.

Long Wavelength (1.3 and 1.55 μm) Quantum Well Lasers

Long wavelength (InGaAsP/InP) QWs generally do not perform as well as GaAs-based QWs; however, with the advent of strained QW lasers significant progress has been made. Narrow bandgap lasers are believed to be significantly effected by nonradiative recombination processes such as Auger recombination[4,106–108] and intervalence band absorption.[109] In Auger recombination (illustrated in Fig. 11) the energy from the recombination of an electron and a hole is transferred to another carrier (either an electron or a hole). This newly created carrier relaxes by emitting a phonon; therefore, no photons are created. In intervalence band absorption (IVBA) a photon is emitted, but is reabsorbed to excite a hole from the split-off band to the heavy hole band. These processes reduce the performance of long wavelength QW lasers enough to make an MQW a lower threshold

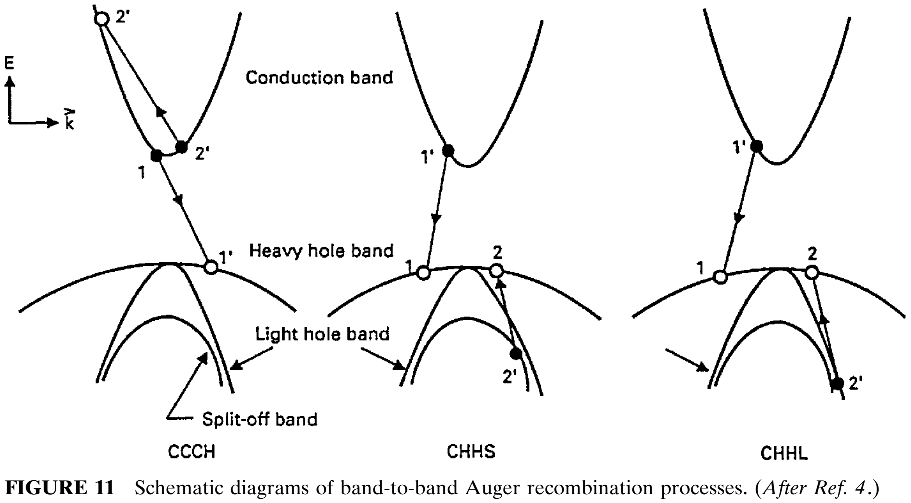

FIGURE 11 Schematic diagrams of band-to-band Auger recombination processes. (*After Ref. 4.*)

device than a single QW. As illustrated by Fig. 9, this means that the threshold gain is above the point where the gain versus current density curve of a single QW crosses that of an MQW. Good threshold current density results for lasers operating at 1.5 μm are 750 A/cm^2 for a single QW and 450 A/cm^2 for an MQW.[110]

Long-wavelength QW lasers can be improved by use of a strained QW. For these narrow bandgap lasers strain has the additional benefits of suppressing Auger recombination[111,112] and intervalence band absorption.[111] Several groups have demonstrated excellent results with compressively strained InGaAsP/InP QW lasers.[113–115] Compressively strained single QW lasers operating at 1.5 μm have been demonstrated with threshold current densities as low as 160 A/cm^2.[115]

Surprisingly, tensile strained InGaAsP/InP QW lasers also show improved characteristics.[115–117] Tensile strained QW lasers operating at 1.5 μm have been fabricated with threshold current densities as low as 197 A/cm^2.[116] These results had not been expected (although some benefit could be expected through suppression of Auger recombination), but have since been explained in terms of TM-mode lasing[118,119] (normally, semiconductor lasers lase in the TE mode) and suppression of spontaneous emission.[118]

Long-wavelength semiconductor lasers are more sensitive to increases in operating temperature than GaAs-based semiconductor lasers. This temperature sensitivity has been attributed to the strong temperature dependence of Auger recombination[106–108] and intervalence-band absorption.[109] The use of a strained QW should therefore improve the high-temperature operation of these lasers. This is in fact the case; the best results are reported for tensile strained QW lasers with continuous operation at 140°C.[115,117]

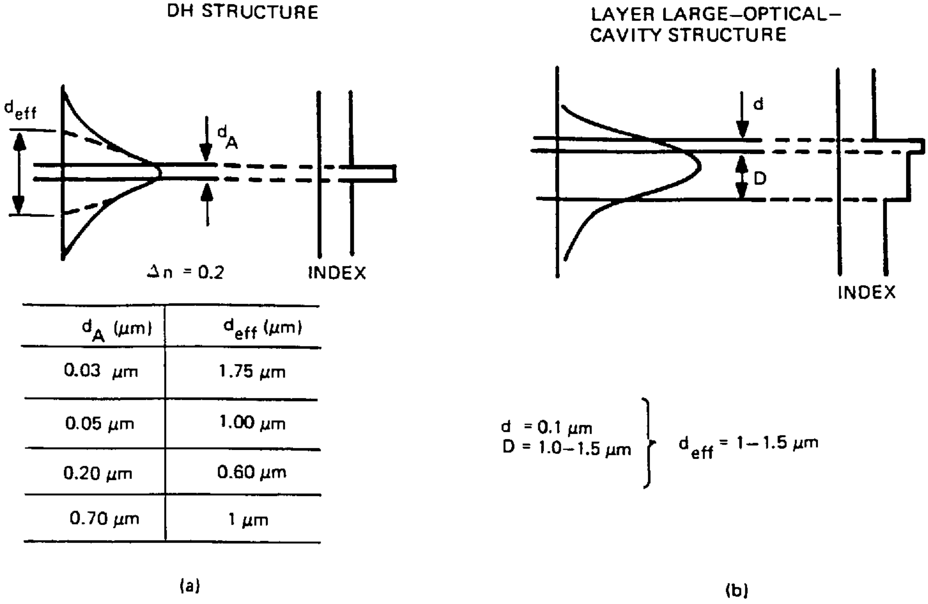
In summary, the use of QW active regions has significantly improved the performance of semiconductor lasers. In this section we have emphasized the dramatic reductions in threshold current density. Improvements have also been realized in quantum efficiency,[119] high-temperature operation,[74–76,115,117] modulation speed (discussed later in this chapter), and spectral linewidth (discussed later). We have limited our discussion to quantum wells. It is also possible to provide quantum confinement in two directions, which is called a *quantum wire,* or three directions, which is called a *quantum dot* or *quantum box.* It is much more difficult to fabricate a quantum wire than a QW, but quantum wire lasers have been successfully demonstrated.[121] For a review of these novel structures we refer the reader to Ref. 122.

13.7 HIGH-POWER SEMICONDUCTOR LASERS

There are several useful methods for stabilizing the lateral modes of an injection laser.[123–129] In this section, we will discuss techniques for the achievement of high-power operation in a single spatial and spectral mode. There are several physical mechanisms that limit the output power of the injection laser: spatial hole-burning effects lead to multispatial mode operation and are intimately related to multispectral mode operation, temperature increases in the active layer will eventually cause the output power to reach a maximum, and catastrophic facet damage will limit the ultimate power of the laser diode (GaAlAs/GaAs). Thus, the high-power laser designer must optimize these three physical mechanisms to achieve maximum power. In this section, we discuss the design criteria for optimizing the laser power.

High-Power Mode-Stabilized Lasers with Reduced Facet Intensity

One of the most significant concerns for achieving high-power operation and high reliability is to reduce the facet intensity while, at the same time, providing a method for stabilizing the laser lateral mode. Over the years, researchers have developed four approaches for performing this task: (1) increasing the lasing spot size, both perpendicular



d_A (μm)	d_{eff} (μm)
0.03 μm	1.75 μm
0.05 μm	1.00 μm
0.20 μm	0.60 μm
0.70 μm	1 μm

FIGURE 12 Schematic diagrams of the two most commonly used heterostructure configurations for fabricating high-power laser diodes. (*a*) DH structure; (*b*) layer large-optical-cavity structure. The d_{eff} calculations are after Botez.[130]

to and in the plane of the junction, and at the same time introducing a mechanism for providing lateral mode-dependent absorption loss to discriminate against higher-order modes; (2) modifying the facet reflectivities by providing a combination of high-reflectivity and low-reflectivity dielectric coatings; (3) eliminating or reducing the facet absorption by using structures with nonabsorbing mirrors (NAM); (4) using laser arrays and unstable resonator configurations to increase the mode volume. Techniques 1 and 2 are the commonly used techniques and will be further discussed in this section. Techniques 3 and 4 (laser arrays) will be discussed shortly.

Given the proper heat sinking, in order to increase the output power of a semiconductor GaAlAs/GaAs laser, we must increase the size of the beam and thus reduce the power density at the facets for a given power level. The first step in increasing the spot size involves the transverse direction (perpendicular to the junction). There are two approaches for accomplishing this, with the constraint of keeping threshold current low: (1) thinning the active layer in a conventional double-heterostructure (DH) laser (Fig. 12*a*) below 1000 Å and (2) creating a large optical cavity structure (Fig. 12*b*).

Thinning the active layer from a conventional value of 0.2 to 0.03 μm causes the transverse-mode spot size to triple for a constant index of refraction step, Δn_r.[130] The catastrophic power level is proportional to the effective beam width in the transverse direction, d_{eff}. the asymmetric large optical cavity (A-LOC) concept[3,131] involves the epitaxial growth of an additional cladding layer referred to as the *guide layer* (d_G), with index of refraction intermediate between the *n*-AlGaAs cladding layer and the active layer. By using a relatively small index of refraction step ($\Delta n_r = 0.1$) versus 0.20–0.30 for DH lasers, it is possible to force the optical mode to propagate with most of its energy in the guide layer. The effective beam width for the A-LOC can be approximately expressed as

$$d_{eff} = d_A + d_G \tag{15}$$

where d_A is the active layer thickness. Mode spot sizes in the transverse direction of approximately 1.5 μm can be achieved.

Important Commercial High-Power Diode Lasers

In the last few years, several important high-power laser geometries have either become commercially available or have demonstrated impressive laboratory results. Table 1 summarizes the characteristics of the more important structures. It is evident that the structures that emit the highest cw power (>100 mW) (QW ridge waveguide (QWR), twin-ridge structure (TRS), buried TRS (BTRS), current-confined constricted double-heterostructure large optical cavity (CC-CDH-LOC), and buried V-groove-substrate inner stripe (BVSIS)) have several common features: (1) large spot size (CDH-LOC, TRS, BTRS, QW ridge); (2) low threshold current and high quantum efficiency; and (3) a combination of low- and high-reflectivity coatings. All the lasers with the highest powers, except for the CDH-LOC, use the thin active laser design. A recent trend has been the use of quantum well active layers.

Figure 13 contains schematic diagrams for five of the more common DH laser designs for high cw power operation, and Fig. 14 shows plots of output power versus current for various important geometries listed in Table 1.

The CC-CDH-LOC device with improved current confinement[136] (Fig. 13*a*) is fabricated by one-step liquid-phase epitaxy (LPE) above a mesa separating two dovetail channels. Current confinement is provided by a deep zinc diffusion and a narrow oxide stripe geometry. The final cross-sectional geometry of the device is very dependent on the exact substrate orientation and LPE growth conditions.[145] By properly choosing these conditions, it is possible to grow a convex-lens-shaped active layer ($Al_{0.07}Ga_{0.93}As$) on top of a concave-lens-shaped guide layer ($Al_{0.21}Ga_{0.79}As$). The combination of the two leads to a structure with antiwaveguiding properties and a large spot size. Discrimination against higher-order modes is provided by a leaky-mode waveguide. The cw threshold current is in the range of 50–70 mA. Single-mode operation has been obtained to 60 mW under 50 percent duty cycle, and the maximum cw power from the device is 165 mW. The power conversion efficiency at this power level is 35 percent considering only the front facet.

The CSP laser[127] (Fig. 13*b*) is fabricated by one-step LPE above a substrate channel. The current stripe is purposely made larger than the channel to ensure uniform current flow across the channel. However, this leads to some waste of current and thus a lower differential efficiency than other similar high-power laser structures (BVSIS, BTRS). Lateral mode control is very effectively obtained by the large difference in the absorption coefficient α between the center and edges of the channel and by changes in the index of refraction that result from changes in the geometry. By proper control of the active and n-cladding layer thicknesses, it is possible to obtain $\Delta\alpha \cong 1000\,\text{cm}^{-1}$ (see Ref. 146) and $\Delta n_r \cong 10^{-2}$. Threshold currents are in the range of 55–70 mA. The transverse far field is relatively narrow due to the very thin active layer. Researchers from RCA have obtained power levels in excess of 150 mW (cw) with a CSP-type laser.[137] A detailed study of the CSP laser has been presented by Lee et al. in a recent publication.[147]

Matsushita[133] has also developed a CSP-like structure called the twin-ridge structure (TRS) that uses a 400-Å active layer thickness (Fig. 13*c*). The structure has demonstrated fundamental-mode cw power to 200 mW and single-longitudinal-mode cw power to 100 mW. The maximum available power for the TRS laser is 115 mW, and threshold currents are in the range of 80–120 mA. It appears that even though their geometry is similar to that of the CSP, lasers with ultrathin and planar-active layers have been fabricated. It should be further pointed out that one of the keys to achieving ultrahigh power from CSP-like structures is the achievement of ultrathin (<1000 Å) active layers that are highly uniform in thickness. Small nonuniformities in the active layer thickness

TABLE 1 Summary of Mode-Stabilized High-Power Laser Characteristics (GaAlAs/GaAs)*†

† Approaches for achieving high-power GaAlAs lasers:

- Thin active (TA) or A-LOC layer to decrease facet power density
- Tight current confinement to produce high current utilization
- Combination of low/high-reflectivity facet coatings (AR/HR) to produced high differential efficiency and lower facet intensity
- Quantum well design with long cavity

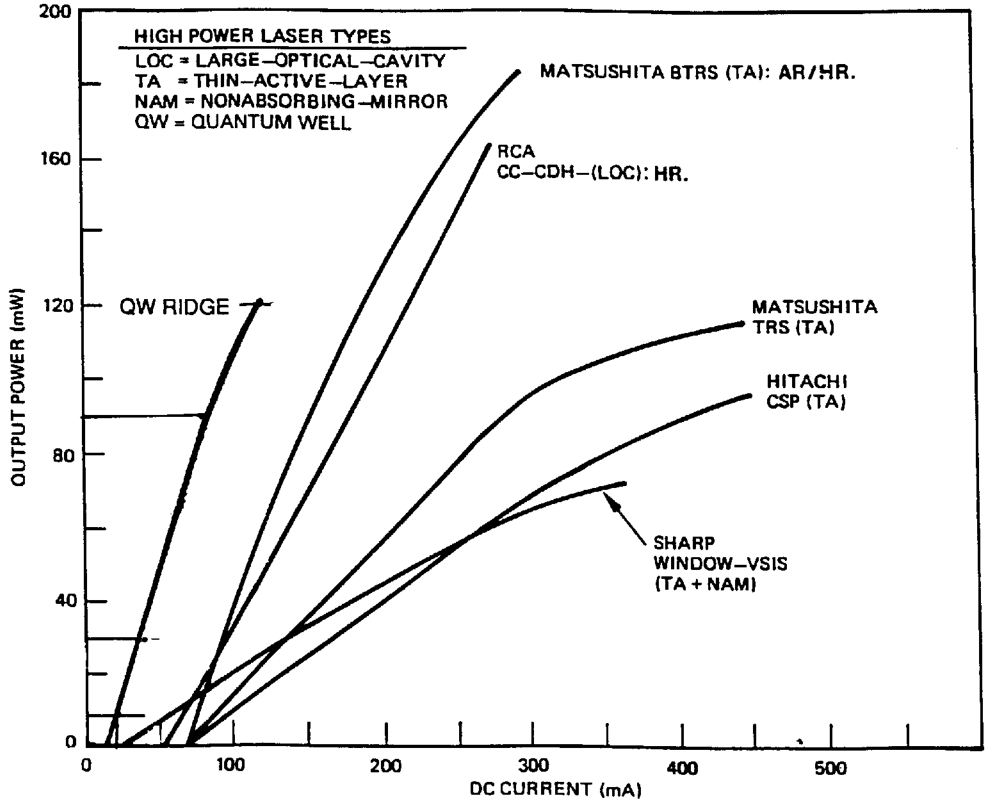

FIGURE 14 Plots showing output power versus cw current for the major high-power laser diodes. The maximum power in a single spatial mode is in the range of 100–150 mW and total cw power can approach 200 mW.

lead to a larger Δn_r difference, and thus a smaller lateral spot size, which will lead to lower power levels and reduced lateral mode stability.

Metalorganic chemical vapor deposition (MOCVD, discussed earlier) has been used to fabricate lasers with higher layer uniformity, which leads to a reduced spectral width and more uniform threshold characteristics. Several MOCVD laser structures with demonstrated high-power capability are schematically shown in Fig. 13, and their characteristics are summarized in Table 1. Figure 13*d* shows the twin-channel substrate mesa (TCSM) laser.[140] The fabrication consists of growing a DH laser structure over a chemically etched twin-channel structure using MOCVD. Optical guiding is provided by the curvature of the active layer. The TCSM laser has achieved cw powers of 40 mW in a single spatial mode and 65 mW in a single longitudinal mode. The inverted channel substrate planar (ICSP) laser[135] is schematically shown in Fig. 13*e*. This structure is one MOCVD version of the very successful CSP structure (Fig. 13*b*).[141] The ICSP laser has achieved powers in excess of 150 mW (50 percent duty cycle) in a single spatial mode and a 100-mW (cw) catastrophic power level.

More recently, quantum well lasers using the separate carrier and optical confinement (see previous section, "Quantum Well Lasers") and ridge waveguide geometries have been used for producing power levels in excess of 150 mW (cw) in a single spatial mode.[143,144] The QW ridge resembles a standard RWG (Fig. 4*e*), but with a QW active region. Such laser structures have low threshold current density and low internal absorption losses, thus permitting higher-power operation.

Future Directions for High-Power Lasers

Nonabsorbing Mirror Technology. The catastrophic facet damage is the ultimate limit to the power from a semiconductor laser. In order to prevent catastrophic damage, one has to create a region of higher-energy bandgap and low surface recombination at the laser facets. Thus, the concept of a laser with a nonabsorbing mirror (NAM) was developed. The first NAM structure was demonstrated by Yonezu et al.[148] by selectively diffusing zinc along the length of the stripe, except near the facets. This created a bandgap difference between the facet and bulk regions and permitted a three- to fourfold increase in the cw facet damage threshold and a four- to fivefold increase in pulse power operation.[149] More recent structures have involved several steps of liquid-phase epitaxy.[150,151]

The incorporation of the NAM structure is strongly device-dependent. For example, in the diffused device structures, such as deep-diffused stripe (DDS)[148] and transverse junction stripe (TJS) lasers, NAM structures have been formed by selective diffusion of zinc in the cavity direction.[149] The n-type region will have a wider bandgap than the diffused region, and thus there will be little absorption near the facets. However, most index-guided structures require an additional growth step for forming the NAM region.[150,151] the NAM structures in the past have suffered from several problems: (1) Due to their complex fabrication, they tend to have low yields. Furthermore, cw operation has been difficult to obtain. (2) Cleaving must be carefully controlled for NAM structures having no lateral confinement, in order to avoid excessive radiation losses in the NAM region. The NAM length is a function of the spot size. (3) The effect of the NAM structure on lateral mode control has not been documented, but could lead to excessive scattering and a rough far-field pattern.

It is now becoming more clear that the use of a NAM structure will be required for the reliable operation of high-power GaAlAs/GaAs laser diodes. Experimental results[152] appear to indicate that laser structures without a NAM region show a decrease in the catastrophic power level as the device degrades. However, most of the approaches currently being implemented require elaborate processing steps. A potentially more fundamental approach would involve the deposition of a coating that would reduce the surface recombination velocity and thus enhance the catastrophic intensity level.[153,154] Such coatings have been recently used by researchers from Sharp and the University of Florida to increase the uncoated facet catastrophic power level by a factor of 2.[155,156]

Recently, the use of NAM technology has been appearing in commercial products. The crank transverse junction stripe (TJS) laser (a TJS laser with NAM) can operate reliably at an output power of 15 mW (cw), while the TJS laser without the NAM can operate only at 3 mW (cw).[147] The Ortel Corporation has developed a buried heterostructure (BH) laser with significantly improved output power characteristics compared to conventional BH lasers.[142] The NAM BH laser is rated at 30 mW (cw)[142] compared to 3–10 mW for the conventional BH/LOC device.

Last, the use of alloy disordering, whereby the bandgap of a quantum well laser can be increased by diffusion of various types of impurities (for example, Zn and Si),[157] can lead to a very effective technique for the fabrication of a NAM structure. Such structures have produced an enhancement of the maximum pulsed power by a factor of 3–4.

High-Power 1.3/1.48/1.55-μm Lasers. Previous sections have discussed high cw power operation from (GaAl)As/GaAs laser devices. In the past several years there have been reports of the increasing power levels achieved with GaInAsP/InP lasers operating at $\lambda = 1.3$ μm. The physical mechanisms limiting high-power operation in this material system are quite different than those for GaAlAs/GaAs lasers. The surface recombination at the laser facets is significantly lower than in GaAlAs/GaAs, and thus catastrophic damage has not been observed. Maximum output power is limited by either heating or carrier leakage effects. With the advent of structures having low threshold current density and high quantum efficiency, it was just a matter of time before high-power results would become

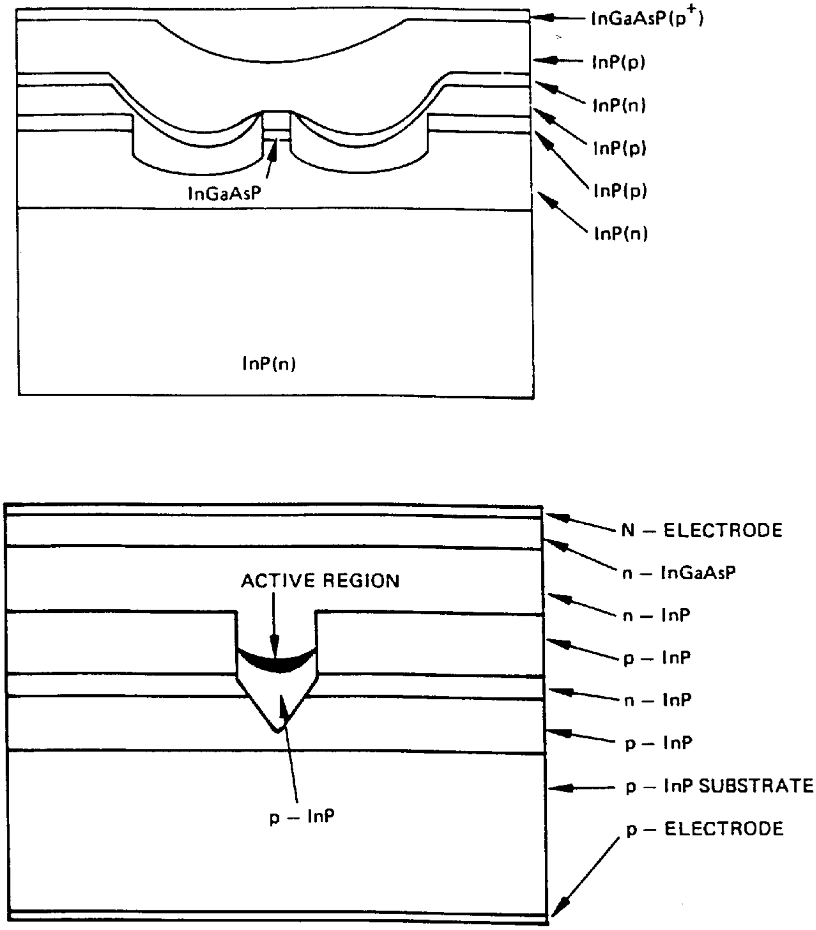

FIGURE 15 Schematic diagrams of the most prominent LPE-based 1.3-μm laser structures. (*a*) Double-channel planar-buried heterostructure (DC-PBH);[158,159] (*b*) buried crescent.[160,161]

available. Furthermore, since facet damage is not a problem, the only real need for facet coatings is for improving the output power from one facet and sealing the device for improved reliability.

In Fig. 15, we schematically show the two most common long-wavelength laser structures that have demonstrated high cw power operation. In Fig. 15*a*, the double-channel planar buried heterostructure (DC-PBH) is systematically shown.[158,159] The structure requires a two-step LPE growth process. The first step is the growth of the first and top cladding layers in addition to the active layer. This is followed by the etching of the structure, which is followed by a regrowth to form the blocking and contact layers. LPE growth of this material system is such that if the mesa region is narrow enough, no growth occurs on top of it during the deposition of the blocking layer, and this occurs for mesa widths of less than ~5 μm. Low threshold current is achieved due to the narrow mesa geometry and the good carrier and current confinement.

The DC-PBH has proved to be a laser structure with excellent output characteristics

and high reliability. NEC has been able to obtain thresholds as low as 10 mA with 70 percent quantum efficiency. Degradation rates of the order of 10^{-6}/hr for an output power of 5 mW at a temperature of 70°C have also been obtained. More recently, NEC has obtained 140-mW power in a single spatial mode.[158] Lasers at 50 mW and 25°C have been placed on lifetest and show relatively low degradation rates after several hundred hours. Degradation rates at 20 and 30 mW (50°C) are 1.3×10^{-5}/hr and 2.22×10^{-5}/hr, respectively. TRW has also worked with DC-PBH/PBC-(planar buried cresent) type laser diodes and has obtained 100 mW cw.[159] A summary of the various high-power $\lambda = 1.3$ μm laser diode structures and characteristics is given in Table 2.

The other structure that has demonstrated high cw power is the buried crescent laser first investigated by Mitsubishi (Fig. 15*b*).[160] The structure is grown using a two-step LPE process and a *p* substrate. The final structure resembles a channel laser with an active layer that tapers to zero near the edges of the channel. The tapering provides good carrier and optical confinement. Researchers from Oki with a structure similar to the Mitsubishi structure have demonstrated maximum power levels of 200 and 140 mW in a single spatial mode.[162] Lifetests[163] on these lasers demonstrated a mean time to failure of $\sim 7 \times 10^5$/hr (at 20°C) at 75 percent of the maximum cw output power (maximum = 25–85 mW). These results appear to indicate that 1.3-μm lasers are reliable for high-power applications.

A more recent development has been the use of multiquantum well (MQW) high-power lasers in the 1.5–1.55-μm wavelength band. The use of a MQW ridge waveguide structure has produced power levels of ~170 mW (cw).[164] The MQW structure consists of five wells of InGaAs, 60 Å thick, separated by four GaInAsP barriers of 100-Å thickness. The two thicker, outermost barriers of GaInAsP provide a separate confinement heterostructure (SCH) waveguide. In addition, buried heterostructure (BH) lasers[165] with power levels in excess of 200 mW have been achieved by incorporating strain into MQW structures. A recent review article by Henshall describes the state of the art in more detail.[166]

High-Power Strained Quantum Well Lasers. Over the last several years, there has been extensive research in the area of strained layer quantum well high-power lasers. As with GaAs QW high-power lasers, the geometry is typically a QW ridge. Table 3 summarizes some of the latest single-spatial-mode high-power results.

Thermal Properties. An important parameter in the operation of high-power laser diodes is the optimization of thermal properties of the device. In particular, optimizing the laser geometry for achieving high-power operation is an important design criterion. Arvind et al.[167] used a simple one-dimensional thermal model for estimating the maximum output power as a function of laser geometry (cavity length, active layer thickness substrate type, etc.). The results obtained for GaInAsP/InP narrow stripe PH lasers were as follows:

- Maximum output power is achieved for an optimum active layer thickness in the 0.15-μm region. This result applies only to nonquantum well lasers.
- Significantly higher output powers (25 to 60 percent) are obtained for lasers fabricated on *p* substrates compared to those on *n* substrates. The result is based on the lower electrical resistance of the top epitaxial layers in the *p* substrate compared to *n* substrate.
- Significantly higher output powers (~60 percent) are obtained for lasers mounted on diamond rather than silicon heat sinks as a result of the higher thermal conductivity of diamond compared to silicon, 22 versus 1.3 W/(°C-cm).
- Significantly higher output powers (~100 percent) are obtained for lasers having a length of 700 μm compared to the conventional 300 μm. The higher power results from the reduced threshold current density and thermal resistance for the longer laser devices.

A plot of the calculation and experimental data from Oki[162] is given in Fig. 16. Note that there are no adjustable parameters in the calculation.

An important conclusion from the thermal modeling is that longer cavity semiconductor lasers (700–1000 μm) will be able to operate at higher heat sink temperatures when the power level is nominal (~5 mW) compared to shorter cavity devices (~100–300 μm). In addition, the reliability of the longer cavity devices is also expected to be better. More recent calculations and experimental results using strained layer lasers have verified this.[95]

Semiconductor Laser Arrays

One of the most common methods used for increasing the power from a semiconductor laser is to increase the width of the emitting region. However, as the width is increased, the occurrence of multilateral modes, filaments, and lateral-mode instabilities becomes more significant. A far-field pattern is produced that is not diffraction-limited and has reduced brightness. The most practical method to overcome this problem is to use a monolithic

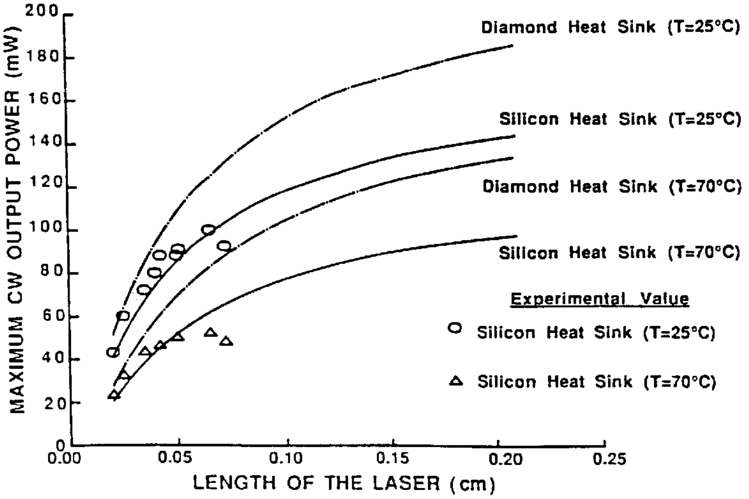

FIGURE 16 Calculation of maximum output power per facet as a function of device length for *n*-*p*-substrate-type lasers and different heat sinks.[167] Note the increased power level achieved for longer lasers and *p*-type substrates.

array of phase-locked semiconductor lasers. Such lasers have been used to generate powers in excess of 10 W (cw)[170] and over 200 W[171] from a single laser bar.

It was not until 1978 that Scifres and coworkers[172] first reported on the phase-locked operation of a monolithic array consisting of five closely coupled proton-bombarded lasers. The original coupling scheme involved branched waveguides, but this was quickly abandoned in favor of evanescent field coupling by placing the individual elements of the array in close proximity (Fig. 17*a*). More recently, arrays of index-guided lasers[173] have been fabricated; one example is shown in Fig. 17*b*.

Recent emphasis has been on achieving higher cw power and controlling the output far-field distribution. Some of the more significant events in the development of practical semiconductor laser arrays are summarized in Table 4.

The subject of array-mode stability has become of great interest. In a series of significant papers, Butler et al.[190] and Kapon et al.[191] recognized that to a first approximation, an array can be modeled as a system of n weakly coupled waveguides. The results indicate that the general solution for the field amplitudes will consist of a superposition of these array modes. The analytic results permitted, for the first time, a simple explanation for the observed far-field patterns and provided a means for designing device structures that would operate in the fundamental array mode (i.e., all elements in phase). This particular mode will provide the greatest brightness.

Many techniques have been used for improving array-mode selection[179,188,192,197] and thus achieving a well-controlled spatial mode. Two of the more successful earlier techniques involve (1) incorporation of optical gain in the interelement regions (gain coupling of the laser array[179–184,193]) and (2) use of interferometric techniques that involves *Y*-coupled junctions.[186,188,192]

The gain-coupled arrays achieve mode selectivity by introducing optical gain in the interelement regions and thus increasing the gain of the fundamental array mode since this mode has a significant portion of its energy in the interelement regions. The first demonstration of this approach was the twin-channel laser (TCL) developed by researchers from TRW;[180–181] since then, there have been other demonstrations.[182,184,193]

The theoretical foundations of the *Y*-coupled junction were first described in a paper by Chen and Wang.[192] Mode-selectivity is accomplished because the in-phase mode adds coherently at each *Y* junction, while the out-of-phase mode has destructive interference, since the single waveguides after the *Y* junction can support only the fundamental mode. Similar interferometric and mode-selective techniques have been used in the development of optical modulators.[198]

Finally, the most recent mode control mechanism for laser arrays involves the resonant phase-locking of leaky-mode elements.[189] With a properly optimized geometry, the fundamental array mode has significant mode discrimination analogous to the high discrimination found in single-element leaky-mode devices. Recent results indicate power levels in excess of 360 mW (cw) in the fundamental array mode, and the beam broadens to ~2 times diffraction limited for output powers of ~500 mW (cw).

At the present time, it is not clear which technique will be most useful for achieving stable, fundamental array mode operation. The gain-coupling concept works well for two or three elements.[199] However, array-mode selection described by the difference in gain between the first and second array modes rapidly decreases as the number of array elements increases beyond two or three.[199] The *Y*-junction and leaky-mode approaches do not appear to have the same limitations. The resonant leaky-mode arrays appear to have the most promising performance at high power levels; however, the structures are complex and thus yield and reliability need to be more fully addressed.

Two-Dimensional, High-Power Laser Arrays

There has been a significant amount of research activity in the past few years in the area of very high power diode lasers.[200–205] The activity has been driven by the significant reductions in threshold current density of GaAlAs/GaAs lasers that can be achieved with metalorganic chemical vapor deposition (MOCVD), utilizing a quantum well design. Threshold current densities as low as 200–300 A/cm^2 with external efficiencies exceeding 80 percent have been achieved using GRIN-SCH quantum well lasers.[200,201] CW powers of ~6–9 W have been achieved from single laser bars. Such power levels correspond to a maximum of 11 W/cm from a single laser bar. Table 5 lists some of the more recent results on very high power diode laser arrays.

In order to increase the output power from laser array structures, researchers have investigated the use of a two-dimensional laser array. One particular configuration, referred to as the ‘‘rack-stack approach,’’ is schematically shown in Fig. 18. In essence, the approach involves stacking a linear array of edge emitters into a two-dimensional array. The two-dimensional arrays are fabricated[203] by (1) cleaving linear arrays of laser diodes from a processed wafer, (2) mounting the bars on heat sinks, and (3) stacking the heat sinks into a two-dimensional array.

As shown in Table 5, the main players in this business are McDonnell-Douglas and Spectra Diode Labs. The largest stacked[204] two-dimensional array has been manufactured by McDonnell-Douglas and has an active area with five laser bars 8 mm in length. The array was operated with 150-μs pulses to the limit of the driver[204] at pulse repetition rates of 20–666 Hz. Approximately 2.5 kW/cm^2 was obtained at 20 Hz (average power ~300 W) and 0.9 kW/cm^2 at 666 Hz (average power ~92 W). Higher output powers will be obtained

TABLE 5 Summary of High-Power Laser Array Results*

Laboratory [reference]	Array type	Maximum output power	Power efficiency (%)	Slope efficiency (W/A)	Power density (W/cm^2)
General Electric [201]	1D array	80 W (200-μs pulse; 10–100 Hz)	20	0.9	80

as a result of achieving the ultimate limits in threshold current density and optical losses in the individual cavities with advances in nonabsorbing mirror and active cooling techniques. Some recent progress has been seen in the latter with the use of etched silicon grooves for fluid flow, which function as radiator elements to remove the heat.

13.8 HIGH-SPEED MODULATION

In many applications semiconductors lasers are modulated in order to carry information. Semiconductor laser dynamics are usually described by the rate equations for the photon and carrier densities:[3–5,205,206]

$$\frac{dN}{dt} = \frac{I}{edLw} - \frac{cg}{n_r\Gamma}P - \frac{N}{\tau_s} \tag{16}$$

$$\frac{dP}{dt} = \frac{c}{n_r}gP - \frac{P}{\tau_p} + \Gamma\beta\frac{N}{\tau_s} \tag{17}$$

where N is the carrier density, P is the photon density, I is the current, e is the charge of an electron, d is the active layer thickness, L is the laser cavity length, w is the laser stripe width, c is the speed of light, n_r is the refractive index of the active region, g is the threshold modal gain, Γ is the optical confinement factor, τ_s is the carrier lifetime, β is the spontaneous emission factor, and τ_p is the photon lifetime of the cavity. (When these equations are written in terms of total gain instead of modal gain, Γ does not appear in Eq. (16), but multiplies the gain in Eq. (17).)

$$\tau_p = \frac{n_r}{c(\alpha_i + (1/2L)\ln(1/R_F R_R))} \tag{18}$$

where α_i is the internal loss and R_F and R_R are the front- and rear-facet reflectivities. β is the ratio of spontaneous emission power into the lasing mode to the total spontaneous emission rate.[207] (Do not confuse β with the other spontaneous emission factor, which is

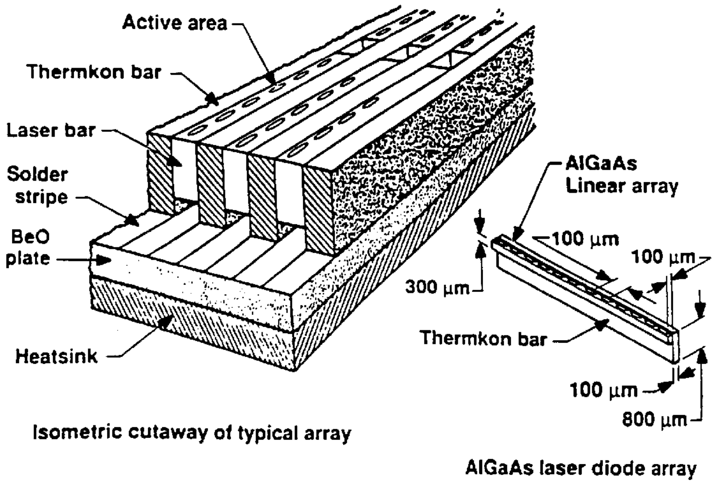

FIGURE 18 Schematic diagram of the two-dimensional rack-stack laser array architecture. (*Courtesy of R. Solarz, Lawrence Livermore.*)

used in linewidth theory and is defined as the ratio of the spontaneous emission power into the lasing mode to the stimulated emission power of the mode.)

When a semiconductor laser is modulated there is some delay before it reaches a steady state. Because it takes time for a carrier population to build up, there will be a time delay τ_d before the final photon density P_{on} is reached (see Fig. 19). Once P_{on} is reached, additional time is required for the carrier and photon populations to come into equilibrium. The output power therefore goes through relaxation oscillations before finally reaching a steady state. This type of oscillation has many parallels in other second-order systems,[208] such as the vibration of a damped spring or an *RLC* circuit.

The frequency of these relaxation oscillations, f_r is called the relaxation, resonance, or corner frequency. By considering small deviations from the steady state where $N = N_{th} + \Delta N$ and $P = P_{on} + \Delta P$, we can solve Eqs. (16) and (17) for f_r with the result:[5,205]

$$f_r \cong \frac{1}{2\pi}\sqrt{\frac{c}{n_r\Gamma}\frac{dg}{dN}\frac{P_{\text{on}}}{\tau_p}} = \frac{1}{2\pi}\sqrt{\frac{c}{n_r}\frac{dg}{dN}\frac{(I - I_{th})}{edLw}} \tag{19}$$

where dg/dN is the differential modal gain. For bulk double-heterostructure lasers the gain is linearly dependent on the carrier density and $(c/n_r)dg/dN$ is replaced by A, where A is a constant. As discussed earlier in the chapter, the gain-versus-carrier-density relationship of a quantum well is nonlinear, so A is not a constant for a QW laser.

Let us return our attention to the turn on delay τ_d between a current increase and the beginning of relaxation oscillations as illustrated in Fig. 19. If the initial current I_{off} is below I_{th}, the initial photon density P_{off} can be neglected in Eq. (16). Assuming an exponential increase in carrier density we can derive[206]

$$\tau_d = \tau_s \ln\left(\frac{I_{on} - I_{off}}{I_{on} - I_{th}}\right), \qquad I_{off} < I_{th} < I_{on} \tag{20}$$

Since τ_s is on the order of several ns, τ_d is usually very large for semiconductor lasers with I_{off} below I_{th}. For example, with $\tau_s = 4$ ns, $I_{on} = 20$ mA, $I_{th} = 10$ mA, and $I_{off} = 5$ mA, τ_d will be 1.6 ns. If a short current pulse is applied to a laser biased below threshold, τ_d may be so long that the laser barely responds (see Fig. 20). When a current pulse ends, it takes

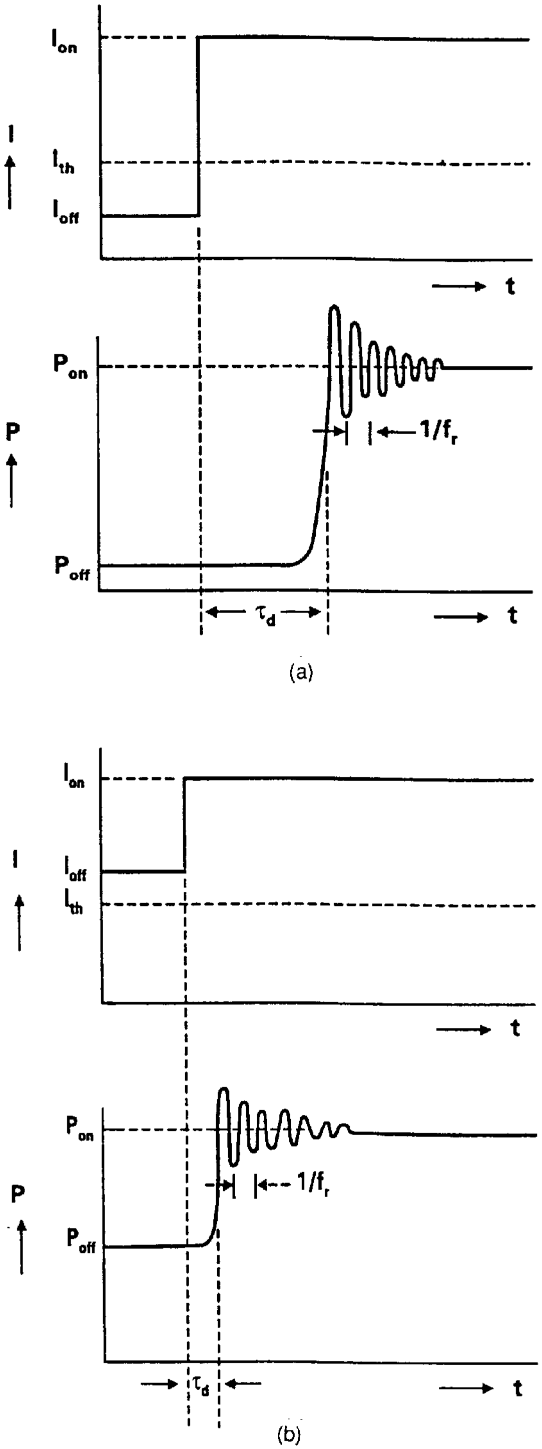

FIGURE 19 Schematic diagrams of the turn on delay and relaxation oscillations for a semiconductor laser (*a*) prebiased below threshold and (*b*) prebiased above threshold. (*After Ref. 206.*)

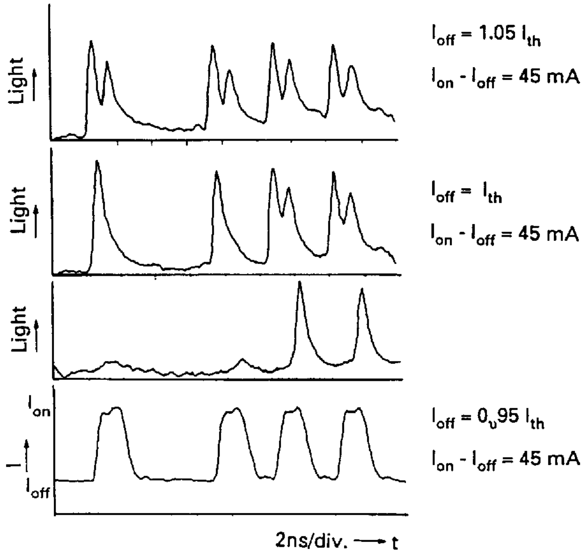

FIGURE 20 An illustration of the pattern effect for a AlGaAs laser diode with a 280 Mbit/s 10111 return to zero pattern. (*From Ref. 210.*)

time for the carrier population to decay. If another identical pulse is applied before the carrier population decays fully, it will produce a larger light pulse than the first current pulse did. This phenomenon, which is illustrated in Fig. 20, is called the *pattern effect.*[209] The pattern effect is clearly undesirable as it will distort information carried by the laser modulation. The pattern effect can be eliminated by prebiasing the laser at a current sufficient to maintain a carrier population; for most semiconductor lasers this will mean prebiasing at or above threshold. In order to modulate with a prebias below threshold, I_{on} must be much greater than I_{th}. For most lasers this will require an impractically large I_{on}, but if I_{th} is very low it may be possible.[211,212]

Even a semiconductor biased above threshold will have a nonzero τ_d before it reaches its final photon density. Equations (16) and (17) may be solved for τ_d above threshold:[206]

$$\tau_d = \frac{1}{2\pi f_r}\sqrt{2\ln\left(\frac{P_{on}}{P_{off}}\right)} = \frac{1}{2\pi f_r}\sqrt{2\ln\left(\frac{I_{on}-I_{th}}{I_{off}-I_{th}}\right)} \qquad I_{th} < I_{off} < I_{on} \tag{21}$$

τ_d will be much shorter for a prebias above threshold. For example if $f_r = 5$ GHz, $I_{on} = 40$ mA, $I_{off} = 15$ mA, and $I_{th} = 10$ mA, $\tau_d = 60$ ps. τ_d will be shortest for large P_{on} and P_{off}, so the shortest time delays will be achieved for small-scale modulation at high photon density. For digital applications in which fairly large-scale modulation is required, the maximum modulation speed of a semiconductor laser is to a large extent determined by τ_d.

For very high speed microwave applications, lasers are prebiased at a current greater than the threshold current and modulated at high frequencies through small amplitudes about the continuous current prebias. The frequency response of a semiconductor laser has the typical shape expected from a second-order system. (For a discussion of the frequency response of a second-order system see Ref. 208.) The laser amplitude response is fairly uniform at frequencies less than the relaxation oscillation frequency. At f_r the response goes through a resonance and then drops off sharply. The relaxation oscillation frequency is therefore the primary intrinsic parameter determining the modulation bandwidth. The

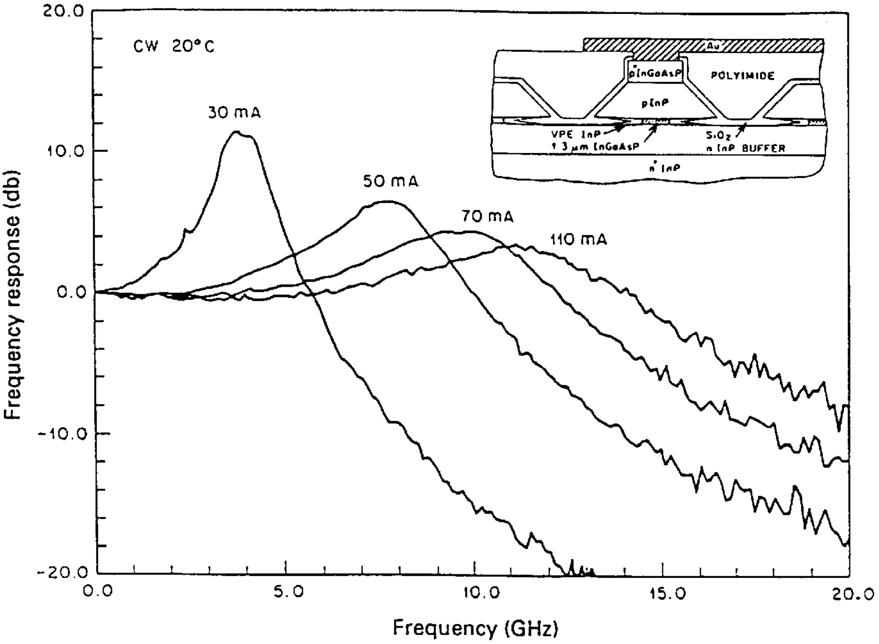

FIGURE 21 The small-signal modulation response of a 1.3-μm InGaAsP-constricted mesa laser for different bias levels. The cavity length is 170 μm and the stripe width is 1 μm. Inset: Schematic diagram of a 1.3-μm InGaAsP-constricted mesa laser (*From Refs. 213 and 214.*)

actual useful bandwidth is generally considered to be the frequency at which the response of the laser drops by 3 dB. Figure 21 is an example of the frequency response of a semiconductor laser under amplitude modulation.[213,214] In this example, the maximum 3-dB bandwidth is 16 GHz. If the 3-dB bandwidth is measured in electrical dB, as in our example, it is located at approximately $1.55f_r$. Sometimes the 3-dB frequency is quoted as that at which the optical power is reduced by a factor of 2; this actually corresponds to 6 dB in electrical power and occurs at approximately $1.73f_r$. The 0-dB frequency occurs at approximately $1.41f_r$.[213–215]

The description of the relaxation oscillation frequency given here is rather simplistic since it is based on rate equations, which consider only one type of carrier, neglect the spatial dependances of the carrier and photon distributions, and neglect the effects of carrier diffusion and nonlinear gain. In addition, the spontaneous emission term of Eq. (17) was neglected in the derivation. The neglected effects are particularly important when considering damping of the relaxation oscillations.[204–206] With significant damping[215] the measured peak frequency f_p will be more accurately determined by:

$$f_p^2 = f_r^2 - \frac{f_d^2}{4} \tag{22}$$

where f_d is the damping frequency.

We have also neglected, however, the electrical parasitics of the laser and its operating circuit (bonding wires, etc.). Figure 22 is a simple equivalent circuit, which describes the parasitic elements influencing a semiconductor laser. Here L is the inductance of bond wire, R is the laser resistance including contact resistance, and C is capacitance primarily due to bonding-pad capacitance and capacitance of the current-confining structure of the

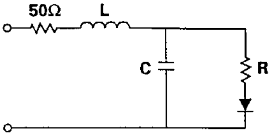

FIGURE 22 Simple equivalent circuit of the parasitics affecting the modulation of a semiconductor laser.

laser stripe.[213,214] The 50-Ω resistance is included to represent a 50-Ω drive. The resonant frequency of this circuit is

$$f_o = \frac{1}{2\pi}\sqrt{\frac{R+50}{LRC}} \tag{23}$$

The circuit is strongly damped so no resonance peak occurs; instead, the response simply drops off.[205,218] The amplitude response of a modulated semiconductor laser will begin to drop off at frequencies at which the response of the parasitics drops off even if the intrinsic peak frequency of the laser is higher. Therefore, the maximum practical modulation bandwidth may be determined by f_o instead of f_r. Figure 23 shows the modulation response of a semiconductor laser strongly affected by parasitics.[219]

The most significant parasitic limiting the performance of a semiconductor laser is normally the capacitance.[205] In order to achieve high speeds, the laser stripe must be very narrow [see Eq. (18)]; practical narrow stripe lasers are often some form of buried heterostructure (see Fig. 4*c*). The substrate doping and confinement-layer doping of buried heterostructure form a parallel plate capacitor. In order to reduce the capacitance the laser can be fabricated on a semi-insulating substrate,[205,218] the confinement layers can be semi-insulating,[124] the active area of the device can be isolated from the confinement layers by etching trenches on either side of it,[124,125] or the confinement layers can be replaced by a thick dielectric layer such as polyimide.[213,214] The inset on Fig. 21 is a schematic diagram of the high-speed laser stripe whose frequency response is shown in Fig. 21.

Assuming that the parasitics have been minimized, consider how a semiconductor laser

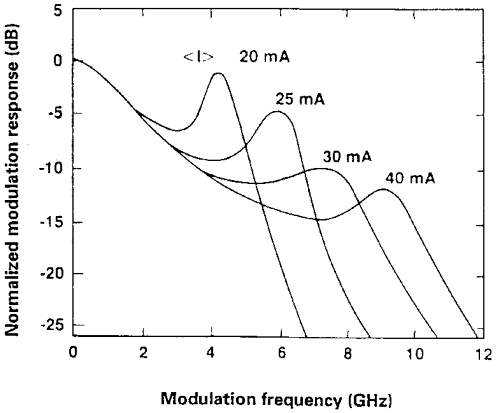

FIGURE 23 The modulation response of a 1.3-μm double-channel, planar-buried heterostructure laser with a cavity length of 80 μm and a threshold current of 18 mA. The effect of parasitics is apparent. (*From Ref. 219.*)

can be optimized for high-speed operation. As already mentioned, minimizing the stripe width is desirable. Figure 21 illustrates that increasing the photon density (or equivalently the current) increases the speed. Of course there will be a limit as to how much the photon density can be increased; when the photon density of a semiconductor laser is increased, eventually a maximum power is reached at which the laser fails due to catastrophic facet damage. InGaAsP/InP lasers have a higher threshold for catastrophic facet damage than AlGaAs/GaAs lasers; InGaAsP/InP lasers, therefore, tend to have higher bandwidths.[214]

Consideration of Eq. (19) shows that decreasing the cavity length will also increase the speed.[205,213,214,218,219] (Decreasing the length reduces τ_p.) Increasing dg/dN will also increase the speed. With a bulk active region dg/dN is approximately constant, so use of a short cavity length will not affect it. As illustrated in Fig. 6, however, dg/dN of a QW laser will decrease with increasing threshold gain, and therefore with decreasing cavity length. A single QW laser will, therefore, make a relatively poor high-speed laser. An MQW laser, however, will have higher dg/dN than a single QW. In the past, the highest modulation bandwidths were achieved with InGaAsP/InP bulk active region InGaAsP/InP lasers[213,214,222,223] with the best results on the order of 24 GHz[223] for room-temperature CW measurements. The advent of strained MQW lasers has, however, recently resulted in higher bandwidths because strain increases dg/dN.[224–226] Strained GaAs-based $\mathrm{In_{0.3}Ga_{0.7}As}$ MQW lasers with bandwidths as high as 28 GHz have been demonstrated.[226]

So far our discussion has dealt only with the amplitude response to modulation. The phase and lasing wavelength (or optical frequency) are also affected by modulation. Figure 24 is an example of the phase response which accompanies the amplitude response of a semiconductor laser under modulation.

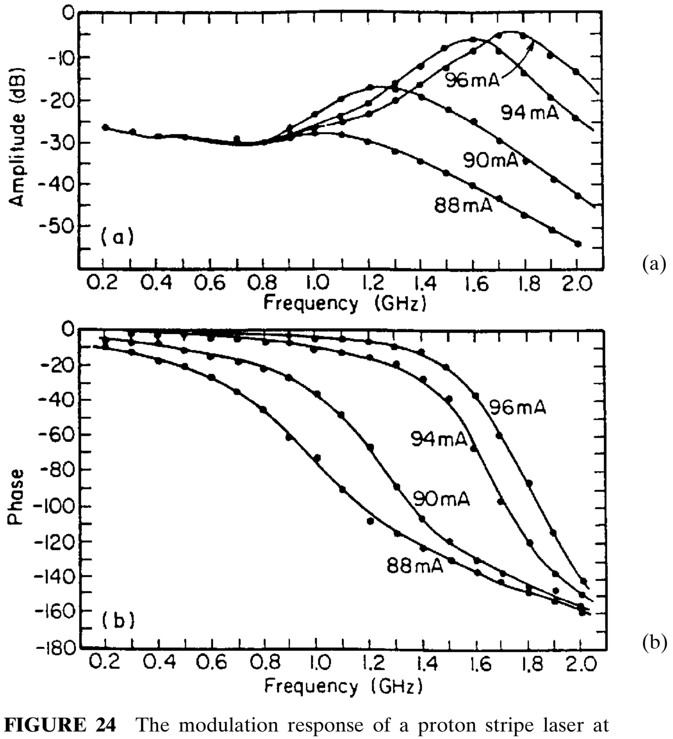

FIGURE 24 The modulation response of a proton stripe laser at various bias currents: (*a*) amplitude response and (*b*) phase. The threshold current is approximately 80 mA. (*From Ref. 205.*)

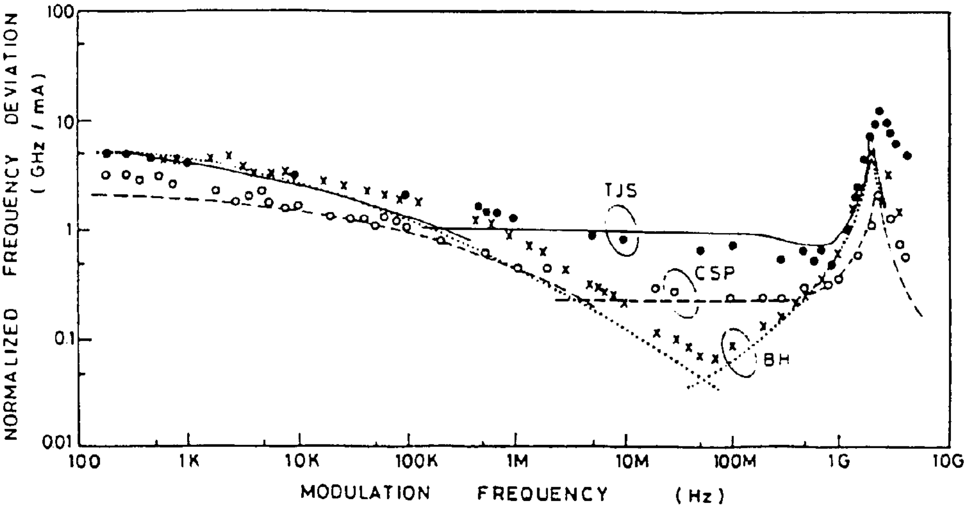

FIGURE 25 The FM response of TJS, BH, and channeled substrate planar (CSP) lasers. All the lasers are biased at 1.2 times threshold. (*From Ref. 229.*)

Assuming that a semiconductor laser lases in a single longitudinal mode under static conditions, high-frequency modulation can cause it to shift to another mode or to become multimode.[227] The tendency to become multimode increases with the depth of modulation. For many applications single-mode operation under modulation is required. In this case a laser with built-in frequency selectivity such as a distributed feedback laser[228] (DFB) (see "Spectral Properties," following) can be used to maintain single-mode operation. Even with single-mode operation under modulation, the linewidth of the lasing mode will be broadened.[206,227] This broadening, which is often called *chirp,* is discussed in more detail in the next section.

While the frequency changes associated with small-scale modulation are generally undesirable in amplitude modulation (AM) they can be utilized for frequency modulation[206,229,230] (FM). In digital systems, FM is often called frequency shift keying (FSK). FM requires only a very small amplitude modulation, so it normally refers to the effect of modulation on a single mode. In FM modulation, very fine shifts in optical frequency are detected; frequency stabilized lasers such as DFB lasers[230] as well as standard semiconductor lasers will show an FM response. Typically, FM response shows a low frequency decay below f_r and a resonance at f_r[206,229] (see Fig. 25).

If the reader requires more in-depth information on high-speed modulation of semiconductor lasers, the book by Petermann[206] or the review by Lau and Yariv[205] will be particularly helpful. For a recent review of the state of the art see the tutorial by Bowers.[215] References 3, 4, and 5 also contain chapters on high-speed modulation.

13.9 SPECTRAL PROPERTIES

One of the most important features of a semiconductor laser is its high degree of spectral coherence. There are several aspects to laser coherence. First, the laser must have spatial coherence in the various transverse directions. This is usually accomplished by controlling

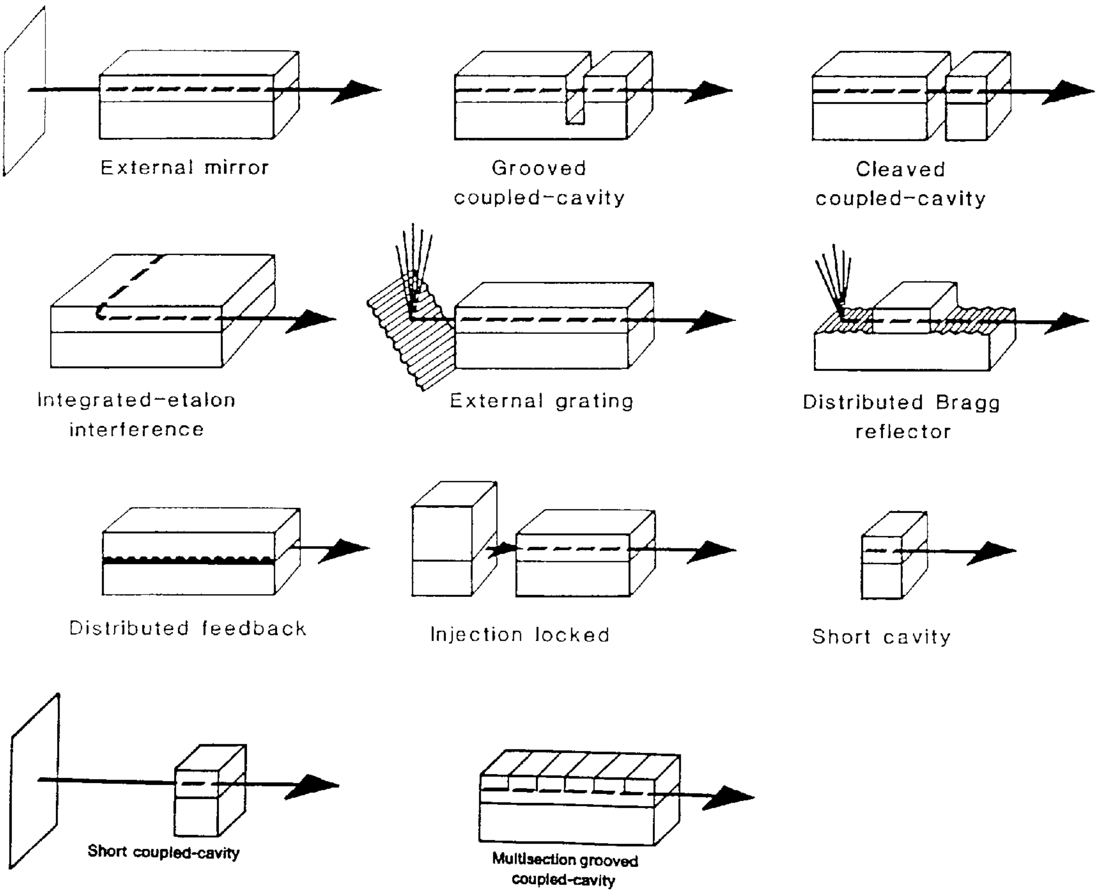

FIGURE 26 Eleven major designs for single-frequency lasers. The three in the top row and the first in the second row are coupled cavity lasers; the next three are frequency-selective-feedback lasers; the next is an injection-locked laser; the last one in the third row is a geometry-controlled laser. The left two are hybrid designs. (*From Ref. 232.*)

both the geometry and the lateral-mode geometry using a structure with a built-in index as discussed earlier under "Fabrication and Configurations." In order to achieve high spectral coherence, the semiconductor laser must operate in a single longitudinal mode. There are four technical approaches for accomplishing this:[231,232] (1) coupled cavity, (2) frequency selective feedback, (3) injection locking, and (4) geometry control. The various techniques for achieving spectral control are described in Fig. 26.

The temporal coherence of the laser is related to the spectral width of the stimulated emission spectrum by:

$$L_c = K\frac{\lambda_o^2}{\Delta\lambda_{1/2}} \tag{24}$$

where K is a constant dependent on the distribution of spectral output function, L_c is coherence length, λ_o is the wavelength of the stimulated emission peak, and $\Delta\lambda_{1/2}$ is the halfwidth of the spectral emission. $K = 1$ for rectangular; $K = 0.32$ for a lorentzian; and $K = 0.66$ for a gaussian.

The spectral linewidth, $\Delta f_{1/2}$, for a single longitudinal mode can be expressed as:[233]

$$\Delta f_{1/2} = \frac{n_{sp}}{4\pi\tau_p}\left(\frac{J}{J_{th}} - 1\right)^{-1}(1 + \alpha^2) \tag{25}$$

where n_{sp} is the spontaneous emission factor, defined as the ratio of spontaneous to stimulated emission in the lasing mode, τ_p is the cavity lifetime, and α is the linewidth enhancement factor.

Typical linewidths for a solitary single-longitudinal-mode laser are in the range of 5–20 MHz. Narrower linewidths can be achieved by using some of the techniques described in Fig. 26. More recently, the use of QW lasers, as described earlier, has led to a significant reduction in the linewidth enhancement factor and the corresponding laser linewidths.[234] Typical linewidths in the range of 0.9 to 1.3 MHz have been achieved.

Coupled cavity lasers make up a family of devices whereby spectral control is achieved by reinforcing certain wavelengths which resonate in several cavities.[235] A typical configuration is shown in Fig. 26, whereby the long cavity is cleaved into two smaller cavities. By properly controlling the length ratios and the gap width, good longitudinal mode discrimination (better than 20-dB side-mode suppression) can be obtained.

Another important technique is the use of an external resonant optical cavity (frequency-selective feedback) as shown in Fig. 27. This technique has been used by researchers at Boeing to achieve extremely narrow linewidth ($\Delta f_{1/2} \sim 1$–2 KHz) single-longitudinal-mode operation.[236]

Frequency-selective feedback can also be achieved by using either a distributed feedback (DFB) or distributed Bragg reflector (DBR) laser. As shown in Fig. 26, it differs from other types of lasers in that the feedback is provided by a grating internal to the diode laser. By using a DFB/DBR in combination with a long external cavity, it is possible to achieve linewidths below 1 MHz in a monolithic diode.[237]

Injection-locked lasers have also been under investigation at several research labs.[238] In

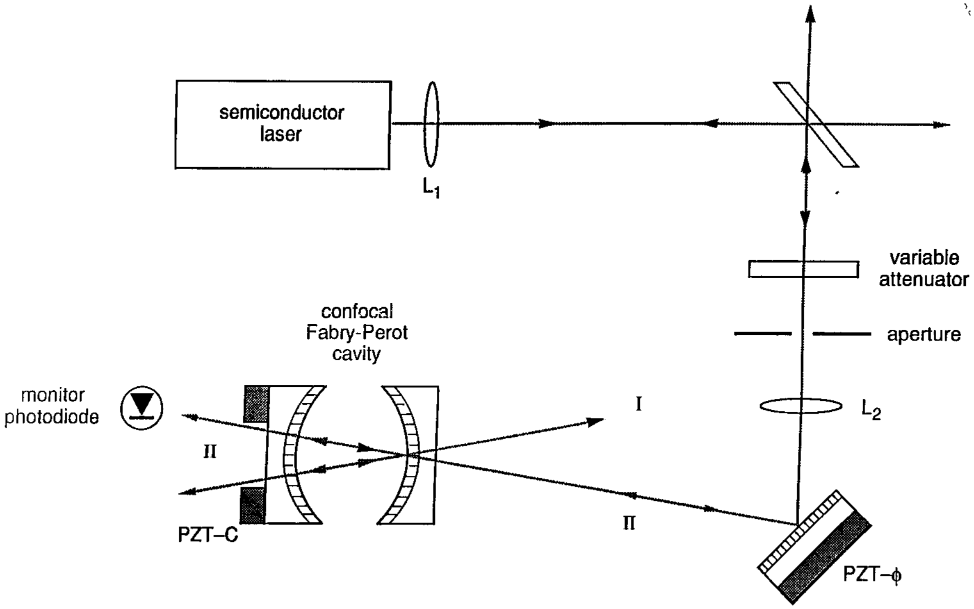

FIGURE 27 Semiconductor laser using resonant optical feedback.

this technique, a low-power, single-frequency laser, which does not have to be a semiconductor laser, is coupled to a single-mode semiconductor laser by injecting the continuous wave emission of a single wavelength of radiation into the laser's cavity.

The last technique for achieving single-longitudinal-mode operation involves the geometry-controlled cavity. Basically, this involves a short cavity 50 μm or less in length, since the longitudinal-mode spacing $\Delta\lambda_L$ in a semiconductor laser is given by:[128]

$$\Delta\lambda_L = \frac{\lambda_o^2}{2n_{eff}L} \tag{26}$$

where n_{eff} is the effective index of refraction and L is the cavity length. Then if $L < 50$ mm, $\Delta\lambda_L > 20$ Å, and the gain available to modes away from the gain maximum falls rapidly, the laser operates in a single longitudinal mode. However, the width of the spectral model can still be rather large as dictated by Eq. (25), unless special precautions are made (e.g. ultrahigh mirror reflectivities).

SURFACE-EMITTING LASERS

Monolithic two-dimensional (2-D) laser arrays are key to many important applications such as massive parallel data transfer, interconnect, processing, computing, and high-power, diode-pumped, solid-state lasers. Conventional lasers, as described in previous sections, require a pair of parallel crystalline facets (by cleaving) for delineating the laser cavity, thus limiting laser emission parallel to the junction plane. In this section, we describe laser structures and fabrication techniques which allow light to emit perpendicular to the junction plane, namely, surface-emitting lasers (SEL). SEL structures are compatible with monolithic 2-D laser array integration and requirements.

There are three designs for the fabrication of surface-emitting lasers and arrays: (1) in-plane laser with a 45° mirror, (2) in-plane laser with a distributed grating coupler, and (3) vertical cavity laser. The main body of the first two structures is very similar to the conventional cavity design with the axis parallel to the junction plane (in-plane). Light is coupled out from the surface via an integrated mirror or grating coupler. The third structure is an ultrashort cavity (10 μm) "microlaser" requiring no cleaving and compatible with photodiode and integrated-circuit processing techniques. High-density, surface-emitting laser arrays of this type have been demonstrated jointly by AT&T and Bellcore.[239] The following subsections will summarize each of the three structures.

Integrated Laser with a 45° Mirror

The development of this SEL structure requires the wafer processing of two 90° laser mirrors as well as a 45° mirror for deflecting the laser output from the junction plane as shown in Fig. 28. Dry etching techniques such as reactive ion (beam) etching (RIE), chemical assisted ion beam etching (CAIBE), and ion beam milling are usually used for the fabrication. In combination with a mass-transport process,[240] a smooth parabolic sidewall has been demonstrated for the 45° mirror of InGaAsP/InP lasers.

This approach for an SEL takes advantage of well-established layer structure growth for typical lasers. The laser performance relies on the optical quality and reliability of the facet mirrors formed. The etched-mirror lasers have been improved over the past decade to the stage very comparable with the cleaved lasers. Two-dimensional, high-power (over 1 W) laser arrays have been demonstrated by both TRW[241] and MIT Lincoln Laboratory.[240] These structures would require injection-locking or other external optical techniques in

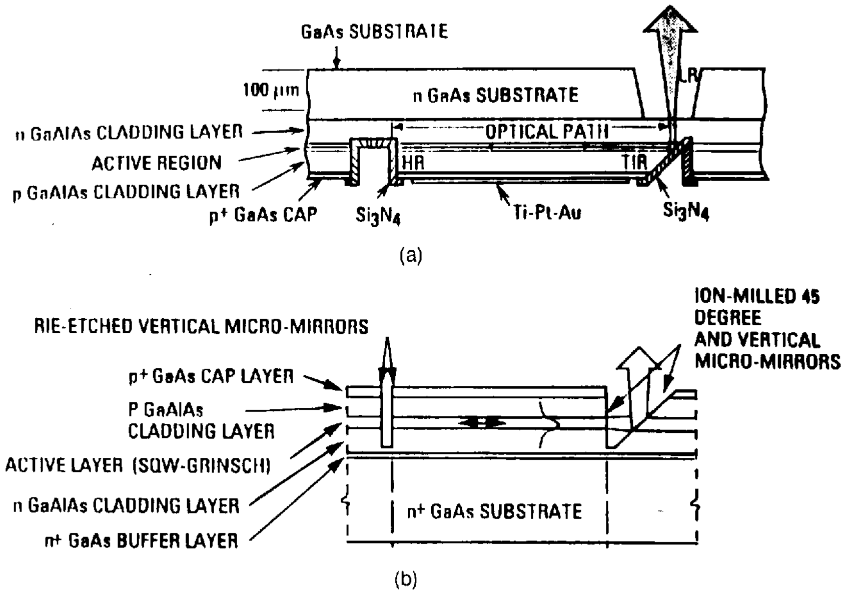

FIGURE 28 Monolithic in-plane-cavity surface-emitting lasers with 45° mirrors: (*a*) Junction-down and (*b*) junction-up configurations. (*From Ref. 241.*)

order to achieve coherent phased array operation as mentioned in the high-power laser section.

Distributed Grating Surface-Emitting Lasers

Distributed feedback (DFB) (see under "Spectral Properties," discussed earlier) and distributed Bragg reflector (DBR) lasers were proposed and demonstrated in the early 1970s. It is well known that for the second-order gratings fabricated in the laser, the first-order diffraction will be normal to the grating surface as shown in Fig. 29. Since early demonstrations, it has taken over 10 years for both the applications and processing techniques to become mature. Low-threshold, high-reliability DFB lasers with true single-mode characteristics are readily fabricated. The critical issue involved in the fabrication of the laser structure is the fabrication of the gratings with a period on the order of 2000 Å. Holographic interference techniques with an Ar^+ or He-Cd laser are generally used in many laboratories. The fabrication of large-area gratings with good throughput can be easily achieved by this technique. Another technique involves direct electron-beam writing which is effective for design iterations.

The development of DBR structure with second-order gratings for surface-emitting lasers did not occur until it was funded by the U.S. Air Force pilot program. This type of laser does not require discrete mirrors for the laser action, so that one could link an array of the lasers with residual in-plane light injection (leaking) across neighboring lasers for coherent operation. A near-diffraction-limited array operation has been demonstrated with this type of SEL. The concept was recently used for a high-power MOPA (master oscillator power amplifier) laser amplifier demonstration with the slave lasers' grating slightly off the resonant second-order diffraction condition. High-power laser arrays of this type have been demonstrated by SRI DSRC[242] and Spectra Diode Laboratories.[243] Coherent output powers of 3 to 5 W with an incremental quantum efficiency in excess of 30 percent have been obtained with the array.

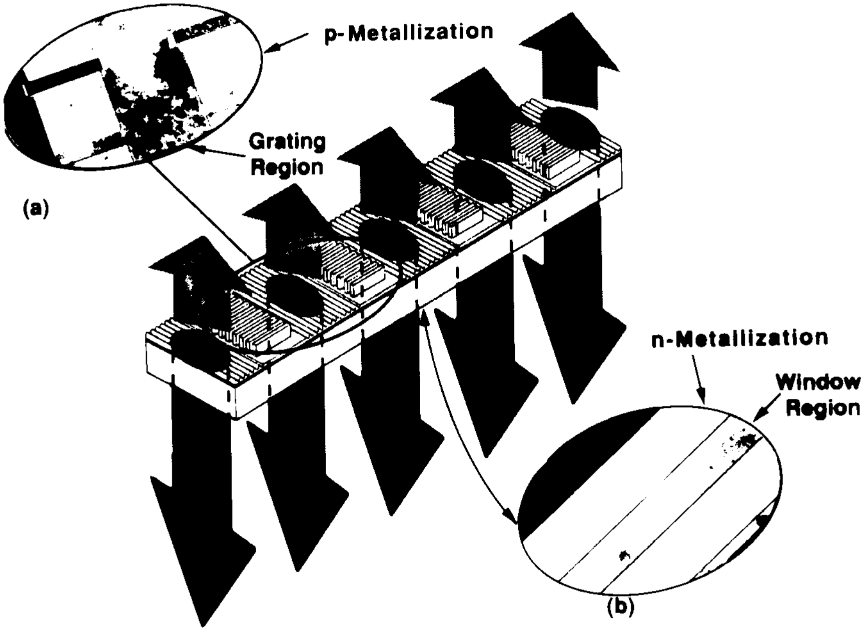

FIGURE 29 Grating surface-emitting laser array. Groups of 10 parallel ridge-guide lasers are laterally coupled in each gain section. (*From Ref. 242.*)

Vertical Cavity Lasers

The term "vertical" refers to the laser axis (or cavity) perpendicular to the wafer surface when it is fabricated. Conventional lasers have a relatively long cavity, on the order of 250 μm. It is not practical to grow such a thick layer for the laser. From the analysis, if we reduce the cavity length down to 10 μm, one needs to have a pair of very high reflectivity mirrors to make it lase at room temperature. To satisfy these conditions, researchers at Tokyo Institute of Technology[244] have used a metal thin-film or a quarter-wavelength stack of dielectric layers (Bragg reflectors) of high- and low-index material for the mirror post to the growth of laser layers. The advances in epitaxial growth techniques allow an accurate control of semiconductor layer compositions and thicknesses such that Bragg reflectors with 99.9 percent reflectivity can be attained. Therefore, a complete vertical cavity laser structure as shown in Fig. 30 consisting of a gain medium and high-reflectivity (more than 10 periods of alternate layers due to incremental index difference) mirrors can be grown successfully in one step by MBE or MOCVD techniques.

It is important to optimize the structure for optical gain. To maximize the modal gain, one can locate the standing wave field peak at the thin quantum well active layer(s) (quantum well lasers were discussed earlier in this chapter) to form a resonant periodic gain structure.[245] The issue associated with the semiconductor superlattice Bragg reflectors is the built-in carrier resistance across the abrupt heterojunction discontinuity. Without modifying the structure, the series resistance is on the order of several hundred to a thousand ohms. There have been two techniques applied to lower the resistance, namely, the use of graded junctions[246] and peripheral Zn diffusion[247] for conducting current to the active region. Both have demonstrated improvement over the original design.

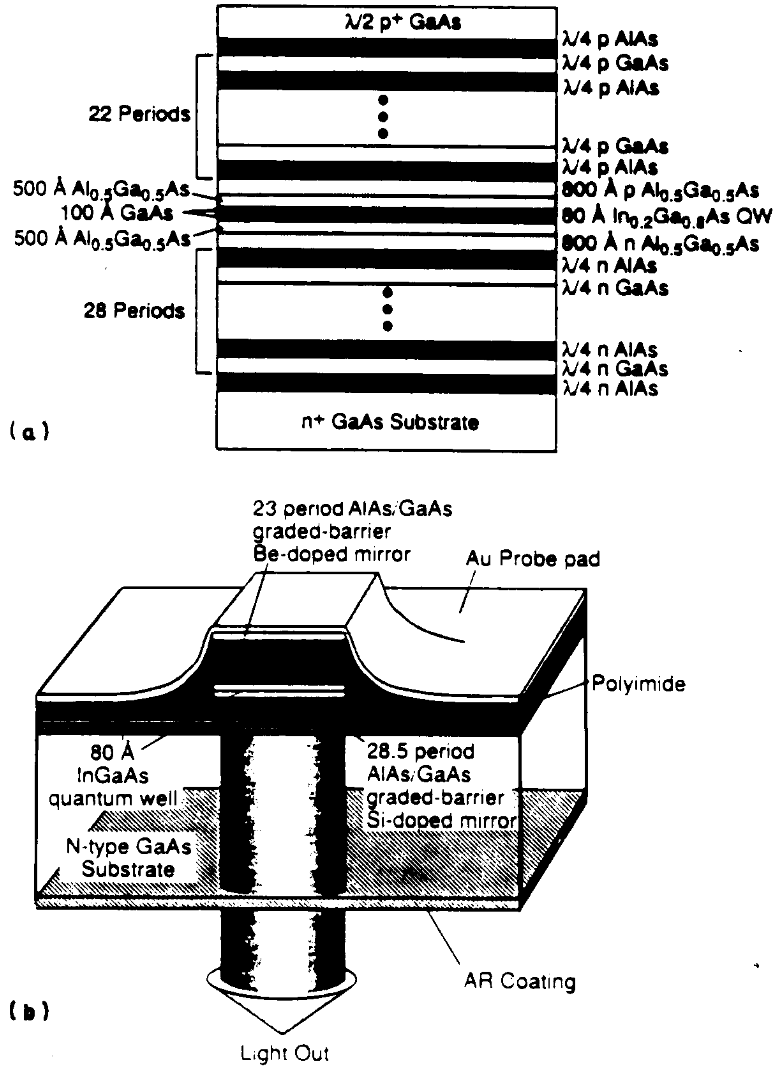

FIGURE 30 Vertical cavity surface-emitting laser with (*a*) layer structure and (*b*) device geometry. (*From Ref. 249.*)

The laser size is defined by etching into a circular column that can be mode-matched to a single-mode fiber for high coupling efficiency. It is desirable that the lasers can be planarized. Proton-bombardment-defined lasers[248] with good performance and high yield have been obtained. Meanwhile, the small size of the laser has resulted in low threshold currents close to 1 mA.[249] The differential quantum efficiency has been improved from a few percent to more than 30 percent; the output power level, modulation frequency, and maximum operating temperature have also increased over the past several years. As mentioned previously, the advantage of this SEL structure is the potential of high packing density. Bellcore researchers[250] have demonstrated a novel WDM (wavelength division multiplexing) laser source with a good histogram of wavelength distribution. The grading

of layer thickness across the wafer during a portion of growth translates into different lasing wavelengths. Two-dimensional, individually addressable lasers in a matrix form have also been demonstrated.[251] In the future, 2-D laser arrays operating at a visible wavelength will be very useful for display and optical recording/reading applications. The performance characteristics of vertical cavity SELs reported are shown in Table 6.

13.11 CONCLUSION

In this chapter we have introduced the basic properties of semiconductor lasers and reviewed some areas of the field, including high-power operation, high-speed operation, coherence, and surface-emitting lasers. We have particularly emphasized the advantages of quantum well lasers and strained quantum well lasers. Up until very recently, all the major laser diodes were fabricated using GaAs/GaAlAs and GaInAsP/InP heterostructures. However, there have been such significant advances in the use of strained quantum wells that these lasers have performance levels which exceed, in many cases, that found for the unstrained lasers. Coupled with the measured excellent reliability results and better output power/temperature performance, these types of lasers will experience a high demand in the future. High-power strained InGaAs/GaAs quantum well lasers are also of interest because their lasing wavelength range includes 0.98 μm, which makes them useful for pumping erbium-doped fiber amplifiers.[17]

Another trend in the future will be the extension of commercial semiconductor lasers to a wider variety of lasing wavelengths. Just as with the standard lasers, strained quantum wells result in significant performance improvements in these more novel laser systems. Shorter wavelength ($\lambda < 0.75\ \mu m$) lasers with high output powers are of interest for high-density optical recording and printing. In the last few years, much progress has been made in developing short wavelength semiconductor lasers. In the near future, practical visible wavelength lasers will be in the red-to-yellow range, but progress has begun on even shorter wavelengths in the blue. Recent work on very long wavelength ($\lambda > 2.0\ \mu m$) GaInAsSb/AlGaAsSb lasers is also very promising. Long wavelengths ($>1.55\ \mu m$) are of interest for eye-safe laser radar, metrology, and medical instrumentation.

Currently, commercial lasers are of the edge-emitting variety, but two-dimensional surface-emitting laser arrays have advanced considerably in the past few years. When they reach maturity, they will be used for pixel interconnect and display applications.

In a limited chapter such as this it is impossible to cover all areas of the field of semiconductor lasers in depth. One of the most important areas neglected is that of tunable lasers.[255–257] Single-mode tunable DFB and DBR lasers are of great interest for future coherent optical transmission systems. These lasers lase in a single longitudinal mode, but that mode can be tuned to a range of frequencies.

Another area not discussed in detail here is amplifiers. Amplifiers are of great interest for long-haul communication systems, for example, submarine cable systems. Amplifiers can be laser pumped fiber amplifiers[17] or laser amplifiers.[258–262] A laser amplifier has a structure similar to that of a semiconductor laser and has some optical gain, but only enough to amplify an existing signal, not enough to lase on its own.

It is hoped that the information presented in this chapter will satisfy readers who are interested in the basics of the subject and will give readers interested in greater depth the understanding necessary to probe further in order to satisfy their specific requirements.

CHAPTER 14
ULTRASHORT LASER SOURCES

Xin Miao Zhao
Jean-Claude Diels
Department of Physics and Astronomy
The University of New Mexico
Albuquerque, New Mexico

14.1 GLOSSARY

$A_c(\tau)$	autocorrelation
a	linear small-signal attenuation
a_g	average (saturated) gain prior to the arrival of perturbation
d	crystal thickness
d_g	thickness of gain medium
$\mathscr{E}_s(t)$	pulse amplitude
g	linear small-signal amplification
I	pulse intensity
l	attenuation inside nonlinear medium
n	number of round-trips
P_p	amplitude of a fluctuation
P_{av}	noise of average power
p	group velocity mismatch
r	amplitude reflectivity
r	reflectivity
T_{1a}	energy relaxation time of absorbing transition
t_e	pulse rise time to reach saturation energy density
t_g	gain existing time
t_{RT}	cavity round-trip time
W	pulse energy
W_{sa}	saturation energy
W_{sg}	gain saturation energy

α	absorption coefficient
α_g	gain absorption coefficient
ΔP	power fluctuation
δ	mismatch between cavity round-trip time and the pump pulse spacing
$\epsilon(t)$	small noise burst
κ	nonlinear parameter proportional to the length and nonlinear index of medium
σ	gain cross section
σ_a	growth rate
τ_c	decay time for fluctuation
τ_p	duration of fluctuation
Φ	intensity-dependent phase
$\chi^{(2)}$	second-order susceptibility
ω_p	pump radiation frequency
ω_s	pulse frequency

14.2 INTRODUCTION

Ultrashort pulses are often generated by locking in phase a large comb of modes sustained by the laser gain bandwidth. Mode locking has been studied and used in many different lasers. A typical laser consists of a resonator formed of two mirrors and a gain medium. The simplest mode-locked laser is a resonator with an intracavity modulator. This modulator, whether it is a saturable absorber, an acousto-optic (A-O) or electro-optic (E-O) modulator, or a self-phase modulating component, modulates the amplitude or the phase of the field inside the cavity to generate short pulses. We will devote this chapter to the different aspects and variations of the mode-locking mechanism.

There are two broad categories of mode-locking mechanisms: passive and active. In the former, some intensity-dependent loss or dispersion mechanism is used to favor operation of pulsed over continuous radiation. In the latter, a coupling is introduced between cavity modes, ‘‘locking’’ them in phase. Between these two classes are ‘‘hybrid’’ and ‘‘doubly mode-locked’’ lasers in which both mechanisms of mode locking are used. In parallel to this categorization in ‘‘active’’ and ‘‘passive’’ lasers, one can also classify lasers as being modulated inside (the most common approach) or outside (usually in a coupled cavity) the lasers.

14.3 PASSIVELY MODE-LOCKED LASERS

Evolution of the Pulse Train

In a laser, many modes are allowed along the resonator axis with frequency separation of $c/2L$, where L is the optical length of the cavity and c is the speed of light. These modes usually oscillate with random phases and irregular amplitudes resulting in a randomly time-varying amplitude within the round-trip period $t_{RT} = 2L/c$. However, if these modes have the same phase ϕ, they will constructively interfere at the same instant $t_c = (\phi/2\pi)t_{RT}$ of the round-trip time. The output will thus consist of a series of pulses centered at $t_c, t_c + t_{RT}, t_c + 2t_{RT}, \ldots,$ and the laser is said to be ‘‘mode locked.’’ The element to fix these relative phases is referred to as the *mode locker.* The width of each of the successive pulses is approximately equal to the inverse of the frequency range spanned by the modes being locked in phase. In the laser resonator, mode locking in the time domain corresponds to a single pulse traveling back and forth between mirrors with loss on the output mirror being compensated by the gain from pumping at each round-trip.

A passive mode-locking element can be a saturable absorber, a nonlinear lens, a nonlinear mirror, or a combination of dispersion and phase modulation. Before looking at individual mode-locking elements, let us review the general mechanism of passive mode locking.

The passive mode-locking element can most often be represented by intensity-dependent intracavity loss. Larger losses at low intensity imply that the laser has less gain—and may be below threshold—for low-intensity continuous wave (cw) radiation than for pulses with higher peak intensity. This leads to the emergence of a pulse out of the amplified spontaneous emission noise of the laser. Rather than concern ourselves with the primary process of formation of a precursor of a pulse from random noise, let us follow the evolution of the pulse from its birth from noise until it has blossomed into a fully shaped stable laser pulse. We will look for simple evolution equations for the pulse energy $W = \int_{-\infty}^{\infty} I(t)\, dt,$ with $I(t)$ being the pulse intensity.

The element responsible for saturable losses (gain) should have typically a *linear* loss (gain) factor at low energies, and a *constant* loss (gain) at higher energies. We thus have, at low energies: $dW/dz = \mp\alpha W$. At large energies $W \gg W_s$: $dW/dz = \mp\alpha W_s$ where W_s is the saturation energy for the chosen geometry. The simplest differential equation to combine these two limits is

$$\frac{dW}{dz} = \alpha_g W_{sg}[1 - e^{-W/W_{sg}}] \tag{1}$$

Equation (1) is written for a medium with a linear gain α_g and a saturation energy W_{sg}. It can be integrated to yield the energy W_2 at the end of the amplifier of thickness d_g, as a function of the input energy W_1:

$$W_2 = G(W_2, W_1)W_1 = W_{sg} \ln \{1 - e^{\alpha_g d_g}(1 - e^{W_1/W_{sg}})\} \tag{2}$$

A similar equation applies to the saturable absorber, with a negative absorption coefficient $-\alpha_a$ and a smaller saturation energy W_{sa}:

$$W_2 = A(W_2, W_1)W_1 = W_{sa} \ln \{1 - e^{-\alpha_a d_a}(1 - e^{W_1/W_{sa}})\} \tag{3}$$

The dominant linear loss element is the output coupler, with reflectivity r. The transfer function for that element is simply

$$W_2 = L(W_2, W_1)W_1 = rW_1 \tag{4}$$

and the energy of the output pulse is $(1 - r)W_1$. The evolution of the pulse energy in a single round-trip can be simply calculated from the product of all three transfer functions given by Eqs. (2) (3), and (4). For instance, if we consider a ring laser with the sequence: mirror, gain, and absorber, the pulse energy W_4 after the absorber is given by the product $A(W_4, W_3)G(W_3, W_2)L(W_2, W_1)$. One can also express the relation between the energy W_4 and the pulse energy W_1 before the output mirror by the algebraic relation:[1]

$$1 + a[e^{W_4/W_{sa}} - 1] = \{1 + g[e^{rW_1/W_{sg}} - 1]\}^{W_{sg}/W_{sa}} \tag{5}$$

where $a = \exp\{-\alpha_a d_a\}$ is the *linear* small-signal attenuation of the passive element and $g = \exp\{\alpha_g d_g\}$ is the *linear* small-signal amplification.

The recent trend has been to develop high-power mode-locked oscillators, for which both numbers a and g can be large, and the reflectivity of the output coupler r can be as low as 50 percent. As a result, the *order* of the elements matters in the design of the laser, and in its performances. To illustrate this point, let us assume that the passive element is totally saturated in normal operation. In full saturation, the input energy $W(0)$ is related to the output energy $W(d)$ by

$$W(d) = W(0) - \alpha_a d_a W_{sa} \tag{6}$$

Given an initial energy W_1, the energies W_4 after single passage through three different sequences of the same elements are given below. For the sequence mirror-absorber-gain

$$e^{W_4/W_{sg}} = 1 - g[1 - e^{(rW_1 - \alpha_a d_a W_{sa})/W_{sg}}] \tag{7}$$

For the sequence absorber-mirror-gain

$$e^{W_4/W_{sg}} = 1 - g[1 - e^{r(W_1 - \alpha_a d_a W_{sa})/W_{sg}}] \tag{8}$$

For the sequence absorber-gain-mirror

$$e^{W_4/W_{sg}} = \{1 - g[1 - e^{(W_1 - \alpha_a d_a W_{sa})/W_{sg}}]\}^{1/r} \tag{9}$$

Let us take a numerical example for a high-gain system such as the flash-lamp pumped Nd:glass laser, with $W_{sa}/W_{sg} = 0.1$, $\alpha_a d_a = 1$, $\alpha_g d_g = 1.5$ and output coupling of $r = 0.5$. For an initial energy $W_1/W_{sg} = 0.5$, we find for the sequence mirror-absorber-gain $W_4/W_{sg} = 0.545$, for the sequence absorber-mirror-gain $W_4/W_{sg} = 0.689$, and for the sequence absorber-gain-mirror $W_4/W_{sg} = 0.582$.

The order of the elements, the relative saturation of the gain to that of the passive element, as well as the output coupling influence the stability and output power of the laser, as shown in Ref. 1. The evolution of the pulse in the cavity can be calculated by repeated applications of products of operations such as $A(W_4, W_3)G(W_3, W_2)L(W_2, W_1)$ for the sequence (passive element, gain, output coupler), starting from a minimum value of W_1 above threshold for pulsed operation,[1] and recycling at each step the value of W_4 as the new input energy W_1. Figure 1 shows the growth of intracavity pulse energy, as a function of the round-trip index j, for different orders of the elements. The initial pulse energy is 1 percent of the saturation energy W_{sg} in the gain medium. The saturation energy and optical thickness of the absorbing medium are, respectively, $W_{sa} = 0.8W_{sg}$ and $\alpha_a d_a = 1.2$. The linear gain is $\alpha_g d_g = 1.5$, and the output coupling $r = 0.8$.

The main point of this exercise is that the order of the elements *is* important, a fact confirmed by measurement on high-gain lasers such as Ti:Al$_2$O$_3$. Such dependence on the order of the elements proves the inadequacy of analytical theories based on the approximation of infinitesimal change per element and per cavity round-trip.

Numerical codes have been developed that attempt to include all physical phenomena affecting pulse shape and duration.[2,3] Unfortunately, the shear number of these mechanisms makes it difficult to reach a physical understanding of the pulse-generation process, or even identify the essential parameters. Therefore, the most popular approach is to construct a simplified analytical model on a selected mechanism. The next section gives a brief summary of the various mode-locking methods.

Pulse Shaping in Passive Mode Locking

It is beyond the scope of this chapter to review the numerous theories of passive mode locking that have emerged since the early 1970s. An overview of these theories can be found in Refs. 1 and 4. We will limit ourselves here to a qualitative description of pulse shaping.

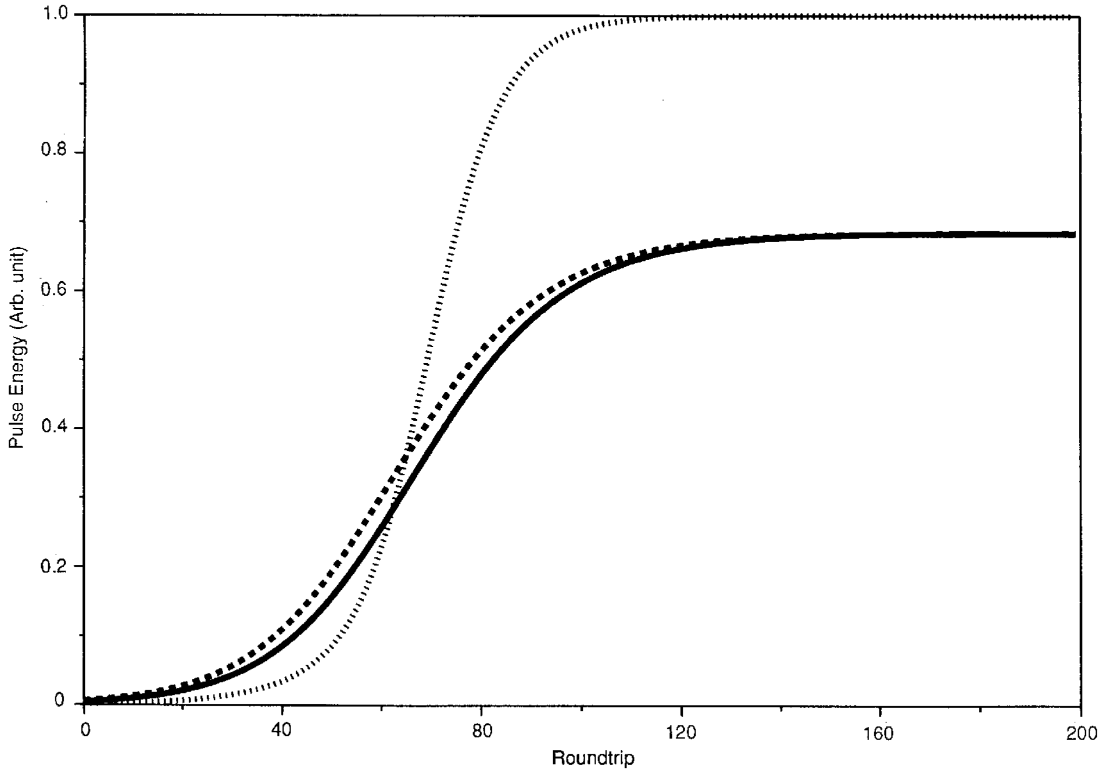

FIGURE 1 Intracavity pulse energy versus round-trip index number *j*. The solid, dashed, and dotted lines correspond to the sequence *m*(irror)-*a*(bsorber)-*g*(ain), *a-g-m* and *a-m-g*, respectively.

The main influence of the saturable absorber is to steepen the leading edge of the pulses circulating in the cavity. At the early stage of the pulse formation, the portion of the pulse prior to $t = t_s$ (t_s is the time to reach saturation) is absorbed. It is assumed at this early stage that $I(t_s) = I_{sa}$ is reached at a time $t_s \ll T_{1a}$, where T_{1a} is the energy relaxation time of the absorbing transition. As the pulse intensity increases, the pulse duration shortens because the leading edge of the pulse from $t = 0$ to $t = t_s$ is eroded by absorption, while there is much less attenuation at the trailing edge of the pulse for $t > t_s$. However, as the pulse is amplified in the cavity, the onset of saturation moves toward the earlier part of the pulse. As a result of the decreasing t_s, absorption saturation becomes less and less effective as a compression mechanism because it affects a smaller and smaller fraction of the pulse leading edge. As the pulse duration becomes much smaller than T_{1a}, the absorber affects the pulse only up to the time t_e for which the accumulated energy density reaches the saturation energy density W_{sa}:

$$\int_0^{t_e} I(t)\, dt = I_{sa} T_{1a} = W_{sa} \tag{10}$$

Trailing edge pulse shaping generally is the result of the gain depletion by stimulated emission. This mechanism becomes significant as the pulse energy approaches a steady state.

The above considerations are sufficient to establish broad criteria for the gain and absorber in a passively mode-locked laser. For the gain medium, a larger inversion at minimum cost of pump power calls for a long energy relaxation time T_{1g}. At moderate pumping, the gain recovery time (between pulses separated by the cavity round-trip time t_{RT}) is equal to—or less than—T_{1g}. Stable single-pulse operation of a passively mode-locked laser requires that the cavity round-trip time does not exceed the gain lifetime T_{1G} by more than a factor of 4 or 5.

The saturable absorber should have a larger or equal saturation cross section than the gain medium, and a relaxation time T_{1a} shorter than the cavity round-trip time. The requirement for a large saturation cross section can be relaxed by using standing wave saturation (factor of 3 effective reduction of the saturation intensity) as in the ring laser or an antiresonant ring laser,[1] or by focusing more tightly in the absorber than in the gain.

Optimal pulse compression through saturable absorption requires that the saturation energy be as large as is compatible with the self-starting requirement (buildup of the oscillation from noise).

Phase Modulation and Dispersion

In most practical situations involving passive mode locking with a saturable absorber dye, the laser radiation is applied *below resonance* with the absorber. Consequently, the index of refraction of the dye solution decreases as the absorber saturates, leading to a *downchirp* of the pulse and *self-defocusing* of the beam. Both processes can simultaneously affect the mode-locking process.[1]

A downchirped pulse has higher frequency components at its leading edge. Therefore, the pulse front will propagate slower than the pulse tail in a normally dispersive medium such as glass, and the pulse will be compressed.[5] Depending on the particular cavity configuration, the self-defocusing may result in a significant loss modulation. The induced lens, which may have a focal distance of several centimeters, will nearly always modify the beam geometry because of astigmatism.[6] The z-scan technique[7] was used to measure the lensing effect in the absorber jet of diethyloxadicarbocyanine iodide (DODCI) mixed in ethylene glycol. When a dye laser at 620 nm was used as pumping source, a focal length of -3.1 cm was measured for the induced lens in the dye jet, which corresponds to a $\lambda/100$ phase front distortion[6] at the beam waist. This lensing effect results in a total change of intensity on axis of 2.6 percent when the absorber jet is translated along the z direction[6] away from the focal point of the mirrors.

Both the self-defocusing and the phase modulation are maximum if the pulse-energy density in the dye amounts to approximately 6 times the saturation-energy density. This is the condition for which the fastest change in index takes place near the peak of the pulse. If this mode of operation is sought, the spot size in the absorber should be large enough to avoid excessive saturation of the dye. Positive dispersion—such as provided by an adjustable thickness of glass—is sufficient to compensate the downchirp and achieve pulse compression.

Positive phase modulation or ''upchirp'' can be obtained in a cavity where the Kerr effect dominates. This is the case in laser cavities with tight focusing in the absorber jet,[8,9] or in a solid-state gain medium such as the Ti:Al_2O_3.

The amount of phase modulation can be made very large either by using additives with large Kerr constant such as 2-methyl-4-nitroaniline (MNA) to the saturable absorber solution,[9,10] or using an external fiber in additive-pulse mode locking as discussed later, or using amplifier crystals (such as is the case for Ti:Al_2O_3). When self-phase modulation is combined with an appropriate amount of group velocity dispersion, some important effects occur. One of them is the formation of ''soliton.'' Solitons in fibers were first observed in 1980.[11] Pulse narrowing was demonstrated associated with soliton formation by Mollenauer et al.[12] This work led subsequently to the design of a soliton laser.[13] If the modulation due to the Kerr effect dominates—such as in the Ti:sapphire laser—the steady-state pulse can also be calculated from the nonlinear Schrödinger equation.[1,14,15] The approximations made in modeling the soliton laser by the nonlinear Schrödinger equation neglect loss mechanisms. In particular, the modulation of the beam parameters caused by transient self-focusing associated with the Kerr effect is generally ignored. Recently, the importance of the spatial effect—in particular for Ti:sapphire lasers—was recognized and included in the laser analysis.[16]

Passive Pulse-Shaping Elements

The most common passive mode-locking element is the saturable absorber dye with a saturation energy of the order of $1\,\mathrm{mJ/cm^2}$, and an energy relaxation time ranging from picoseconds to nanoseconds. Its functions include pulse shaping by saturation, phase modulation leading to downchirp, saturation-induced self-focusing, Kerr-effect-induced upchirp, and self-defocusing.

In addition, the absorbing dye jet provides a common time reference for the counterpropagating pulses of a ring cavity. Since the pulses generate a transient standing wave pattern in the absorber jet, a complex single- and two-photon resonant degenerate four-wave mixing coupling takes place between the two pulses.[17]

Multiple quantum wells provide a substitute saturable absorber with a smaller saturation energy required to mode-lock semiconductor lasers.[18] Also, ‘‘artificial saturable absorbers’’ can be designed with nonlinear optics. A detailed analysis of this concept is given in a later section, ‘‘Nonlinear Optical Sources,’’ under the subheading ‘‘Mode Locking with Intracavity Second Harmonic Generation’’ and the section following it.

A last and rather complex pulse-shaping element is a two-photon absorbing semiconductor associated with a limiting aperture. The function of that element is to limit the pulse intensity to roughly the saturation intensity, and provide pulse compression through self-defocusing by the two-photon-induced carriers. A detailed description of this laser operation is given in the section ‘‘Passive Negative Feedback.’’

14.4 SYNCHRONOUS, HYBRID, AND DOUBLE MODE LOCKING

Synchronous Mode Locking

Short pulses can be created by exciting the gain medium at a repetition rate synchronized with the cavity-mode spacing. This simple method is called *synchronously pumped mode locking.* As compared to passive mode locking, fewer internal elements are needed in this type of laser. In its simplest form, synchronous mode locking has the advantage of a higher pumping efficiency. Indeed, no energy is wasted in trying to maintain a gain between pulses. A larger number of dyes is available for synchronously pumped operation, including dyes with a very short energy relaxation time which would be too difficult to be pumped continuously. Another important advantage over passively mode-locked lasers is its higher average output power. The reason is the low duty cycle of the pump, enabling more pump power to be concentrated in the gain jet, resulting in a larger inversion and gain than in a continuously pumped laser.

Unfortunately, the same degree of stability cannot be achieved for purely synchronously pumped lasers as for passively mode-locked lasers. Typically, the autocorrelation

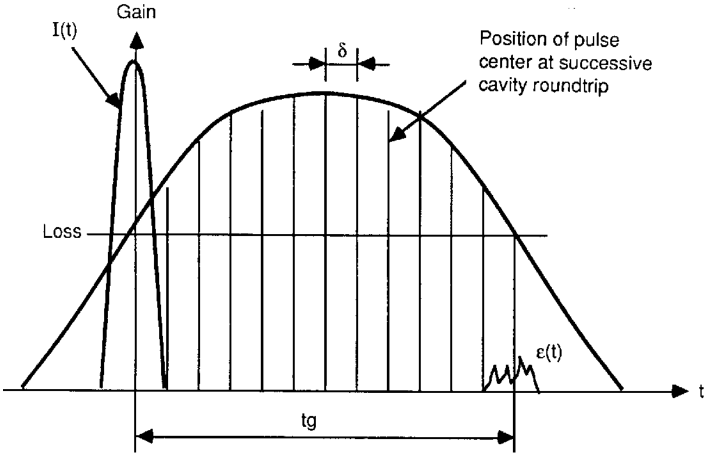

FIGURE 2 Net gain development inside a laser cavity.

trace of such a laser has exponential wings, indicating a random distribution of pulse duration along the train.[19] If the laser cavity were slightly longer than required for exact synchronization, amplified spontaneous emission would constantly accumulate at the leading edge of the pulses, resulting in long pulse durations. For best stability, the cavity length should be slightly shorter than that required for exact synchronism with the pump radiation. In fact, if δ is the mismatch between cavity round-trip time and the pump pulse spacing (synchronous with the pulsed gain $\alpha(t)$), the intracavity intensity of the jth round-trip is related to the previous one by

$$I_j(t) = I_{j-1}(t - \delta)[e^{\alpha(t-\delta)d_g} - l] \tag{11}$$

In Eq. (11), d_g is the thickness of the gain medium and l is the loss per cavity round-trip.

The net gain $(e^{\alpha(t)d_g} - l)$ exists in the cavity for a time t_g (Fig. 2). Any pulse will experience gain for $n = t_g/\delta$ round-trips. The laser oscillation will start from a small noise burst $\epsilon(t)$. The fully developed intracavity pulse is simply

$$I(t) = \epsilon(t - tg)[e^{\alpha_{\mathrm{av}}dg-l}]^n \tag{12}$$

where we have defined an average gain $\alpha(1/tg) \int \alpha(t'/dt')$. Equation (12) indicates that in the absence of any spectral filtering mechanism, and neglecting the distortion of the gain curve $\alpha(t)$ by saturation, the pulse should be roughly n times shorter than the duration of the gain.

The somewhat oversimplified representation of Fig. 2 includes nevertheless an important noise feature of the laser. The seed $\epsilon(t)$ has random phase. As pointed out by Peter et al.,[20] the aleatory phase of the spontaneous emission source is at the origin of the noise of the laser.

The phase randomization of the "starting" pulse can be reduced by adding to $\epsilon(t)$ a minimum fraction $\eta E(t)$ of the laser output field, just large enough so that the phase of $\eta E(t) + \epsilon(t)$ comes nearly equal to the phase of the output fields $E(t)$. Both calculation and experiment have demonstrated a dramatic noise reduction by seeding the cavity with a small fraction of the pulse *in advance* of the main pulse.[20] The practical implementation is to provide a weak reflection from a microscope slide ahead of the output mirror. Since a

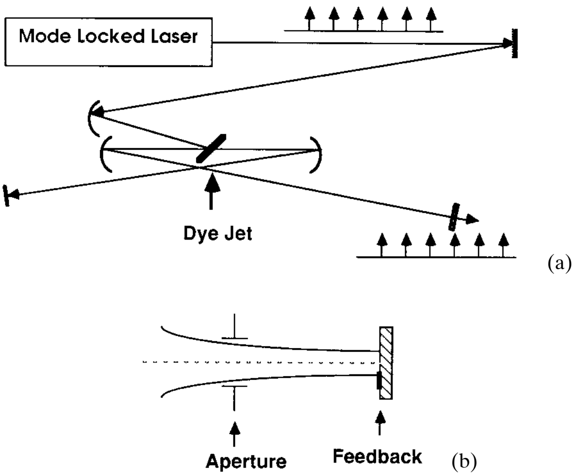

FIGURE 3 (*a*) Synchronously pumped laser, (*b*) modified end mirror.

feedback of less than 10^{-5} is required, the microscope slide needs only to interact with the edge of the beam, as shown in Fig. 3.

Ideally, the gain medium in a synchronously pumped laser should have a short lifetime, so that the duration of the laser pulse is not longer than that of the pump pulse. If the gain medium has a longer lifetime than the cavity round-trip time, there is hardly a modulation of the gain, and we would expect mode locking to be impossible. However, even a small modulation of the gain may grow because of gain saturation by the modulated intracavity radiation, resulting in a shortening of the function $\alpha(t)$, and, ultimately, ultrashort pulses. Phase modulation and dispersion may also lead to the growth of a steady-state pulse out of a small modulation. We will discuss the synchronous pumping of a very long lifetime gain medium in the section on Ti:sapphire lasers.

Hybrid and Double Mode Locking

As mentioned above, synchronously pumped mode-locked lasers have the disadvantage that their pulse (usually longer than those from passive mode-locked lasers) are unstable in duration[19] and in frequency.[21]

To improve the laser characteristics, a saturable absorber can be inserted in the cavity.[22,23] Such a laser is called *hybrid mode-locked laser.* Depending on the concentration of the absorber dye, the hybrid mode-locked laser is either a synchronously mode-locked laser perturbed by the addition of saturable absorption or a passively mode-locked laser pumped synchronously. Detailed discussion of the distinctions can be found in Ref. 1.

Double Mode Locking

Numerous applications require multiple-wavelength femtosecond sources. One possibility is to cascade several lasers synchronously pumping each other.[24] This technique allows us to obtain various synchronized sources of increasing wavelength, but such a complex setup has a low efficiency. More sophisticated and efficient is the method of *double mode*

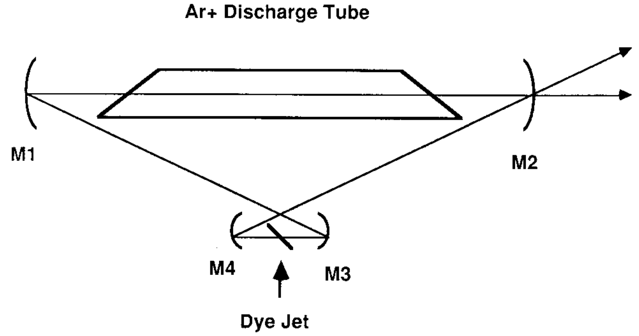

FIGURE 4 Double colliding pulse mode locking, M1, M3, and M4 are high reflectors and M2 has partial transmission at both laser wavelengths.

locking,[25,26] used in a passively mode-locked laser to serve essentially the same purposes. In the latter technique, the saturable absorber of the primary laser is the gain medium for the secondary laser. Although one would have expected pulses shorter than with simple passive mode locking because the lifetime of the common dye—absorber for the primary laser, gain for the secondary—is shortened by the secondary laser action, the improvement was not achieved. Combining double mode locking with pulse collision in the absorber (standing wave saturation), Wang[27] et al. succeeded in double mode locking an Ar^+ and dye laser in a ring cavity. A simple configuration of this double colliding mode-locked laser is shown in Fig. 4. This technique eliminates the need for active mode locking of the Ar^+ laser for synchronous or hybrid mode locking. It also has a high overall efficiency: the average output power was 50 mW for an Ar^+ pump power of 1 W. Another example of cascade operation involves a Ti:sapphire laser synchronously pumping a dye laser.[28]

Multiple wavelength operation is easily achievable within a laser cavity, provided the bandwidth of the gain medium is sufficiently large. This is in particular the case of the Ti:sapphire laser, for which various configurations for two-color femtosecond (fs) operation have been demonstrated. Simultaneous operation of two *synchronized* pulse trains is generally desired. One synchronization mechanism exploited by Dykaar and Darack[29] is cross-phase modulation via the Kerr effect, in a region of the gain medium where the pulses are spatially and temporally close enough to interact. The pump beam (an Ar^+ laser) is split to excite two adjacent volumes of the same piece Ti:sapphire crystal. These two adjacent gain volumes are associated with two cavities tuned to different wavelengths. Up to the largest wavelength offset observed of about 20 nm, the two pulse trains appear perfectly synchronous, as indicated by a cross-correlation width of 70 fs.

Another technique is to use the traditional prism sequence needed to adjust the group velocity dispersion as a spectral device to select two spectral regions in the cavity. Barros and Becker[30] inserted a double slit between the prism pair and the end cavity mirror to select two center frequencies. Dual wavelength spacing as large as 60–75 nm with less than 20 fs time jittering was achieved. A third technique applies to even larger wavelength spacing. Evans et al.[31] used two prism pairs with three prisms (sharing of the first one) and two output couplers. They obtained wavelength range as large as 90 nm and less than 70 fs time jittering between two pulse sequences.

As noted by Kafka[32] and Luo,[33] *unsynchronized* dual wavelength pulse trains can be quite useful for pump-probe spectroscopy. Let us consider, for instance, a transient transmission experiment, with a pump laser operating at a repetition rate of ν_{cp} and the probe at a repetition rate of ν_{ct}. On the screen of an oscilloscope triggered on the pump pulses, transmitted probe pulses will appear at time intervals $\Delta t = (1/\nu_{cp}) - (1/\nu_{ct})$, providing a direct display of the transient phenomena being observed, with a temporal resolution equal to Δt.

14.5 ACTIVE AND PASSIVE NEGATIVE FEEDBACK

A typical flash-lamp pumped mode-locked Nd laser generates a train of only 5 to 10 pulses of all different intensity. "Negative feedback" is a technique to modulate cavity losses and stretch the pulse train. It increases cavity losses when the peak intensity of the pulses tends to increase beyond a well-defined value. By limiting the intracavity pulse energy, the rate of depletion of the population inversion is reduced, resulting in an extended pulse train. As told by their names, active (passive) negative feedback is the implementation of this technique actively (passively) using an intracavity energy limiter. The intracavity pulse compression can work more efficiently on a pulse of constant energy that circulates for at least 100 round-trips in the cavity. Pulse duration as short as the bandwidth limit of the gain medium is achieved.[34]

The first report on active feedback is from Martinez and Spinelli,[35] who proposed to use an electro-optic (E-O) modulator to actively limit the intracavity energy in a passively mode-locked glass laser. They demonstrated that the pulse train could be extended. A fast high-voltage switching of the E-O modulator led to the generation of microsecond pulse trains in a passively mode-locked glass laser[36] and in *hybrid* mode-locked Nd:glass lasers.[37] These systems provided an alternative to cw subpicosecond[38] and femtosecond[39] lasers. If we substitute a piece of glass of high thermal conductivity for the laser rod, a microsecond long train of pulses could be generated at a repetition rate of 10 Hz. Used as a source for synchronously pumping a ring dye laser, pulses of less than 50 fs and 25 nJ are routinely extracted from the oscillator.

These electronic feedback systems are expensive and sophisticated. There is a minimum response time of one cavity round-trip before the feedback can react.[37] As a result, the pulse train envelope still exhibits some modulation. On the contrary, a passive feedback system can provide immediate response, i.e., on the time scale of the pulse duration rather than on the time scale of the cavity round-trip. The mechanism of passive negative feedback is as follows. Self-defocusing in a semiconducting two-photon absorber (typically a millimeter-thin piece of polished GaAs) sets in at a power level close to the saturation intensity in the saturable absorber dye. Because the pulse intensity is close to the pulse saturation intensity, there is an optimal pulse compression at the pulse leading edge by saturable absorption. On the other hand, because of self-defocusing by the two-photon generated carriers, the pulse trailing edge is clipped off, resulting in further pulse compression.

Stretching and stabilization of Q-switched pulses with intracavity two-photon absorbers was first demonstrated in 1967.[40,41] Simultaneous extension of the pulse train and compression of the individual pulses was only observed two decades later, with the insertion of a GaAs sample in an actively and passively mode-locked Q-switched laser.[42,43,44] A detailed experimental and theoretical analysis of the mechanism by which GaAs affects the pulse evolution in the mode-locked train is given in Ref. 34. The essential components are (1) a high-gain solid-state laser, (2) a pulse-shaping element (A-O modulator and saturable absorber), (3) an intracavity GaAs sample, and (4) a beam-limiting aperture. Typical results[45] are a *rectangular* pulse train of 100 to 200 *identical* pulses, with pulse durations of 5 to 10 ps in an Nd:YAG laser. The pulse energy is about 10 μJ pulse, and a shot-to-shot stability better than 0.5 percent, measured over 10,000 pulses.

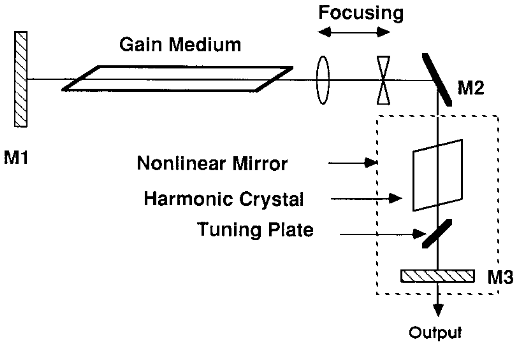

FIGURE 5 Model of laser mode locked by harmonic generation inside cavity.

14.6 NONLINEAR OPTICAL SOURCES

Mode Locking with Intracavity Second Harmonic

A new method of passive mode locking has been investigated, which uses the intracavity harmonic generation as a mode-locking mechanism. In both active and passive mode-locked lasers, harmonic generation has been observed and predicted to have a pulse-broadening effect.[46,47] Stankov proposed that intracavity harmonic generation could be used for pulse narrowing,[48] and subsequently demonstrated passive mode locking in a Q-switched laser by means of a nonlinear mirror consisting of a nonlinear crystal with a second-order nonlinearity and a dichroic mirror.[48,49] A simple cavity model for mode locking through harmonic generation (second harmonic or sum frequency) inside a laser cavity is shown in Fig. 5. The end mirror can be translated to adjust the relative phases (through the dispersion of air) between the fundamental and second harmonic wavelengths as they reenter the crystal. The phases are adjusted for reconversion of the fundamental from the second harmonic on the second passage. The whole assembly of crystal-air gap-end mirror has then a reflectivity *increasing* with intensity.

The mode-locking mechanism with intracavity harmonic generation has been studied and analyzed in the time domain[49] and the frequency domain.[50] The analysis shows that the nonlinear reflection from the nonlinear mirror behaves like a saturable absorber. This mechanism allows one to obtain two synchronized coherent wavelengths from one laser.

Intracavity Parametric Mode Locking

Another mode-locking mechanism called *parametric mode locking* was demonstrated by Zhao and McGraw.[51] This laser can be viewed as a hybridly mode-locked laser using a nonlinear process as the passive pulse-shaping element. Here, the third-order nonlinearity of a crystal applied to sum and difference frequency generation is used in the mode-locking process. Similar to the previous second harmonic case, a nonlinear mirror is used in the cavity. Instead of air, a glass plate for tuning the relative phases of the three wavelengths is inserted between the crystal and the trichroic end mirror. This nonlinear mirror generates a reflectivity at one wavelength as an increasing function of the intensity at another wavelength and therefore modulates the intracavity loss at the first wavelength inside the laser. In the particular experiment of Zhao and McGraw,[51] an infrared dye laser is pumped synchronously by a frequency doubled Nd:YAG laser. Sum and difference parametric generation synchronized with the 1.06 μm radiation of the pump source is obtained intracavity. The crystal is located near the end mirror which reflects both the generated blue and infrared dye laser radiation. Optimal pulse compression is obtained when, at the second passage through the crystal, the phase of the blue radiation, relative to the infrared radiation, is such that the blue radiation is reconverted back to the infrared radiation oscillating in the cavity. It has been shown[51] that both parameteric amplitude modulation (AM) and frequency modulation (FM) contribute to the mode locking.

This technique is useful for pulse narrowing, mode locking, and frequency upconverting of lasers. In addition, because the reflectivity of the parameteric mirror is intensity-dependent, the mechanism can be used to adjust the intracavity chirp. It provides us a unique opportunity to generate ultrashort pulses in various wavelength ranges, such as in the blue, where direct short-pulse generation is difficult due to the lack of suitable pump sources and mode-locking materials.

Optical Parametric Oscillator

Optical Parametric Oscillation. Optical parametric amplification (OPA) is a second-order nonlinear optical process. A nonlinear crystal is excited by a pump radiation of frequency ω_p. A “signal” of amplitude $\mathscr{E}_p(t)$ and frequency ω_s will grow exponentially in a crystal of thickness d, if pump depletion can be neglected:

$$\mathscr{E}_s(t) = \mathscr{E}_{s0} e^{\sigma_a d \xi_p(t)} \tag{13}$$

with the growth rate σ_a proportional to the second-order susceptibility:

$$\sigma_a \propto \chi^{(2)} \tag{14}$$

An “idler” photon of frequency $\omega_i = \omega_p - \omega_s$ is generated with the emission of each signal photon. Two types of phase matching conditions can be achieved, either type I:

$$\mathbf{k}^{e(o)}(\omega_p) = \mathbf{k}^{o(e)}(\omega_s) + \mathbf{k}^{o(e)}(\omega_i) \tag{15}$$

or type II:

$$\mathbf{k}^{e(o)}(\omega_p) = \begin{cases} \mathbf{k}^{e}(\omega_s) + \mathbf{k}^{o}(\omega_i) \\ \mathbf{k}^{o}(\omega_s) + \mathbf{k}^{e}(\omega_i) \end{cases} \tag{16}$$

where $\mathbf{k}^{o(e)}$ is the wave vector for ordinary (extraordinary) beam.

Optical parameteric generation is achieved by single-passage amplification of vacuum fluctuation (superfluorescence OPA).[52] Optical parametric oscillation (OPO) can be obtained from an optical parametric amplifier with a cavity feedback. The cavity can be made resonant with the idler or the signal (singly resonant OPO) or with both (only practical for degenerate OPO).[53] For synchronous pumping by mode-locked solid-state lasers, the length of the OPO cavity should match that of the pump laser. A unidirectional ring cavity for the OPO is preferable because of lower loses.[54] The mechanisms of pulse compression are similar to those of other synchronously pumped lasers, except that there is no pulse compression through gain saturation as observed in dye lasers. The most important are the pulse compression through phase modulation in the gain medium and intracavity group velocity dispersion. Pulses as short as 65 fs over a broad tuning range were obtained by synchronously pumping an OPO resonant or with an Nd:glass laser with negative feedback.[55] The same approach leads to fs pulse generation, using as pump the intracavity fs pulses of a dye laser,[56] or of a Ti:sapphire laser.[57] Since the method of parameteric generation is intracavity to a mode-locked laser, there is little possibility for scaling up the energy of the pulses (typically 1 pJ). The main advantage of this method is the high repetition rate. Such parametric generators pumped by mode-locked Ti:sapphire lasers has extended the wavelength range of high-repetition-rate ps and fs sources from the near UV to the middle IR.[58,59,60,61,62] For complete recent trends in OPO, refer to Diels and Rudolph (Ref. 4).

Parametric Chirp Enhancement and Pulse Compression. Since the pump frequency is the sum of the idler and signal frequencies, the idler and signal are chirp-reversed of each other.[62] This has an important consequence for seeded-pulse parametric generation. If a seed signal (idler) pulse is sent (before passing through the nonlinear crystal) through a dispersion line, it will be broadened and chirped. The same dispersion line will act as a perfect pulse compressor for the generated idler (signal).

In some circumstances, the chirp of a pump pulse may be amplified in the parametric process. In the case of near degenerate parametric generation in type I cut KDP, a small change in the wavelength of the pump (visible) results in a larger change in the wavelength of the signal and idler. As a result, a slightly chirped pump pulse generates signal and idler with enhanced and opposite chirps.[63] The instantaneous departure from average carrier frequency of the signal ($\delta\omega_s$) and idler ($\delta\omega_i$) can be related to the frequency deviation of the pump ($\delta\omega_p$):

$$\begin{aligned}\delta\omega_s &= p\delta\omega_p \\ \delta\omega_i &= (1-p)\delta\omega_p\end{aligned} \tag{17}$$

The chirp enhancement factor p is related to the group velocity mismatch:

$$p = \frac{1/v_{gp} - 1/v_{gi}}{1/v_{gs} - 1/v_{gi}} \tag{18}$$

where the subscripts p, i, and s denote pump, idler, and signal. The signal pulses with enhanced chirp can be compressed in a grating pair compressor. Pulses of 50 femtosecond at 920 nm were obtained by this technique[63] with the natural chirp of frequency-doubled pulses from an Nd:glass laser.

14.7 ADDITIVE AND SELF-MODE-LOCKING

Mode locking through phase modulation by a Kerr liquid has been observed in a Ruby laser[65] in 1968. The presence of Kerr liquids in the Q-switched resonator gave rise to ultrashort pulses. Other means to introduce a modulation in the cavity include self-phase-modulation inside the laser material,[66,67,68,69] spatial soliton propagation,[13,70] and coherent addition of pulses from coupled cavities.[71,72] Some aspects of these various mechanisms will be discussed below.

Additive Pulse Mode Locking

There has been a large effort devoted to the development of additive pulse mode locking (APML) involving coupled cavities. One of the basic ideas—to establish the mode coupling outside the main laser resonator—was suggested in 1965[73] and later applied to mode-lock a He-Ne laser.[74] In that earlier implementation, an A-O modulator, operating at half the intermode spacing of the laser, coupled adjacent modes (outside the cavity) before reinjecting them into the cavity through the output mirror. The output mirror of the laser, together with the mirror used to reinject the modulated radiation, formed a cavity of a mode spacing equal to that of the main laser cavity. Each upshifted mode, reinjected in the cavity, will force laser oscillation in phase with the mode ("injection locking"). Since all adjacent pairs of modes are coupled in phase, the laser is mode locked.

The recent APML methods are passive implementation of this older technique. In the purely dispersive version, a pulse from the coupled cavity is given some phase modulation such that the first half of the pulse fed back into the laser adds in phase with the intracavity pulse, while the second half has opposite phase. At each round-trip, the externally injected pulse compresses the intracavity pulse, by adding a contribution to the leading edge and subtracting the same amount from the trailing edge, as sketched in Fig. 6. This technique has first been applied to shortening pulses generated through other mode-locking

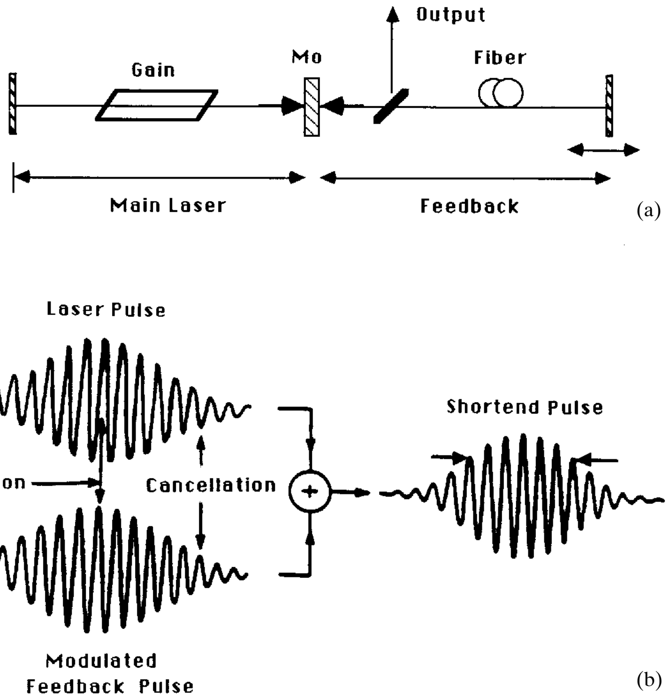

FIGURE 6 (*a*) A typical additive-pulse mode locked laser, and (*b*) modeling of its coherent field addition.

mechanisms. A reduction in pulse duration by as much as two orders of magnitudes was demonstrated with color-center lasers[72,75,76] and with Ti:Al_2O_3 lasers.[77]

It was subsequently realized that the mechanism of pulse addition through a nonlinearly coupled cavity is sufficient to passively mode lock a laser. This technique has been successfully demonstrated in a Ti:sapphire laser,[78] Nd:YAG,[79,80] Nd:YLF,[81,82] Nd:glass,[83] and KCl color-center lasers.[84] Ippen et al.[85] presented a detailed description of the coherent addition of pulses from the main laser and the extended cavity which takes place in additive-pulse mode locking.

Coherent field addition is only one aspect of the coupled-cavity mode-locked laser. The nonlinearity from the coupled cavity can be an amplitude modulation, as in the soliton laser,[13] or a resonant nonlinear reflectivity via a quantum well material.[18]

Some analyses of APML[76,85] have shown that the coupling between a laser and an external nonlinear cavity can be modeled as an intensity-dependent reflectivity of the laser end mirror. In the round-trip from the output mirror through the auxiliary cavity, the pulse accumulates a total phase shift $\phi + \Phi$ consisting of a constant (linear) part ϕ and a nonlinear part (intensity-dependent) Φ. Assuming a small nonlinear shift, we can replace the phase factor $\exp(i\Phi)$ by its first-order expansion which leads to the equation governing the reflection coefficient:[76]

$$\Gamma = r + l(1 - r^2)e^{-i\phi}(1 - i\Phi) \tag{19}$$

Here, r is the amplitude reflectivity of the output coupler; l is the attenuation inside the nonlinear medium, for instance, a fiber. In the latter case, the intensity-dependent phase is $\Phi = \kappa[|\mathscr{E}_2(t)|^2 - |\mathscr{E}_2(0)|^2]$ with $\mathscr{E}_2(t)$ ($\mathscr{E}_2(0)$) being the amplitude (peak) of the waves incident on the fiber and κ is proportional to the length and nonlinear index of the fiber. There is a differential reflectivity for different parts of the pulses. If one sets $\phi = -\pi/2$, then Γ has a maximum value at the pulse center where $\Phi = 0$, and smaller values at the wings. Adjustment of this dynamic reflectivity produces pulse shortening at each reflection until a steady-state balance is achieved between the pulse shortening and pulse spreading due to bandwidth limitation and dispersion.

Self-Starting Mode Locking

Self-Starting Mechanism. In the case of a laser mode locked passively with a saturable absorber, the oscillation builds up gradually from noise fluctuations saturating the absorber. The starting mechanism is not obvious in the case of the laser mode locked by a dispersive process, particularly when the gain medium has a long lifetime. Some lasers require an external starting mechanism; some others, such as the Ti:sapphire lasers, are ‘‘self-starting.’’

In a self-mode-locked laser, like in any other mode-locked system, there are intensity-dependent loss mechanisms. Temporal phase modulation implies necessarily a spatial modulation of the wavefront, hence, self-lensing. This effect is not unique to the Ti:sapphire laser: it also plays an important role in the operation of dye lasers.[6] It has been suggested[86] that mode locking can be achieved through a Kerr-induced self-focusing effect in the gain medium—an effect thereafter referred to as Kerr lens mode locking. The decreased loss with intensity for all these nonlinear effects can also be interpreted as a *net gain.* There is another effect that *opposes* the nonlinear compression mechanism, often referred to as *dynamic gain saturation.*[87,88] Laser mode locking will be self-starting if the intracavity nonlinearity—responsible for the growth of a noise spike—dominates the dynamic gain saturation.

If we define P_p as the amplitude of one fluctuation rising above the noise of average power P_{av}, the response of the nonlinear compression mechanism can be seen as a *net gain* for a power fluctuation $\Delta P = P_p - P_{av}$. To the first-order approximation the gain increase is proportional to the fluctuation

$$\Delta g(t) = b[P_p(t) - P_{av}] = b\ \Delta P(t) \tag{20}$$

where b is a characteristic of the nonlinearity and proportional to κ. The equation for the growth of the perturbation $P_p(t)$ is then

$$\frac{\partial P_p}{\partial t} = \frac{b}{t_{RT}} P_p^2 - f(P_p) \tag{21}$$

In Eq. (21), t_{RT} is the cavity round-trip time. The various theories of starting mechanism differ as to the origin of the fluctuation damping term $f(P_p)$. One school[87,88] associates the function $f(P_p)$ with the decrease in gain related to a positive power fluctuation P_p. That the derivative of Eq. (21) should be positive leads to a self-starting condition:

$$\frac{b}{a_g} \gg \sigma\tau_p \tag{22}$$

where τ_p is the duration of the fluctuation, σ is the gain cross section, and a_g is the average (saturated) gain prior to the arrival of the perturbation. Another approach is that of Krausz et al.,[89] who uses a simple damping term $-P_p/\tau_c$ for $f(P_p)$. The decay time τ_c for the fluctuation is the inverse linewidth of the first beat note. Assuming that unequal axial-mode spacing due to spatial hole burning is the major contribution to the beat note linewidth $1/\tau_c$, Krausz et al.[89] predict the following self-starting condition:

$$bP_{av} > \frac{1}{\ln(m_i)} \frac{t_{RT}}{\tau_c} \tag{23}$$

where m_i is the number of initially oscillating modes.

Kerr Lens Mode Locking. The use of the nonlinearity of Kerr effect for pulse shortening and mode locking has been investigated theoretically and experimentally for more than two decades.[66] In 1972, Dahlström succeeded in mode locking an Nd:glass laser by means of the optical Kerr effect. However, due to the weak nonlinear response of the devices, this technique was constrained to pulsed systems[66,71,90] because of the high intensities needed to produce a sufficient nonlinearity to couple the axial modes.

A breakthrough for cw pumped passive mode locking of solid lasers was achieved when strong self-phase-modulation[91] was observed in fibers and, subsequently, in Ti:sapphire crystals. The self-focusing effect in the laser rod which leads to a modification of the cavity parameters was analyzed in the Gaussian beam approximation by Salin et al.[16] In some configurations, the self-focusing results in a higher gain for pulsed than for cw operation because of an increasing overlap of the pump gain volume with the cavity mode of the circulating pulse. When observing the beam structure of a Ti:sapphire, we find a high-order transverse mode for cw operation, and a smaller one when the laser is mode locked. If an aperture is inserted to increase loss for cw operation, the laser will eliminate the cw mode and be self-mode-locked. The combination of self-lensing with the aperture acts as intensity-dependent losses, just as does a saturable absorber.

***Ti*:*Sapphire Lasers*.** The large bandwidth of the Ti:sapphire laser has made it one of the most attractive candidates for ultrashort pulse generation. All mode-locking techniques developed for dye lasers have been attempted with this laser: passive mode locking,[92] acousto-optic mode locking,[93,94] injection seeding,[95] additive-pulse mode locking,[78] moving-mirror mode locking,[77] hybrid mode locking,[84] and synchronous pumping.[96,97] Naganuma et al.[98] obtained pulses as short as 50 fs, using the dye HITCI as a saturable absorber in an antiresonant ring. Unidirectional ring operation was also demonstrated.[99]

The simplest configuration, however, to produce a self-mode-locking or Kerr lens mode locking is unique to Ti:sapphire lasers. Spence et al. produced 60 fs pulses with a self-mode-locking laser without any internal mode-locking elements.[100] The label ‘‘Kerr lens mode locking’’ was first applied to a similar cavity configuration,[91] except that an adjustable slit inserted in front of the output coupler ensured additional loss for the cw mode. In this type of laser, the sapphire rod itself is an effective phase modulator through the nonlinearity of its index at high-peak laser intensities. Balance of phase modulation and dispersion led to the generation of pulses shorter than 35 fs by several groups.[101,102,103] The shortest pulse duration obtained, so far, from a Ti:sapphire laser is 11 fs by the group at Washington State University.[103]

The fascinating aspects of self-mode-locking or Kerr lens mode locking are still being actively investigated.[104] Whatever the details of the mechanisms involved, this type of ‘‘self-mode-locked laser,’’ avoiding the need for active or passive mode lockers, has reduced the number of optical elements inside the cavity. Thereby, it reduced the sources of instability, increased the available power, simplified the design and operation, and, most important, reduced the cost.

14.8 OTHER ULTRASHORT PULSE SOURCES

Soliton Laser

We have seen in preceding sections that there are loss mechanisms (saturation, induced lensing) and dispersive mechanisms (phase modulation followed by dispersion) that can contribute to pulse shaping in a laser. If the mechanism of pulse compression by self-phase-modulation and dispersion dominates, the equation of the pulse evolution in the cavity can be shown to reduce to the nonlinear Schrödinger equation. The physical model for the laser is reduced to a succession of infinitesimal phase modulation followed by an infinitesimal dispersion per cavity round-trip.

Under appropriate assumptions, manipulations, and renormalizations, the nonlinear Schrödinger equation takes the form

$$i\frac{\partial \tilde{E}}{\partial z}+\frac{\partial^2 \tilde{E}}{\partial t^2}+|\tilde{E}|^2\,\tilde{E}=0 \tag{24}$$

where z, t, and $\tilde{E}$ are normalized distance, time, and electric field, respectively. The solutions of this equation are described in an article by Zakharov and Shabat.[105]

Numerically, a soliton is an eigenfunction $\tilde{E}$ associated with eigenvalues ζ_i of the coupled differential equations. The order of the soliton is the number of poles associated with that solution. Solitons of order one are stationary solutions, which have a stable secant hyperbolic shape and propagate without distortion. Solitons of order $n > 1$, however, are periodic solutions with n characteristic frequencies.

In a soliton laser, at each round-trip, there is an infinitesimal amount of self-phase-modulation succeeded by an infinitesimal gain. In the development leading to Eq. (24), the gain and losses are assumed to be linear and nullify each other. The same mathematic development leading to the Schrödinger equation also applies to a single mode fiber, at a wavelength of negative dispersion. The physics governing the propagation equation of a short pulse also includes a combination of self-phase-modulation, negative dispersion, and negligible losses. The solitons, solutions of Eq. (24), represent steady-state pulses either circulating in some type of mode-locked laser cavities, or propagating in single-mode fibers.

In the case of fibers, because of their inherent stability, solitons can propagate without distortion over very long distance. If information can be stored and maintained in a particular time sequence of solitons, then solitons may be opening a new era of optical communications.

It is possible to combine the soliton-shaping characteristics of a fiber and a mode-locked laser cavity to produce a soliton laser. The fiber generates a soliton which is fed back into the cavity. Such a soliton laser was invented by Mollenauer in 1984.[13] The laser produced $n = 2$ soliton subpicosecond pulses at infrared wavelength (1.5 μm) for the first time. A polarization preserving fiber with anomalous dispersion is inserted into the feedback loop of a mode-locked laser. This is accomplished by directing part of the intracavity power into the fiber with a beamsplitter and a lens. A lens and a mirror at the other end of the fiber reflect the pulse back toward the cavity. A variable path portion of the feedback loop is required for adjusting the fiber arm to an integral multiple of the main cavity length. The soliton pulse duration can be adjusted from several picoseconds[13] to 50 fs[106] by selecting the length of the generating fiber.

Miniature Dye Lasers

It seems somewhat paradoxical to be using large (of the order of meters) resonators to generate pulses of spatial extension in the micron range. Two methods of short-pulse generation use either an ultrashort cavity (Fabry-Perot dye cells of thickness in the micron range) or no cavity at all (distributed feedback lasers).

Distributed Feedback Lasers. In a linear resonator, the counterpropagating pulses create a standing wave pattern in the gain medium. Stimulated emission can take place only where a stimulating field is present. There is neither emission nor gain depletion at the nodes of the standing wave pattern of the laser. Gain occurs mainly at the antinodes of this pattern. Conversely, if the radiation is produced from a spatial pattern corresponding to such standing waves, it will have the same characteristics as if a cavity were present. In the distributed feedback laser, the inversion (hence the emission) is only *produced* at the antinodes of a standing wave pattern. The wavelength selectivity $\Delta\lambda/\lambda$ is simply the inverse of the number of gain lines in the pattern. The gain pattern is produced by interfering two pump beams in the gain medium. If 1 mm-wide pump beams are used to make a pattern for 600 nm, $\Delta\lambda/\lambda = \Delta\nu/\nu \approx 1/1700$. The bandwidth of this grating is in the THz range, broad enough to support the generation of picosecond pulses.

It seems at first that a coherent source is required to pump such a laser. In principle,

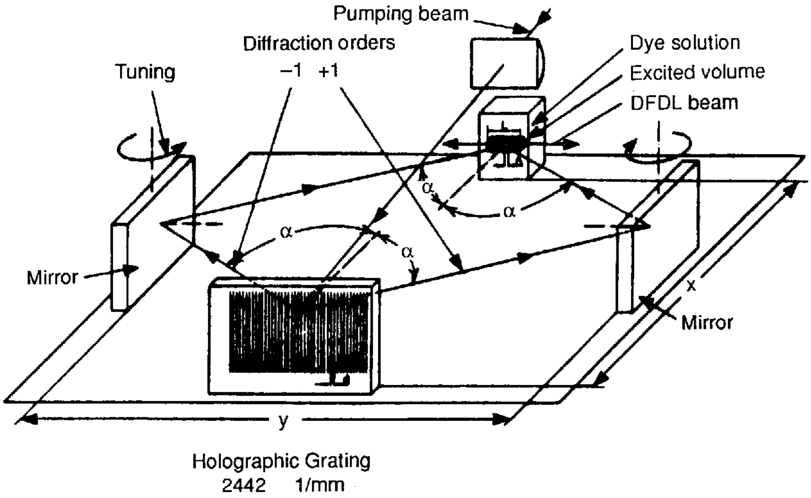

FIGURE 7 Creating an inversion grating with a source of low coherence, using a holographic grating [*courtesy of F. P. Shaefer*].

even white light can be used, if the grating is formed by imaging a holographic grating into the gain medium with the pump radiation. As shown in Fig. 7, in a perfectly symmetric configuration, the pump beam diffracted into the +1 order is made to interfere with the −1 order in a dye cell.[107]

As that laser is being pumped, a series of pulses is generated—each pulse being terminated by gain depletion. There is, however, a range of pump pulse power leading to the generation of only a single pulse, with a duration about 50 times shorter than the pump pulse. Quenching of the emission can eventually be achieved by an additional laser pulse which terminates the gain.[108] A detailed review of various experimental arrangements and applications of picosecond distributed feedback lasers can be found in a publication by Bor and Müller.[109]

Short-Cavity Lasers. Another approach to generate single short pulses is the short-cavity laser. The laser cavity has to be short enough to have a free spectral range exceeding the gain bandwidth. In a typical "short-cavity" laser,[110] the wavelength is tuned by adjusting the thickness of the dye cell within a 3- to 5-μm range with a transducer bending slightly the back mirror of the cavity. With a round-trip time only of the order of 10 femtosecond, it is obvious that the pulse duration will not be longer than that of a picosecond pump pulse. As with the distributed feedback laser, the dynamics of pump depletion can result in pulses shorter than the pump pulses. The basic operational principles of this laser can be found in Ref. 111. Technical details are given in Ref. 110.

Other Techniques

For completeness, we will list several other methods being used for pulse shortening or mode locking.

In 1990, Krausz et al.[112] reported active mode locking of lasers by piezoelectrically induced diffraction modulation. They used a piezoelectric transducer to create standing surface waves on a photo-elastic crystal ($LiNbO_3$). The standing wave causes a diffraction modulation of the light and therefore mode locking of the laser. A detailed discussion of the principles of this technique, which led to the generation of 3.8-ps pulses, can be found in Ref. 113.

In 1991, Turi and Krausz reported a mode-locked laser by regenerative feedback. The conditions to be satisfied can be found in a paper by Hugett,[114] where he referred the feedback scheme as a *regenerative feedback loop.* The natural longitudinal mode beating detected by a photodiode is amplified and used to drive an A-O modulator. In the standard active mode-locking technique, the cavity (round-trip) frequency and the electronic driver for the mode locker are independently stabilized with an accuracy of one part in 10^6. Both frequencies are simply coupled together in the regenerative feedback laser, without the need for thermal stabilization of the cavity or the stabilization of an oscillator. This technique has been successfully implemented to the mode locking of a Ti:sapphire laser.[115]

Another example, which was published in 1992 by Zhang et al.,[116] is to mode lock an Nd:YAG laser with a GaAs crystal. They used a 0.5-mm thick undoped GaAs crystal to mode lock the Nd:YAG laser and produced pulses of 10 ps. The physics is the same as for passive negative feedback discussed earlier, except that the cavity configuration is such that self-defocusing in GaAs leads to a reduction rather than an increase in losses.

14.9 AMPLIFICATION

Amplification of femtosecond pulses to higher energies is traditionally done by using relatively short dye cells transversally pumped by the second or third harmonic of a Q-switched Nd:YAG laser (see, for instance, Fork et al.[117]). A review of dye amplifiers pumped by Nd:YAG, Nd:glass, and excimer lasers can be found in a paper by Knox.[118] Sometimes, the pump module itself can be substituted to the gain dye cell, as for a 248-nm KrF amplifier[119] or the 308-nm XeCl laser.[120,121]

A trend of the last decade is to use amplifiers of higher repetition rate. From the detection point of view, the laser oscillator itself is an ideal stable clock; the pulse train has small amplitude noise at the cavity round-trip frequency, and offers a good reference signal for heterodyne detection. Often, the peak power of the laser is not sufficient for the nonlinear experiments to be performed. One solution is the CW amplification of the laser in a similar gain medium. However, because of the large pump energy required and possible resultant thermal problems, a pulsed source is desired. A cavity-dumped argon laser provides an ideal source to amplify cavity-dumped pulses from a femtosecond dye laser.[122] An elegant structure with four passes through two gain jets was used, resulting in amplification to pulse energies of roughly 10 nJ at 3 MHz.[122]

The next step in compromising repetition rate for gain is made with the introduction of copper vapor laser amplifiers, providing typically microjoule pulses at 10 to 20 kHz. Various types of configurations have been proposed and implemented, starting with an efficient but complex nine-mirror structure,[123] to a series of four-mirror amplifiers in a confocal structure,[124] to a two-mirror 13-pass structure.[125] The first challenge associated with the design of such an amplifier is to maintain a maximum gain without saturating the amplifying transition. In the 13-pass structure just mentioned, the first 11 paths are focused to a small beam waist in the gain medium: this amplifier is intentionally operating at saturation for the last few passes in order to reduce its sensitivity to fluctuations of the input. The beam is sent back for two more passes through the center of the 2-mm-diameter amplifying cell, providing unsaturated amplification to 15 μJ. In amplifiers, thermal fluctuations associated with flow turbulence cause random beam deflection and lensing. This technical difficulty, which is particularly severe with high-repetition-rate amplifiers, can be solved in the case of water soluble amplifying dyes. No observable fluctuation of the pulse output power is observed with an aqueous gain dye solution cooled down to 4°C (or 11.7°C if the solvent is heavy water) at which the thermal index change dn/dT reaches zero.[125]

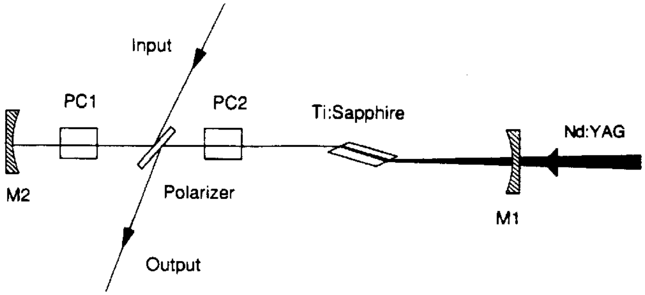

FIGURE 8 Regenerative Ti:sapphire amplifier pumped by a Nd:YAG laser, *Pc*s are Pockel cells and *P* is a polarizer beam splitter (*from Ref. 113*).

The low-repetition-rate amplifier chain has seen dramatic reduction in size and cost and increase in output energy, thanks to the method of chirped pulse amplification.[126] The principle of this method is to stretch the pulse to be amplified by a *linear, reversible* method in order to prevent catastrophic nonlinear effects due to the high peak powers. Martinez[127] has shown that a combination of gratings can chirp and broaden a pulse by as much as 3000 times. A pair of lenses added to the pair of gratings can have the effect of a *negative* distance *l,* hence have the opposite group velocity dispersion, and restore the original pulse duration.[128] Contrary to the particular high-repetition-rate amplifiers cited above, it is essential in this technique to have *linear* amplification in order to be able to reconstruct the original pulse duration. The method has been applied to stretch 50-ps pulses to 1 ns, amplify to 2 mJ, and recompress to 1 ps.[129] More recently, peak powers of 20 TW have been achieved through the chirped pulse amplification.[130]

The method of chirped pulse amplification is also being used to amplify femtosecond pulses from Ti:sapphire lasers. A particularly efficient system is the regenerative amplifier configuration,[131] in which a Q-switched Nd:YAG pumps a Ti:sapphire rod. The femtosecond pulse to be amplified is successively injected and extracted after several tens of roundtrips through the control of the two Pockel cells (Fig. 8).

14.10 DIAGNOSTIC TECHNIQUES

The femtosecond time scale is beyond the range of standard electronic display instruments. Many new methods have been designed to measure the duration, shape, and modulation of repetitive pulses as well as a single pulse. The subject of ultrashort pulse-shape measurement is far beyond the scope of this chapter. Only a brief overview of some of the techniques is presented in this section.

Correlations

Intensity Autocorrelation. The intensity autocorrelation is generally used to quote a "pulse duration." The standard procedure is to *assume* a pulse shape (generally a secant hyperbolic square or a gaussian shape), and to "determine" the pulse duration from the known ratio between the full width at half maximum (FWHM) of the autocorrelation and that of the pulse. A table in Ref. 21 lists these ratios for a variety of simple pulse shapes.

If a shorter pulse of known shape $I_r(t)$ is available, the temporal profile $I_s(t)$ of an optical signal can be easily determined. The method is to measure the intensity cross-correlation of the two signals:

$$A_c(\tau) = \int_{-\infty}^{+\infty} I_s(t) I_r(t - \tau)\, dt \tag{25}$$

In the ideal limit where the reference can be assimilated to a delta function, the shape of the correlation $A_c(\tau)$ is identical to that of the signal $I_s(t)$. In general, as long as the shorter pulse shape is known, the shape of the signal $I_s(t)$ can be extracted from the measurement of $A_c(\tau)$ through manipulations of Fourier transforms. Even in that ideal case of $I_r(t) \approx \delta(t)$, the intensity cross-correlation has a grave limitation: it does not provide any information on the phase content (frequency or phase modulation) of the pulse being analyzed.

A reference pulse much shorter than the signal cannot always be generated. In the ideal cases where such a pulse is available, a technique to determine the shape of that reference signal is still needed. It is therefore important to consider the limit where the signal itself has to be used as a reference. Equation (25) with $I_s(t) = I_r(t) = I(t)$ is called an *intensity autocorrelation.* An autocorrelation is always a symmetric function—this property can be understood from a comparison of the overlap integral for positive and negative arguments τ. The Fourier transform of the autocorrelation is a real function, consistent with a symmetric function in the time domain. As a result, the intensity autocorrelation provides only very little information on the pulse shape, since an infinite number of asymmetric pulse shapes can have the same autocorrelation. Nevertheless, the intensity autocorrelation is the most widely used diagnostic technique, because it can be easily implemented, and is the first tool used to determine whether a laser is producing short pulses rather than intensity fluctuations of a continuous background. A detailed discussion of the various signal "signatures" provided by the autocorrelations is given in Refs. 21 and 132.

An example of a simple second-order autocorrelator is sketched in Fig. 9. The beams to be correlated are cross-polarized, and combined with a polarizing beamsplitter. An optical delay is used to adjust the delay of the reference signal $I_r(t - \tau)$. The cross-polarized beams (polarization directions x and y) are sent into a nonlinear crystal which is cut for type II phase matched second harmonic generation. The second harmonic field is proportional to the product of the fundamental fields along each axis x and y. Design parameters for optical correlators (crystal thickness and optical components) can be found in Ref. 4.

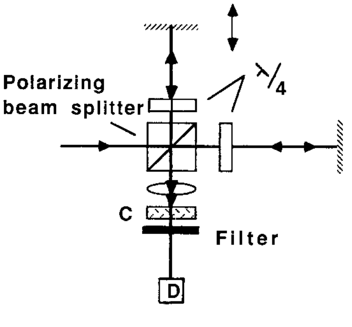

FIGURE 9 Basic intensity autocorrelator, using second harmonic type II detection.

Interferometric Correlations. With the polarizing beamsplitter replaced by a standard beamsplitter, the quarter-wave plates eliminated, and a type I phase matching crystal instead of the type II, the instrument sketched in Fig. 9 records an interferometric autocorrelation. It is essentially a Michelson interferometer in which second harmonic detection has been substituted to the standard detection. The main difference with the intensity autocorrelation is that the interferometric correlation is sensitive to phase modulation.

Instead of Eq. (25), the detected signal is now a second-order interferometric correlation, proportional to the function:

$$G_2(\tau) = \int_{-\infty}^{\infty} \{|E(t-\tau) + E(t)|^2\}^2 \, dt$$
$$= A(\tau) + B(\tau)\cos(\omega\tau) + C(\tau)\cos(2\omega\tau) \qquad (26)$$

If we average out the fast oscillation terms, we measure only the d.c. term $A(\tau)$. At $\tau = 0$, the peak value of the function $A(\tau)$ is $6 \int \mathscr{E}^4(t)\, dt$, where $\mathscr{E}(t)$ is the amplitude of $E(t)$. For delays larger than the pulse duration, the cross-product vanishes, leaving a background of $2 \int \mathscr{E}^4 \, dt$. The $A(\tau)$ term which is in fact an intensity autocorrelation has thus a peak-to-background ratio of 3 to 1.

When all terms of the autocorrelation are recorded, the constructive interference terms at zero delay add up to $16 \int \mathscr{E}^4(t)\, dt$. The peak-to-background ratio for the interferometric autocorrelation is thus 8 to 1.

As is any autocorrelation, the interferometric autocorrelation is a symmetric function. However, as opposed to the intensity autocorrelation, it contains phase information. There are three different ways to exploit the shape and phase sensitivity of the interferometric autocorrelation:

1. As a *qualitative* test of the absence or presence of phase modulation and, eventually, a determination of the type of modulation
2. As a quantitative measure of *linear* chirp
3. In combination with the pulse spectrum, to determine the pulse shape and phase by fitting procedures

There are various patterns or "signatures" for different types of chirp. For instance, the lower and upper envelopes of the interference pattern split evenly from the background level in the case of an unchirped pulse. In the case of a linearly chirped pulse, the interference pattern is much narrower than the pulse-intensity autocorrelation.[21] With increasing delay, the upper and lower envelopes of the interferometric autocorrelation merge to coincide with the intensity autocorrelation (for delays exceeding the coherence time of the pulse, the terms B and C of Eq. (26) average to zero, leaving only the term A, which is the intensity autocorrelation). The level at which the interference pattern starts can be used as a measure of the chirp.[21]

Single-Shot Technique. A prism can tilt the energy front of a pulse with respect to the wavefront. Szabo et al.[133] have exploited this property to provide a variable delay along a transverse coordinate of the beam. The single-shot interferometric autocorrelator has an advantage over the scanning version used in regular correlators, because the spacing of the fringes is controlled by the tilt of one of the mirrors of the interferometer. It is therefore possible to compromise accuracy and volume of data acquisition.

Iterative Fitting. Since the autocorrelations are symmetric and do not provide any information about the pulse asymmetry, an additional measurement is required to determine the signal shape. The pulse spectrum can provide the additional information. Simple pulse shapes can be fitted to the autocorrelations and pulse spectra. As a guide to such fitting procedures, analytical expressions have been derived for three functions for standard symmetric and nonsymmetric pulse shapes.[21] These functions have been used to tabulate characteristic quantities such as the duration-bandwidth product, and the ratio of the FWHM of the intensity autocorrelation to the pulse duration.

For the cases of complex pulse shapes, a systematic fitting algorithm has been developed by Naganuma et al.[34] which converges to the final signal amplitude and phase function without any a priori knowledge of the pulse parameters.

Pulse Amplitude and Phase Reconstruction

We have already introduced in the previous sections the method of iterative fitting of the interferometric autocorrelations and pulse spectra.[21,134] Numerous other methods have been proposed and implemented. For the sake of conciseness and clarity, we will present only a few examples in this section.

As mentioned earlier, a cross-correlation between a short pulse and a longer one is an approximation of the shape of the latter. Several techniques provide the pulse shape and phase by stretching or compressing the pulse of one arm of the autocorrelator, hence transforming it into a cross-correlator.

For instance, the symmetry of an autocorrelator is broken by insertion of a block of glass in one of its arms. A downchirped pulse is compressed by propagation through glass.[21] As the delay is being scanned, the measured-intensity cross-correlation is an approximation of the pulse-intensity profile. From the interferometric cross-correlation, we can easily extract phase information. Indeed, the depth of modulation of the interference pattern is a measure of the frequency offset of the probing (compressed) femtosecond pulse, as compared to the portion of the pulse being probed.

The pulse is completely determined by the measurement of the intensity and interferometric cross-correlation. The same technique applied to unchirped or upchirped pulses will determine the amplitude and phase of the pulse broadened through quadratic dispersion in glass. But, since the dispersion properties of the glass are known, the shape of the original shorter pulse can be calculated from the amplitude and phase of the broadened one. A detailed analysis of this method can be found in Ref. 135.

Methods of higher nonlinearity have been developed recently such as fringe resolved optical gating,[136] where the spectrum of a gated signal is recorded. Research is still in progress on methods of low nonlinearity, applicable to weak fs pulses.[137,138]

PART 5

OPTICAL DETECTORS

CHAPTER 15
PHOTODETECTORS

Paul R. Norton
Santa Barbara Research Center
Santa Barbara, California

Revised and updated from article by **Stephen F. Jacobs***

15.1 SCOPE

The purpose of this chapter is to describe the range of detectors commercially available for sensing optical radiation. Optical radiation over the range from vacuum ultraviolet to the far-infrared or submillimeter wavelength (25 nm to 1000 μm) is considered. We will refer to the following spectral ranges:

25–200 nm	vacuum ultraviolet	VUV
200–400 nm	ultraviolet	UV
400–700 nm	visible	VIS
700–1000 nm	near-infrared	NIR
1–3 μm	short-wavelength infrared	SWIR
3–5 μm	medium-wavelength infrared	MWIR
5–14 μm	long-wavelength infrared	LWIR
14–30 μm	very long wavelength infrared	VLWIR
30–100 μm	far-infrared	FIR
100–1000 μm	submillimeter	SubMM

We begin by giving a brief description of the photoesensitive mechanism for each type of detector. The usefulness and limitations of each detector type are also briefly described. Definitions of the technical terms associated with the detection process are listed. The concept of sensitivity is defined, and D-star (D^*) is presented as a measure of ideal performance. Examples are then given of the limiting cases for D^* under several conditions. In addition, other detector performance parameters are described which may be of critical interest in a specific application, including spectral response, responsivity, quantum efficiency, noise, uniformity, speed, and stability. Finally, manufacturers' specifications for a range of available detectors are compiled and a list of manufacturers is included for each type of detector.

The sensitivity of many detectors has reached the limit set by room-temperature background photon fluctuations (radiation shot noise). For these detectors, sensitivity may be enhanced by providing additional cooling, while restricting their spatial field of view and/or spectral bandwidth. At some point, other factors such as amplifier noise may limit the improvement.

* In *Handbook of Optics,* first edition, McGraw-Hill, 1978. Section 4, "Nonimaging Detectors," by Stephen F. Jacobs, Optical Sciences Center, University of Arizona, Tucson, Arizona.

Techniques for evaluating detector performance are not covered in this treatment but can be found in references (Wolfe, 1965; IRE, 1962; RCA, 1963; Vincent, 1989; Dereniak, 1984; *The Infrared and Electro-Optical Systems Handbook,* vol. 3, 1993).

15.2 THERMAL DETECTORS

Thermal detectors sense the change in temperature produced by absorption of incident radiation. Their spectral response can therefore be as flat as the absorption spectrum of their blackened coating and window* will allow. This makes them useful for spectroscopy and radiometry. These detectors are generally operated at room temperature, where their sensitivity is limited by thermodynamic considerations (Jones, 1949; Bauer, 1943) to 3 pW for 1-s measurement time and 1-mm^2 sensitive area. This limit has been very nearly reached in practice, whereas cooled bolometers have been made to reach the background photon noise limit.

Construction of the detector seeks to minimize both the thermal mass of the sensitive element and the heat loss from either conductive or convective mechanisms. Heat loss may ideally be dominated by radiation. This allows the incident photon flux to give a maximum temperature rise (maximum signal), but results in a correspondingly slow response time for this class of detectors. The response time τ of thermal detectors is generally slower than 1 ms, depending on thermal capacity K and heat loss per second per degree V, through the relation

$$\tau = \frac{K}{V}$$

A short time constant requires a small K. However, for room-temperature operation, ultimate sensitivity is limited by the mean spontaneous temperature fluctuation

$$\Delta T = T\sqrt{\frac{k}{K}}$$

where k is Boltzmann's constant. There is thus a tradeoff between time constant and ultimate sensitivity.

Thermocouple / Thermopile

The thermocouple receiver is a thin, blackened flake connected thermally to the junction of two dissimilar metals or semiconductors. Heat absorbed by the flake causes a temperature rise of the junction, and hence a thermoelectric emf is developed which can be measured, for example, with a voltmeter.

Thermocouples are limited in sensitivity by thermal (Johnson-Nyquist) noise but are nevertheless respectably sensitive. Their usefulness lies in the convenience of room-temperature operation, wide spectral response, and their rugged construction. Thermocouples are widely used in spectroscopy.

Thermopiles consist of thin-film arrays of thermocouples in series. This device multiplies the thermocouple signal corresponding to the number of junctions in series. The device may be constructed with half the thermocouples acting as reference detectors attached to a heat sink.

* No windows exist without absorption bands somewhere between the visible and millimeter region. Some useful window materials for the far-infrared are diamond, silicon, polyethylene, quartz, and CsI.

Bolometer/Thermistor

The receiver is a thin, blackened slab whose impedance is highly temperature dependent. The impedance change may be sensed using a bridge circuit with a reference element in the series or parallel arm. Alternatively, a single bolometer element in series with a load and voltage source may be used.

Most bolometers in use today are of the thermistor type made from oxides of manganese, cobalt, or nickel. Their sensitivity closely approaches that of the thermocouple for frequencies higher than 25 Hz. At lower frequencies there may be excess or $1/f$ noise. Construction can be very rugged for systems applications. Some extremely sensitive low-temperature semiconductor bolometers are available commercially.

Pyroelectric

Ferroelectric material exhibits a residual polarization in the absence of any electric field. Dipole moments, initially aligned by applying an external field, result in a surface charge which is normally slowly neutralized by leakage. This polarization is temperature-dependent (pyroelectric effect), and when a pulse of incident radiation heats a portion of an electroded sample, there is a change in surface charge (open-circuit voltage) which is proportional to the incident radiation power. Electrically, the device behaves like a capacitor, requiring no bias and therefore exhibiting no current noise. The signal, however, must be chopped or modulated. Sensitivity is limited either by amplifier noise or by loss-tangent noise. Response speed can be engineered, with a proportional decrease in sensitivity, making pyroelectric detectors useful for moderately fast laser pulse detection. Other common applications include power meters. Microphonic noise in applications associated with vibrations can be a problem with some of these devices.

15.3 QUANTUM DETECTORS

Photon detectors respond in proportion to incident photon rates rather than to photon energies (heat). Thus, the spectral response of an ideal photon detector is flat on an incident-photon-rate basis but linearly rising with wavelength on an incident-power (per watt) basis. The sensitivity of efficient quantum detectors can approach the limits of photon noise fluctuations provided that the detector temperature is sufficiently low for photon-induced mechanisms to dominate thermally induced mechanisms in the detector. Quantum detectors generally have submicrosecond time constants. Their main disadvantage is the associated cooling required for optimum sensitivity. (These remarks do not apply to photographic detection, which measures cumulative photon numbers.)

Photoemissive

The radiation is absorbed by a photosensitive surface which usually contains alkali metals (cesium, sodium, or potassium). Incident quanta release photoelectrons, via the photoelectric effect, which are collected by a positively biased anode. This is called a diode phototube; it can be made the basis for the multiplier phototube (photomultiplier phototube, or photomultiplier) by the addition of a series of biased dynodes which serve as secondary emission multipliers.

In spectral regions where quantum efficiency is high ($\lambda < 550$ nm), the photoemissive detector is very nearly ideal. Sensitivity is high enough to count individual photons. Amplification does not degrade the signal-to-noise ratio. The sensitive area is conveniently large. Photomultiplier signal response time (transit spread time) can be made as short as 0.1 ns. Since the sensitivity in red-sensitive tubes is limited by thermally generated electrons, sensitivity can be improved by cooling.

Photoconductive

The radiation is absorbed by a photoconductive material, generally a semiconductor, either in thin-film or bulk form. Each incident quantum may release an electron-hole pair or an impurity-bound charge carrier, thereby increasing the electrical conductivity. The devices are operated in series with a bias voltage and load resistor. Very low impedance photoconductors may be operated with a transformer as the load. Since the impedance of photoconductors varies with device type and operating conditions from less than 50 ohms to more than 10^{14} ohms, the load resistor and preamplifier must be chosen appropriately. Photoconductors which utilize excitation of an electron from the valence to conduction band are called *intrinsic* detectors. Those which operate by exciting electrons into the conduction band or holes into the valence band from an impurity-bound state are called *extrinsic* detectors. Intrinsic detectors are most common at the short wavelengths, out to about 20 μm. Extrinsic detectors are most common at longer wavelengths. A key difference between intrinsic and extrinsic detectors is that intrinsic detectors do not require as much cooling to achieve high sensitivity at a given spectral response cutoff as extrinsic detectors. Thus, intrinsic photoconductors such as HgCdTe will operate out to 15 to 20 μm at 77 K, while comparable extrinsic detectors with similar cutoff must be cooled below 30 to 40 K.

A further distinction may be made by whether the semiconductor material has a direct or indirect bandgap. This difference shows up near the long-wavelength limit of the spectral response where detectors made from direct bandgap materials such as InGaAs, InSb, or HgCdTe have a sharper spectral cutoff than indirect bandgap materials such as silicon and germanium.

Photoconductors can have high quantum efficiency from the visible region out to the far-infrared but lack the nearly ideal high amplification of photomultipliers. They are therefore most commonly used in the spectral region beyond 1 μm, where efficient photoemitters are unavailable. Photoconductors do, however, provide current gain which is equal to the recombination time divided by the majority-carrier transit time. This current gain leads to higher responsivity than is possible with (nonavalanching) photovoltaic detectors. For applications where photovoltaic detection would be amplifier-noise-limited, the larger photoconductive responsivity makes it possible to realize greater sensitivity with the photoconductor. In general, lower-temperature operation is associated with longer-wavelength sensitivity in order to suppress noise due to thermally induced transitions between close-lying energy levels. Ideally, photoconductors are limited by generation-recombination noise in the photon-generated carriers. Response time can be shorter than 1 μs and in some cases response times can be shorter than 1 ns for small elements. Response across a photoconductive element can be nonuniform due to recombination mechanisms at the electrical contacts, and this effect may vary with electrical bias.

Photovoltaic*

The most widely used photovoltaic detector is the *pn* junction type, where a strong internal electric field exists across the junction even in the absence of radiation. Photons incident

* The use of a photovoltaic detector at other than zero bias is often referred to as its *photoconductive mode* of operation because the circuit then is similar to the standard photoconductor circuit. This terminology is confusing with regard to detection mechanism and will not be used here.

on the junction of this film or bulk material produce free hole-electron pairs which are separated by the internal electric field, causing a change in voltage across the open-circuited cell or a current to flow in the short-circuited case.

As with the photoconductor, quantum efficiency can be high from the visible to the very long wavelength infrared, generally about 20 μm. The limiting noise level can ideally be $\sqrt{2}$ times lower than that of the photoconductor, thanks to the absence of recombination noise. Lower temperatures are associated with longer-wavelength operation. Response times can be less than a nanosecond, and are generally limited by device capacitance. The *pin* diode has been developed to minimize capacitance for high-bandwidth applications. The advantages of nearly ideal internal amplification have now become available in avalanche photodiodes sensitive out to 1.55 μm. This internal gain is most important for high-frequency operation, where external load resistance must be kept small and would otherwise introduce limiting thermal noise.

Photoelectromagnetic

A thin slab of photoconductive material is oriented with radiation incident on a large face and a magnetic field perpendicular to it. Electron-hole pairs generated by the incident photons diffuse through the material and are separated by the magnetic field, causing a potential difference at opposite ends of the detector.

These detectors require no cooling or biasing electric field but do require a (permanent) magnetic field. Photoelectromagnetic InSb at room temperature has response out to 7.5 μm, where it is as sensitive as a thermocouple of equal size, and has a response time less than 1 μs. Another competing uncooled detector is InAs, which is far more sensitive out to 3.5 μm. Cooled infrared detectors are one to two orders of magnitude more sensitive.

Photographic

The receiver is an emulsion containing silver halide crystals. Incident photons are absorbed by the halide ion, which subsequently loses its electron. This electron eventually recombines with a silver ion and reduces it to a neutral silver atom. As more photons are absorbed, this process is repeated until a small but stable cluster of reduced silver atoms is formed within the crystal (latent image). Internal amplification is provided by introduction of an electron donor (photographic) developer, which, using the latent image as a catalytic center, reduces to silver all the remaining silver ions within the exposed crystal. The density of reduced crystals is a measure of the total radiation exposure.

The spectral region of sensitivity for photographic detection coincides rather closely with that of the photoemissive detector. For $\lambda > 1.2$ μm there is too little energy in each photon to form a stable latent image. The basic detection process for both detectors operates well for higher frequency radiation. The problem in ultraviolet and x-ray operation is one of eliminating nonessential materials, e.g., the emulsion which absorbs these wavelengths.

The photographic process is an integrating one in that the output (emulsion density) measures the cumulative effect of all the radiation incident during the exposure time. The efficiency of the photographic process can be very high, but it depends upon photon energy; e.g., in the visible region it takes only 10 to 100 photons to form a stable latent image (developable grain). The photographic process enjoys a large and efficient internal amplification ability (development) wherein the very small energy of the photons' interaction is converted into readily observed macroscopic changes. An extensive discussion of photographic detection is found in Chapter 20, Photographic Films, in Vol. I of this Handbook.

Photoionization

The radiation is absorbed by a gas. If the photon energy exceeds the gas-ionization threshold, ion pairs can be produced with very high efficiency. They are collected by means of an applied voltage. Operating in a dc mode, these detectors are known as *ionization* and *gas-gain chambers.* When a pulse mode is used, the detectors are known as *proportional* and *photon* (*Geiger*) *counters.*

Photoionization detectors have a high sensitivity and a low noise level. They may also be quite selective spectrally since the choice of window and gas independently set upper and lower limits on detectable photon energies. Manufacturers' specifications are not discussed for these detectors as applications are still few enough to be treated as individual cases (Samson, 1967).

15.4 DEFINITIONS

The following definitions will be used:

Background temperature The effective temperature of all radiation sources viewed by the detector exclusive of the signal source.

Blackbody D star, D^*_{BB} (cm Hz$^{1/2}$/W) Similar to $D^*(\lambda)$ or $D^*(T_B f)$ except that the source is a blackbody whose temperature must be specified.

Blackbody detectivity D_{BB} (W^{-1}) A measure of detector sensitivity, defined as $D_{\text{BB}} = (\text{NEP}_{\text{BB}})^{-1}$.

Blackbody noise-equivalent power NEP_{BB} Same as spectral NEP, except that the source has blackbody spectral character whose temperature must be specified, for example, NEP (500 K, 1, 800) means 500-K blackbody radiation incident, 1-Hz electrical bandwidth, and 800-Hz chopping frequency.

Blackbody responsivity R_{BB} Same as spectral sensitivity except that the incident signal radiation has a blackbody spectrum (whose temperature must be specified).

Blip detector or *blip condition* Originally meaning background-limited impurity photoconductor, this term has come to mean performance of any detector where the limiting noise is due to fluctuations in the arrival rate of background photons.

Cutoff wavelength λ_c The wavelength at which the detectivity has degraded to one-half its peak value.

Dark current The output current which flows even when input radiation is absent or negligible. (Note that although this current can be subtracted out for the dc measurements, the shot noise on the dark current can become the limiting noise.)

Detective quantum efficiency The square of the ratio of measured detectivity to the theoretical limit of detectivity.

Detective time constant τ_d $\tau_d = 1/2\pi f_d$ where f_d is the frequency at which D^* drops to 0.707 times its maximum value.

Dewar A container (cryostat) for holding detector coolant.

Equivalent noise input (ENI) A term meaning nearly the same thing as NEP_{BB} (287 K, 1, f). The difference is that the peak-to-peak value of square-wave chopped input flux is used, rather than the rms value of the sinusoidally chopped input flux. (See recommendation IRE, 1962.)

Excess noise A term usually referring to noises other than generation-recombination, shot, or thermal.

Extrinsic semiconductor transition Incident photons produce a free electron in the conduction band and bound hole at a donor impurity site or a bound electron at an acceptor impurity site and a free hole in the valence band by excitation of an impurity level.

Field of view (FOV) The solid angle from which the detector receives radiation.

Flicker noise See *Modulation noise.*

Generation noise Noise produced by the statistical fluctuation in the rate of production of photoelectrons.

Generation-recombination (GR) *noise* Charge carriers are generated both by (optical) photons and (thermal) photons. Fluctuations in these generation rates cause noise; fluctuations in carrier-recombination times cause recombination noise. The phonon contribution can be removed by cooling. The remaining photon contribution is indistinguishable from radiation shot noise (photon noise). With photovoltaic *pn* junctions, carriers are swept away before recombination, so that recombination noise is absent.

Guard ring An electrically biased field plate or surrounding diode used in some photodiodes, usually used to control surface recombination effects and thus reduce the leakage current in the detection circuit.

Intrinsic semiconductor transition Incident photons produce a free electron-free hole pair by direct excitation across the forbidden energy gap (valence to conduction band).

Johnson noise Same as thermal noise.

Jones Unit of measure for D^* cm Hz$^{1/2}$/W.

Maximized D star, $D^*(\lambda_{\mathrm{pk}} f_o)$, cm Hz$^{1/2}$/W The value of $D^*(\lambda_{\mathrm{pk}}, f)$ corresponding to wavelength λ_{pk} and chopping frequency of maximum D^*.

Modulation (or $1/f$) *noise* A consensus regarding the origin(s) of the mechanism has not been established, and although a quantum theory has been proposed, other mechanisms may dominate. As its name implies, it is characterized by a $1/f^n$ noise power spectrum, where $0.8 < n < 2$. This type of noise is prominent in thermal detectors and may dominate the low-frequency noise characteristics of photoconductive and photovoltaic quantum detectors as well as other electronic devices such as transistors and resistors.

Multiplier phototube or *multiplier photodiode* Phototube with built-in amplification via secondary emission from electrically biased dynodes.

NEI photons/cm^{2}sec noise equivalent irradiance is the signal flux level at which the signal produces the same output as the noise present in the detector. This unit is useful because it directly gives the photon flux above which the detector will be photon-noise-limited. See also *Spectral noise equivalent power* (NEP$_\lambda$).

Noise spectrum The electrical power spectral density of the noise.

Nyquist noise Same as thermal noise.

Photo cell See *Photodiode.*

Photoconductive gain The ratio between carrier lifetime and carrier transit time in a biased photoconductor.

Photodiode The term photodiode has been applied both to vacuum- or gas-filled photoemissive detectors (diode phototubes, or photo cells) and to photovoltaic detectors (semiconductor *pn* junction devices).

Photomultiplier Same as multiplier phototube.

Photon counting Digital counting of individual photoelectrons in contrast to averaging of the photocurrent. This technique leads to very great sensitivity but can be used only for extremely low light levels.

Quantum efficiency The ratio of the number of countable output events to the number of incident photons, e.g., photoelectrons per photon, usually referred to as a percentage value.

Rms noise $V_{n,\mathrm{rms}}$ That component of the electrical output which is not coherent with the radiation signal. (Generally measured with the signal radiation removed.)

Rms signal $V_{s,\mathrm{rms}}$ That component of the electrical output which is coherent with the input signal radiation.

Response time τ Same as *Time constant.*

Responsive quantum efficiency See *Quantum efficiency.*

Sensitivity Degree to which detector can sense small amounts of radiation.

Shot noise This current fluctuation results from the random arrival of charge carriers, as in a photodiode. Its magnitude is set by the size of the unit charge.

$$i_{n,\mathrm{ms}} = (2ei_{\mathrm{dc}}\Delta f)^{1/2}$$

Spectral D double star $D^{**}(\lambda, f)$ A normalization of D^* to account for detector field of view. It is used only when the detector is background-noise-limited. If the FOV is 2π sr, $D^{**} = D^*$.

Spectral D star $D^*(\lambda, f)$ (cm Hz$^{1/2}$/W) A normalization of spectral detectivity to take into account the area and electrical bandwidth dependence, e.g., $D^*(1\ \mu\mathrm{m}, 800\ \mathrm{Hz})$ means D^* at $\lambda = 1\ \mu$m and chopping frequency 800 Hz; unit area and electrical bandwidth are implied. For background-noise-limited detectors the FOV and the background characteristics must be specified. For many types of detectors this normalization is not valid, so that care should be exercised in using D^*.

Spectral detectivity $D(\lambda)$ (W^{-1}) A measure of detector sensitivity, defined as $D(\lambda) = (\mathrm{NEP}_\lambda)^{-1}$. As with NEP, the chopping frequency electrical bandwidth, sensitive area, and, sometimes, background characteristics should be specified.

Spectral noise equivalent power NEP_λ The rms value of sinusoidally modulated monochromatic radiant power incident upon a detector which gives rise to an rms signal voltage equal to the rms noise voltage from the detector in a 1-Hz bandwidth. The chopping frequency, electrical bandwidth, detector area, and, sometimes, the background for characteristics should be specified. NEP (1 μm, 800 Hz) means noise equivalent power at 1 μm wavelength, 1 Hz electrical bandwidth, and 800 Hz chopping rate. Specification of electrical bandwidth is often simplified by expressing NEP in units of W/Hz$^{1/2}$.

Spectral responsivity $R(\lambda)$ The ratio between rms signal output (voltage or current) and the rms value of the monochromatic incident signal power. This is usually determined by taking the ratio between a sample detector and a thermocouple detector.

Temperature noise Fluctuations in the temperature of the sensitive element, due either to radiative exchange with the background or conductive exchange with a heat sink, produce a fluctuation in signal voltage. For thermal detectors, if the temperature noise is due to the former, the detector is said to be at its theoretical limit. For thermal detectors

$$\overline{(\Delta T)^2} = \frac{4kT^2K\Delta f}{K^2 + 4\pi^2 f^2 C^2}$$

where $\overline{(\Delta T)^2}$ = mean square temperature fluctuations
K = thermal conductance
C = heat capacity

Thermal noise (also known as *Johnson* or *Nyquist noise*) Noise due to the random motion of charge carriers in a resistive element

$$V_{n,\mathrm{rms}} = (4kTR\Delta f)^{1/2} \qquad k = \text{Boltzmann's constant}$$

Thermopile A number of thermocouples mounted in series in such a way that their thermojunctions lie adjacent to one another in the plane of irradiation.

Time constant τ A measure of the detector's speed of response. $\tau = 1/2\pi f_c$, where f_c is that chopping frequency at which the responsivity has fallen to 0.707 of its maximum value:

$$\mathscr{R}(f) = \frac{\mathscr{R}_0}{(1 + 4\pi^2 f^2 r^2)^{1/2}}$$

15.5 DETECTOR PERFORMANCE AND SENSITIVITY

D*

A figure of merit defined by Jones in 1958 is used to compare the sensitivity of detectors. It is called D^*. Although the units of measure are cm Hz$^{1/2}$/W, this unit is now referred to as a *Jones.* D^* is the signal-to-noise (S/N) ratio of a detector measured under specified test conditions, referenced to a 1-Hz bandwidth and normalized by the square root of the detector area in centimeters. Specified test conditions usually consist of the blackbody signal source temperature, often 500 K for infrared detectors, and the signal chopping frequency. If the background temperature is other than room temperature (295 or 300 K in round numbers), then that should be noted.

By normalizing the measured S/N ratio by the square root of the detector area, the D^* figure of merit recognizes that the statistical fluctuations of the background photon flux incident on the detector (photon noise) are dependent upon the square root of the number of photons and thus increase as the square root of the detector area, while the signal will increase in proportion to the detector area itself. This figure of merit therefore provides a valid comparison of detector types which may have been made and tested in different sizes.

The ultimate limit in S/N ratio for any radiation power detector is set by the statistical fluctuation in photon arrival times. For ideal detectors which are photon-noise-limited, we shall discuss limiting detectivity for three cases:

1. Photon detector where arrival rate of signal photons far exceeds that of background photons (all other noise being negligible)
2. Photon detector where background photon arrival rate exceeds signal photon rate (all other noise being negligible)
3. Thermal detector, background limited

The rate of signal-carrier generation is

$$n = \eta \mathrm{AN}_s \tag{1}$$

where η = detector quantum efficiency, and AN_s = average rate of arrival of signal photons.

It can be shown (Fink, 1940) that in a bandwidth Δf, the rms fluctuation in carrier-generation rate is

$$\delta n_{\mathrm{rms}} = (2P_N \Delta f)^{1/2} \tag{2}$$

where P_N is the frequency dependence of the mean square fluctuations in the rate of carrier generation, i.e.,

$$P_N = A \int_{\nu 0}^{\infty} \eta(\nu)(\Delta N)^2 \, d\nu \tag{3}$$

where $(\Delta N)^2$ is the mean square deviation in the total rate of photon arrivals per unit area and frequency interval including signal and background photons. For thermally produced photons of frequency ν (see Smith et al., 1957)

$$(\Delta N)^2 = \bar{N} \frac{e^{h\nu/kT}}{e^{h\nu/kT} - 1} = \frac{2\pi\nu^2}{c^2} \frac{e^{h\nu/kT}}{(e^{h\nu/kT} - 1)^2} \tag{4}$$

where $\bar{N}$ is the average rate of photon arrivals per unit area and frequency interval. Then, for the special case $h\nu \gg kT$

$$\delta n_{\text{rms}} = (2A\eta\bar{N}\Delta f)^{1/2} \tag{5}$$

This is also the case for a laser well above threshold. Here the photon statistics become Poisson, and $(\Delta N)^2 = \bar{N}$ even when $h\nu$ is not greater than kT.

***Photon Detector*, *Strong-signal Case*.** This is generally a good approximation for visible and higher photon energy detectors since the background radiation is often weak or negligible. When signal photons arrive at a much faster rate than background photons

$$\delta n_{\text{rms}} \approx (2A\eta\bar{N}_s\Delta f)^{1/2} \tag{6}$$

then

$$\text{NEP} = \frac{N_s A h\nu}{(n/\delta n_{\text{rms}})(\Delta f)^{1/2}} = \left(\frac{2N_s A}{\eta}\right)^{1/2} h\nu \tag{7}$$

or the noise-equivalent quantum rate is

$$\text{NEQ} = \left(\frac{2 \times \text{incident photon rate}}{\text{quantum efficiency}}\right)^{1/2} \tag{8}$$

***Photon Detector*, *Background-limited Case*.** This is usually a good approximation for detecting low signal levels in the infrared where background flux levels exceed signal flux levels in many applications. When the background photon rate N_B, exceeds the signal photon rate $(N_B \gg N_s)$

$$\delta n_{\text{rms}} \approx (2A\eta\bar{N}_B\,\Delta f)^{1/2} \tag{9}$$

the noise-equivalent power is

$$\text{NEP} = \frac{N_s A h\nu}{(n/\delta n_{\text{rms}})(\Delta f)^{1/2}} = \left(\frac{2\bar{N}_B A}{\eta}\right)^{1/2} h\nu \tag{10}$$

The noise-equivalent quantum rate is

$$\text{NEQ} = \left(\frac{2 \times \text{incident background photon rate}}{\text{quantum efficiency}}\right)^{1/2} \tag{11}$$

or

$$D^* = \frac{A^{1/2}}{\text{NEP}} = \left(\frac{\eta}{2N_B}\right)^{1/2} \frac{1}{h\nu} \tag{12}$$

or

$$\text{Area-normalized quantum detectivity} = \frac{A^{1/2}}{\text{NEQ}} = \left(\frac{\eta}{2\bar{N}_B}\right)^{1/2} \tag{13}$$

For the general case of a detector with area A seeing 2π sr of blackbody background at temperature T, $(\Delta N)^2$ is that in Eq. (4)

$$\overline{(\delta n)^2} = 2A\,\Delta f \int_0^\infty \eta(\nu)(\Delta N)^2 d\nu = \frac{4\pi A\,\Delta f}{c^2}\int_0^\infty \eta(\nu)\nu^2 \frac{e^{h\nu/kT}}{(e^{h\nu/kT}-1)^2}\,d\nu \tag{14}$$

Then for $\Delta f = 1$ Hz,

$$\text{NEP} = \frac{h\nu}{c\eta}\left[4\pi A \int_0^\infty \eta(\nu)\frac{\nu^2 e^{h\nu/kT}}{(e^{h\nu/kT}-1)^2}\,d\nu\right]^{1/2} \tag{15}$$

or

$$D^*(T, \lambda) = \frac{c\eta}{2\pi^{1/2}h\nu}\left[\int_0^\infty \eta(\nu)\frac{\nu^2 e^{h\nu/kT}}{(e^{h\nu/kT}-1)^2}d\nu\right]^{-1/2} \tag{16}$$

Assuming $\eta(\nu)$ is independent of frequency but falls back to zero for $\nu < \nu_c$

$$D^*(T, \lambda_c) = \frac{c\eta^{1/2}}{2\pi^{1/2}h\nu}\left[\int_{\nu_c}^\infty \frac{\nu^2 e^{h\nu/kT}}{(e^{h\nu/kT}-1)^2}d\nu\right]^{-1/2} \tag{17}$$

Figure 1 shows photon-noise-limited D^* vs. cutoff wavelength λ_c for various thermal-background temperatures (Jacobs and Sargent, 1970). Note that these curves are not independent. $D^*(T, \lambda_c)$ is related to $D^*(T, \lambda_c')$ by the formula

$$D^*(T, \lambda_c) = \left(\frac{T'}{T}\right)^{5/2} D^*(T, \lambda_c') \qquad \text{where } \lambda_c' = \frac{T}{T'}\lambda_c \tag{18}$$

This relation is useful for determining values of $D^*(T, \lambda_c)$, which do not appear in Fig. 1, in terms of a value $D^*(T', \lambda_c')$, which does appear. For example, to find $D^*(1000\text{ K}, 4\ \mu\text{m})$ from the 500-K curve

$$D^*(1000, 4) = \left(\frac{50}{1000}\right)^{5/2} D^*\left(500, 4 \times \frac{1000}{500}\right) = 2.3 \times 10^9 \text{ Jones} \tag{19}$$

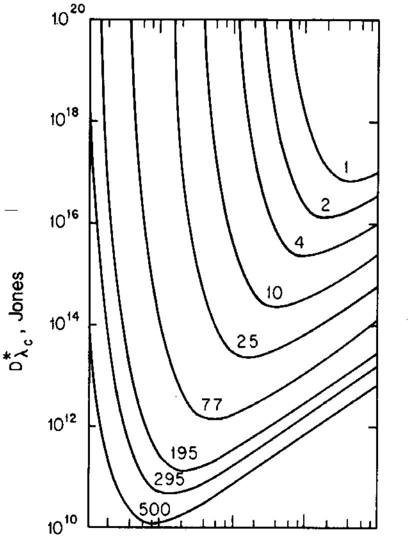

FIGURE 1 Photon-noise-limited D^* at peak wavelength assumed to be cut-off wavelength, for background temperatures 1, 2, 4, 10, 25, 77, 195, 295, and 500 K (assumes 2π FOV and $\eta = 1$). *[Reprinted from* Infrared Physics, *Vol. 10, S. F. Jacobs and M. Sargent, "Photon Noise Limited D* for Low Temperature Backgrounds and Long Wavelengths," pp. 233–235. TABLE 1 D^* vs. λ_c for $T = 295$ K

λ_c, µm	$D^*(\lambda_c)$	λ_c, µm	$D^*(\lambda_c)$	λ_c, µm	$D^*(\lambda_c)$	λc, µm	$D^*(\lambda_c)$
1	2.19×10^{13}	10	5.35×10^{10}	100	1.67×10^{11}	1000	1.55×10^{12}
2	4.34×10^{13}	20	5.12×10^{10}	200	3.20×10^{11}	2000	3.10×10^{12}
3	1.64×10^{12}	30	6.29×10^{10}	300	4.74×10^{11}	3000	4.64×10^{12}
4	3.75×10^{11}	40	7.68×10^{10}	400	6.28×10^{11}	4000	6.19×10^{12}
5	1.70×10^{11}	50	9.13×10^{10}	500	7.82×10^{11}	5000	7.73×10^{12}
6	1.06×10^{11}	60	1.06×10^{11}	600	9.36×10^{11}	6000	9.28×10^{12}
7	7.93×10^{10}	70	1.21×10^{11}	700	1.09×10^{12}	7000	1.08×10^{13}
8	6.57×10^{10}	80	1.36×10^{11}	800	1.24×10^{12}	8000	1.24×10^{13}
9	5.80×10^{10}	90	1.52×10^{11}	900	1.40×10^{12}	9000	1.39×10^{13}

If higher accuracy is desired than can be determined from Fig. 1, one can use the preceding formula in combination with Table 1, which gives explicit values of $D^*(\lambda_c)$ vs. λ_c for $T = 295$ K.

The photon-noise-limited sensitivity shown in Figs. 1 and 2 applies to photovoltaic and photoemissive detectors. For photoconductors, recombination noise results in a $\sqrt{2}$ reduction in D^* at all wavelengths. Figure 3 shows the relative increase in photon-noise-limited D^* achievable by limiting the FOV through use of a cooled aperture.

Thermal Detectors. Limiting sensitivity of an ideal thermal detector has been discussed

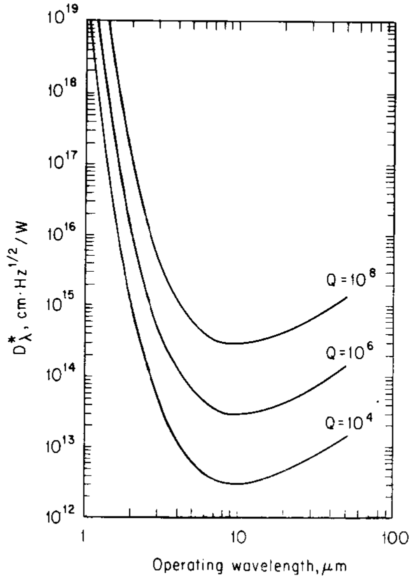

FIGURE 2 Photon noise limit of a narrowband quantum counter as a function of operating wavelength for a 290-K background, 2π FOV, and $\eta = 1$. *(From Kruse et al., 1962)*

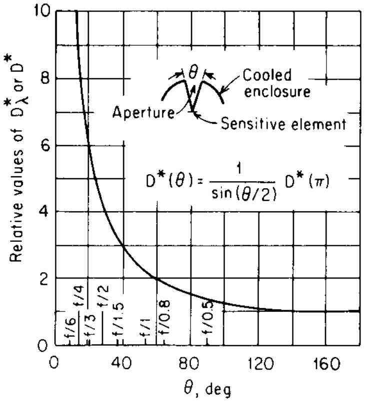

FIGURE 3 Relative increase in photon-noise-limited $D^*(\lambda_{pk})$ or D^* achieved by using a cooled aperture in front of lambertian detector. *(From Kruse et al., 1962)*

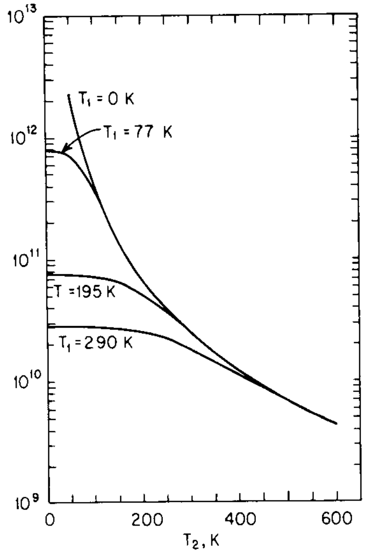

FIGURE 4 Photon-noise-limited D^* for thermal detectors as a function of detector temperature T_1 and background temperature T_2 (2π FOV: $\eta = 1$). *(From Kruse et al., 1962)*

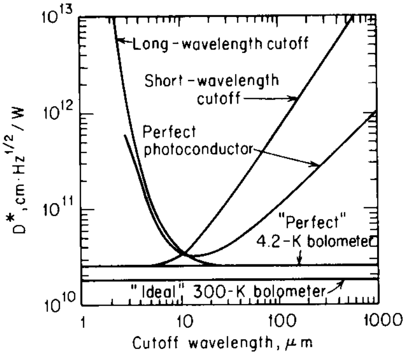

FIGURE 5 The detectivity of a "perfect" bolometer plotted as a function of both short- and long-wavelength cutoffs. Plots for a perfect photoconductor and two other cases are included for comparison. The background temperature is 300 K *(From Low and Hoffman, 1963.)*

previously (Smith et al., 1957; Felgett, 1949; Kruse et al., 1962). Assuming no shortwave or long-wavelength cutoffs exist,

$$D^* = \frac{\varepsilon}{[8\varepsilon\sigma k(T_1^5 + T_2^5)]^{1/2}} = \frac{4.0 \times 10^{16}\varepsilon^{1/2}}{(T_1^5 + T_2^5)^{1/2}}\,\text{Jones} \tag{20}$$

where T_1 = detector temperature
T_2 = background temperature
ε = detector emissivity
σ = Stefan-Boltzmann constant
k = Boltzmann constant

D^* vs. T_2 is plotted for various T_1 in Fig. 4. Figure 5 shows the effect of both short- and long-wavelength cutoffs on bolometer sensitivity (Low and Hoffman, 1963), with the ideal photoconductor curve for reference.

15.6 OTHER PERFORMANCE PARAMETERS

Spectral Response

Spectral response provides key information regarding how the detector will respond as a function of wavelength or photon energy. Spectral response may be limited by the intrinsic detector material properties, a coating on the detector, or by a window through which the radiation must pass. Relative response is the spectral response ratioed against a detector

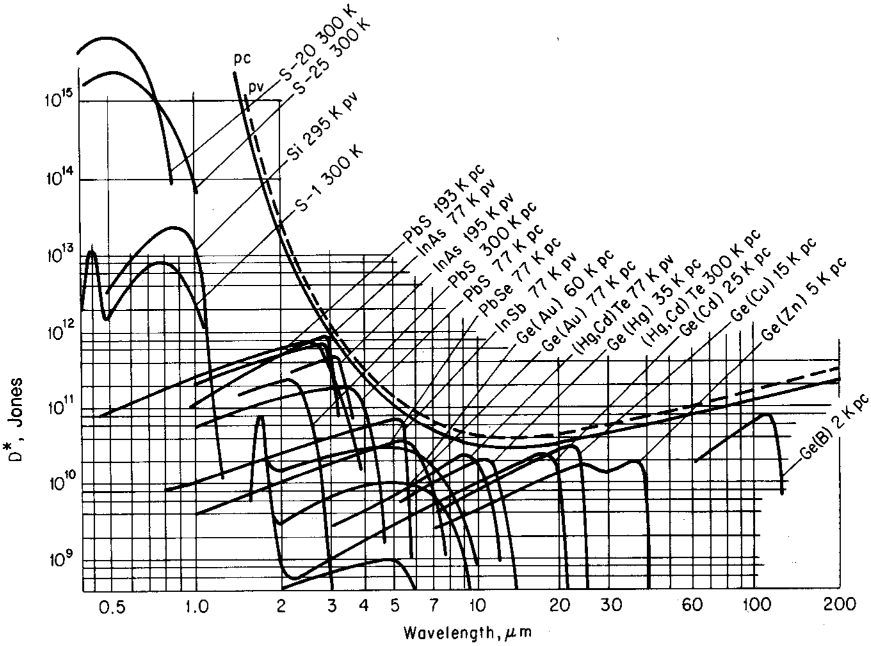

FIGURE 6 D^* vs. λ for selected detectors.

with a nominally wavelength independent response, such as a thermocouple having a spectrally broad black coating. Relative response is plotted as a function of wavelength with either a vertical scale of W^{-1} or photon^{-1}. Thermal detectors tend to be spectrally flat in the first case while quantum detectors are generally flat in the second case. The curves are typically shown with the peak value of the spectral response normalized to a value of 1. The spectral response curve can be used together with the blackbody D^* to calculate D^* as a function of wavelength, which is shown in Fig. 6 for selected detectors.

Responsivity and Quantum Efficiency

Responsivity and quantum efficiency are important figures of merit relating to the detector signal output. Responsivity is a measure of the transfer function between the input signal photon power or flux and the detector electrical signal output. Thermal detectors will typically give this responsivity in volts/watt. Photoconductors will usually quote the same units, but will also frequently reference the value to the peak value of relative response per watt from the spectral response curve. This value is actually realized if the detector bias circuit load resistor is significantly larger than the detector resistance. Photoconductor responsivity is given by:

$$\text{Responsivity}_{\text{peak}} = \frac{\eta \mathbf{q} \mathbf{R_d} \mathbf{E} \tau(\mu_n + \mu_p)}{h\nu\ell} \tag{21}$$

where η is the quantum efficiency, $\mathbf{q}$ is the electronic charge, $\mathbf{R_d}$ is the detector resistance, $\mathbf{E}$ is the electric field, τ is time constant, μ are the mobilities for electrons (n) and holes

(p), $h\nu$ is the photon energy, and ℓ is the device length. Photomultiplier tubes and photovoltaic detectors will usually reference the responsivity in amps per watt, again referenced to peak spectral response.

Detector response performance is also conveyed from the detector quantum efficiency. In the case of photovoltaic detectors which, in the absence of avalanche operation have a gain of unity, quantum efficiency is essentially the current per photon. For a blip photovoltaic detector, the quantum efficiency also determines the D^*. Quantum efficiency is not readily measured for photoconductors and photomultiplier tubes unless the internal gain is carefully calibrated. It is sometimes inferred from the measured D^* for photoconductive devices which are blip (see definition of detective quantum efficiency).

Noise, Impedance, Dark and Leakage Current

Noise has a number of potential origins. Background photon flux limited detectors have noise dominated by the square root of the number of background photons striking the detector per second [see Eq. (9)]. Other noise sources may contribute or dominate. Among these are:

- Johnson, Nyquist, or thermal noise which is defined by the detector temperature and impedance
- modulation or $1/f$ noise which may dominate at lower frequencies
- amplifier noise
- shot noise from dark or leakage current

Thus, the impedance of a photodiode may limit performance, depending upon the detector operating conditions. Fig. 7 illustrates the diode impedance per unit area ($\mathbf{R}_0A$)

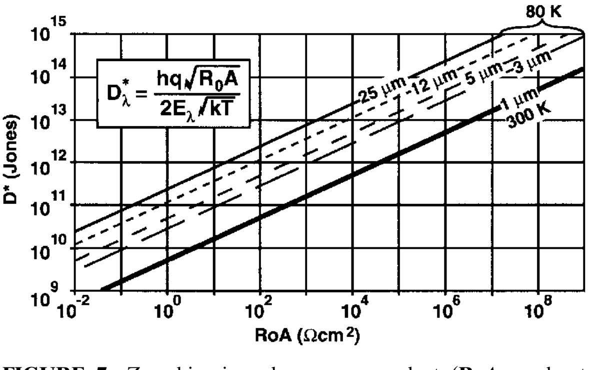

FIGURE 7 Zero-bias impedance-area product ($\mathbf{R}_0A$ or shunt resistance per unit area) of a photodiode can limit the **D*** as shown. The limiting D^* depends on $\mathbf{R}_0A$, temperature and photon energy or wavelength. Examples are illustrated for a 1-µm diode at 300 K, and for 3-, 5-, 12-, and 25-µm devices at 80 K. Other noise mechanisms, such as photon noise, typically limit D^* to lower values than shown here.

limiting value of D^* for silicon detectors at room temperature and longer-wavelength infrared photodiodes at 80 K.

Measurement of the noise as a function of frequency can be valuable for characterizing the relevant noise sources. Selection of an appropriate preamplifier is also critical, particularly for detectors having very low or very high impedance. Integration of preamplifiers together with detectors has significantly improved the overall performance of many detectors. The use of phase-sensitive lock-in amplifiers in combination with a modulated signal can also improve the signal-to-noise ratio.

Uniformity

One cannot assume that the response of a detector will be uniform across its sensitive area. Material inhomogeneity and defects and/or fabrication variables can give rise to nonuniformity. Lateral collection from near the perimeter of a photodiode may give a gradual response decrease away from the edge (this effect will typically be accompanied by a change in response speed as well). Recombination at the electrical contacts to a photoconductor can limit the lifetime, and hence the photoconductive gain, for carriers generated near the contact, a phenomenon called sweep-out. Recombination may be enhanced at surfaces and edges also. Laser spot scanning is useful to check the detector spatial uniformity, although laser sources may not be readily available at all the wavelengths of interest. An alternative method is to move the detector around under a fixed small aperture in conjunction with a light source.

Speed

Detector response speed is often related inversely to detector sensitivity. Thermal detectors often show this characteristic because the signal is proportional to the inverse of response speed, while the noise is amplifier- or Johnson-limited. Excluding detectors with internal carrier multiplication mechanisms, the best detectors from broad experience seem limited to a D^*f^* product of a few times 10^{17} Jones Hz. D^*f^* may be proportionally higher for devices with gain, since speed can be increased to a greater extent by using a lower value of load resistance without becoming Johnson-noise-limited. The user should be aware that with many detectors it is possible to operate them in a circuit to maximize sensitivity or speed, but not both at the same time. Speed may vary across the sensitive area of the detector and with temperature, wavelength, and electrical bias.

Stability

Detector performance may change or drift with time. Changes in operating temperature, humidity, and exposure to elevated temperatures as well as to visible, ultraviolet, and high-energy radiation can affect device operation. These effects arise from the temperature dependence of electronic properties in solids, as well as from the critical role played by electrical charge conditions near the surface of many device types. Sensitivity changes in a sample of silicon detectors from four vendors illustrate this point. Wide variations in

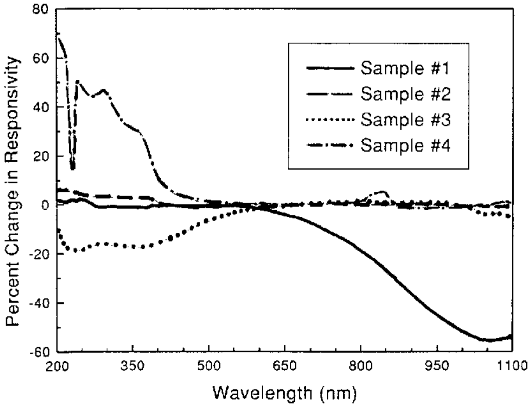

FIGURE 8 After only three hours of UV irradiation, detectors showed great variations in responsivity. *(Reprinted from the September 1993 issue of* Photonics Spectra, *© Laurin Publishing Co., Inc.)*

responsivity change after UV exposure, as shown in Fig. 8. In applications where stability is of significant concern, these effects must be carefully reviewed along with the detector supplier's experience in these matters.

15.7 DETECTOR PERFORMANCE

Manufacturers' Specifications

Detector sensitivity can be the determining factor in the design and performance of a sensor system. Detector performance is subject to the development of improved materials, fabrication techniques and the ingenuity of device engineers and inventors. The descriptions given here may improve with time, and consultation with manufacturers and users is recommended.

Thermocouple. The thermocouple offers broad uniform spectral response, a high degree of stability, and moderate sensitivity. Its slow response and relative fragility have limited its use to laboratory instruments, such as spectrometers.

Compared with thermistors, thermocouples are slower, require no bias, and have higher stability but much lower impedance and responsivity. This increases the amplification required for the thermocouple; however, the only voltage appearing is the signal voltage, so that the serious thermistor problem of bridge-circuit bias fluctuations is avoided. With proper design, performance should not be amplifier-limited but limited instead by the Johnson noise of the thermocouple. Thermocouples perform stably in dc operation, although the instability of dc amplifiers usually favors ac operation.

The inherent dc stability of thermocouples is attractive for applications requiring no

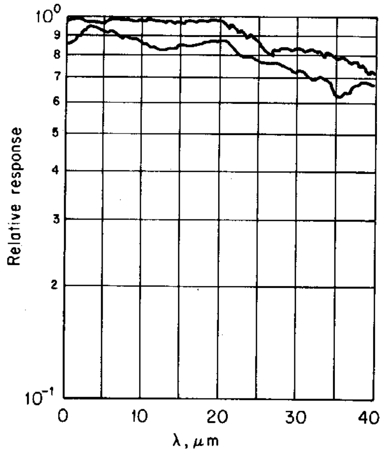

FIGURE 9 Typical thermocouple spectral-response curves (CsI window) (two different manufacturers).

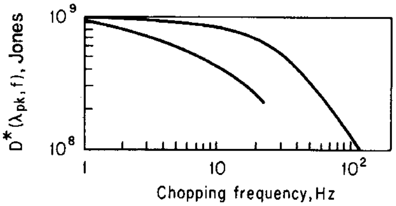

FIGURE 10 Typical thermocouple D^* (noise) frequency spectra (two manufacturers). *(From Wolfe, 1965.)*

moving parts, and recently a relatively rugged solid backed evaporated thermocouple has been developed whose sensitivity approaches that of the thermistor bolometer.

Sensitivity: $D^* = 1 \times 10^9$ Jones for 20-ms response time; spectral response depends on black coating (usually gold black) (see Fig. 9).

Noise: White Johnson noise, falling off with responsivity (see Fig. 10).

Resistance: 5–15 Ω typical.

Responsivity: 5 V/W (typical), 20–25 V/W (selected).

Time constant: 10–20 ms (typical).

Operating temperature: Normally ambient.

Sensitive area: 0.1×1–0.3×3 or 0.6×2 mm (typical).

Linearity: <0.1 percent in region investigated (6×10^{-10}–6×10^{-8} W incident).

Recommended circuit: Transformer coupled into low-noise (FET) amplifier with good low-frequency noise characteristics.

Manufacturers: Perkin-Elmer, Charles Reeder, Beckman Instruments, Farrand, Eppley Laboratory, Barnes Engineering.

Thermopile. Thermopiles are made by evaporating an array of metal junctions, such as chromel-constantan or manganin-constantan, onto a substrate. The thin-film construction is rugged, but the Coblentz-type may be quite delicate. Wire-wound thermopile arrays are also available which are very robust. Devices with arrays of semiconductor silicon junctions are also available. The array may typically be round, square, or rectangular (for matching a spectrometer slit) and consist of 10 to 100 junctions. Configuration options include matched pairs of junction arrays or compensated arrays to provide an unilluminated reference element. A black coating, such as 3M black or lampblack, is used to provide

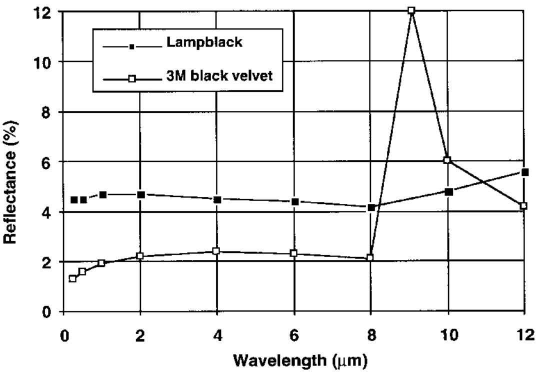

FIGURE 11 Spectral reflectance of two black coatings used in the construction of thermopile detectors. *(From Eppley Laboratory studies.)*

high absorption over a broad spectral range, as illustrated in Figs. 11 and 12. The housing window may limit the spectral range of sensitivity. Typical applications include power meters and radiometers.

Sensitivity: $D^* \approx 0.5$ to 4×10^8 Jones for 30-ms typical response time. D^* may be dependent upon sensitive area; spectral response depends on black coating and window (see Fig. 11 and Fig. 12).

Noise: White Johnson noise, falling off with responsivity, typical range is 5–30 nV/Hz$^{1/2}$.

Resistance: 2 Ω–60 kΩ typical.

Responsivity: 4–250 V/W (typical) depends on the number of junctions and time constant.

Time constant: 10 ms–2 s (typical).

Operating temperature: Normally ambient.

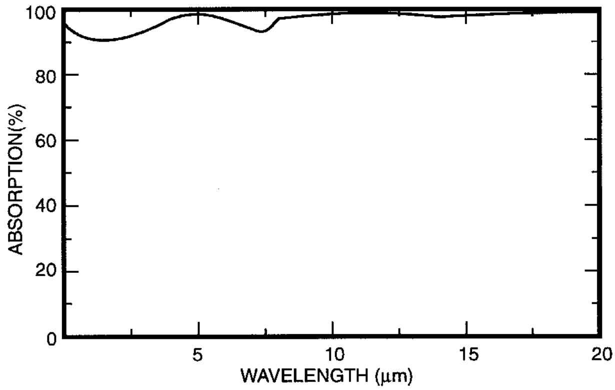

FIGURE 12 Spectral absorption of a thermopile detector coating made from a black metal oxide. *(Oriel Corporation.)*

Sensitive area: 0.5–6-mm dia., 0.025 × 0.025–3 × 3 mm, various rectangular, 0.4 × 3, 0.6 × 2, 0.6 × 4 mm (typical).

Recommended circuit: Low noise (0.5 μV p-p, dc to 1 Hz), low drift with voltage gain of ≈1000 and input impedance of 1 MΩ.

Manufacturers: Armtech, Beckman Instruments, Concept Engineering, Dexter Research Center, Edinburgh Instruments, EDO/Barnes Engineering, Eppley Laboratory, Farrand, Gentech, Molectron Detector, Ophir Optronics, Oriel, Scientech, Scitec, Swan Associates.

Thermistor Bolometer. Thermistors offer reliability, moderate sensitivity, and broad spectral coverage without cooling. Construction is rugged and highly resistant to vibration, shock, and other extreme environments. Response is slower than 1 ms, and tradeoff exists between speed and sensitivity.

Thermistor elements are made of polycrystalline Mn, Ni, and Co oxides. In their final form they are semiconductor flakes 10 μm thick, which undergo a temperature resistance change of ~4 percent/K. Since thermistor resistance changes with ambient temperature enough to alter the biasing significantly, it is usually operated in a bridge circuit, with a nearly identical thermistor shielded from signal radiation and used for a balance resistor.

Sensitivity:

$$\mathrm{NEP} = 8.9 \times 10^{-10} \sqrt{\frac{A(\mathrm{mm}^2)}{\tau_{\mathrm{rms}}}}\,\mathrm{W}$$

$$D^* = 1.1 \times 10^9 \sqrt{\tau_{\mathrm{rms}}}\,\mathrm{Jones}$$

Spectral response: Depends on coating (usually Zapon lacquer); see Fig. 13.

Quantum efficiency: Depends on blackening coating, typically 80 percent.

Noise: Thermal-noise-limited above ~20 Hz ($V_{\mathrm{noise}} = \sqrt{4kTR\Delta f}$); below that, $1/f$ type noise (see Fig. 14). Used in balanced-bridge circuit (two flakes in parallel); limiting noise due to thermal noise in *both* flakes.

Resistance: For standard 10-μm-thick flakes, two different resistivities are available: 2.5 MΩ/sq or 250 kΩ/sq. Note that in a bolometer bridge, the resistance between the output connection and ground is half that of single flake.

Time constant: τ is 1–20-ms standard for nonimmersed detectors and 2–10-ms standard for immersed detectors.

FIGURE 16 Bolometer electrical circuit. *(From Barnes Engineering, Bull. 2-100.)*

Sensitive area: 0.1 × 0.1 mm, 5 × 5-mm standard.

Operating temperature: Normally ambient, 285–370 K.

Responsivity: Depends on bias, resistance, area, and time constant $\mathcal{R} \propto \sqrt{R\tau/A} \approx 10^3$ V/W for 0.1 × 0.1-mm area, 250-kΩ resistance, and $\tau = 4$ ms (see Fig. 15 for frequency-time-constant dependence with given area). Output voltage (responsivity) can be increased to a limited degree by raising bias voltage. Figure 16 shows the deviation from Ohm's law due to heating. Bias should be held below 60 percent of peak voltage. Listed responsivity is that of active flake. In the bridge circuit, responsivity is half this value.

Sensitivity profile: Approximately 10 percent for 10-μm scan diameter over a 1 × 1-mm cell.

Linearity: ±5 percent 10^{-6}–10^{-1} W/cm^2.

Recommended circuit: See Figs. 16 and 17.

Manufacturers: EDO/Barnes Engineering, Servo Corporation of America, Thermometrics.

Pyroelectric. Lithium tantalate ($LiTaO_3$), triglycine sulfate (TGS), and other pyroelectric materials provide an uncooled thermal detector with good sensitivity. The devices are capable of fast response, limited inversely by the preamplifier feedback resistance, but with responsivity and D^* traded for speed. Its principle of operation is the pyroelectric effect, which is the change of electric polarization with temperature. It offers rugged construction and absence of $1/f$ noise because no bias is involved.

Lack of $1/f$ noise, combined with the ability to easily trade off speed and sensitivity, makes pyroelectric detectors useful for scanning applications and energy measurement of pulsed optical sources. In addition, the NEP is independent of area at low frequencies (<10 Hz), so that these detectors are useful for large-area applications (preamplifier $1/f$ noise may limit, however). Pyroelectric detectors are useful for calorimetry since the pyroelectric effect is an integrated volume effect and the output signal is unaffected by spatial or temporal distribution of the radiation, up to damage threshold or depolarizing temperature. For higher damage thresholds, lead zirconate titanate ceramic (Clevite PZT-5) exhibits a much smaller pyroelectric effect than TGS, but its high Curie temperature of 638 K makes it more useful than TGS for high-energy applications.

Sensitivity: Sensitive from ultraviolet to millimeter wavelengths. For $\lambda < 2\ \mu m$, TGS must be blackened, which slows response. Normally ($\lambda > 2\ \mu m$) a transparent electrode is used, since TGS absorption is high from 2 to 300 μm. Beyond 300 μm, poor absorption and increased reflectivity reduce sensitivity. Spectral response depends largely on coating. See Fig. 18 for spectral response with modified 3M black. Fig. 19 illustrates the relative spectral response for a $LiTaO_3$ device. D^* is independent of A at low frequencies (<10 Hz) (see Figs. 20 and 21). Figure 22 shows NEP vs. A for various frequencies.

Quantum efficiency: Depends on coating absorptivity (for 3M black typically $\eta >$ 75 percent).

Noise: (See Figs. 20 and 21). Limited by loss-tangent noise up to frequencies where limited by amplifier short-circuit noise (see Fig. 23).

Operating temperature: Ambient, up to 315 K. Can be repolarized if $T > T_{\text{curie}} = 322$ K for TGS. Irreversible damage at $T = 394$ K (see Fig. 24). Other pyroelectric materials have significantly higher Curie temperatures (398–883 K).

Output impedance: 50 Ω–10 KΩ, set by built-in amplifier (see Fig. 25).

Responsivity: See Figs. 20–22, 24, and 26.

5.0- 6.0	±2.5
6.0- 8.0	±6.0
8.0-10.0	±3.0
10.0-14.0	±1.5
14.0-40.0	±3.0

FIGURE 19 Relative spectral response of $LiTaO_3$ pyroelectric detectors showing both a black spectral coating and an optional coating tuned to the 8–14-μm LWIR band. *(From Molectron Detector, Inc.)*

Capacitance: 5 pF for 0.5 × 0.5 mm; 20 pF for 1 × 1 mm; 100 pF for 5 × 5 mm.

Sensitive area: 2–50-mm dia. round, 0.5 × 0.5-mm–10 × 10-mm square, typical.

Time constant: Not pertinent, response speed set by the preamplifier feedback resistor (see Fig. 26).

Linearity: 5 percent between 10^{-6} and 10^{-1} W/cm^2.

Sensitivity profile: Depends on coating or transparent electrode; 5–7 percent across 12 × 12-mm; spot size < 250 μm.

Recommended circuit: See Figs. 25 and 27. FET amplification stage usually built in.

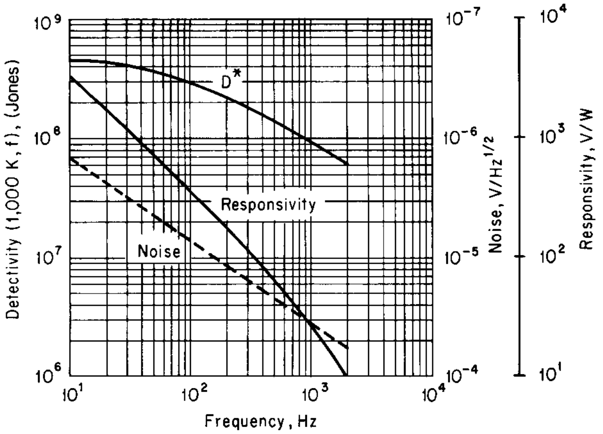

FIGURE 20 Typical D^*, responsivity, and noise vs. frequency for TGS ($A = 1 \times 1$ mm; $T = 296$ K.) *(From Barnes Engineering, Bull. 2-220A.)*

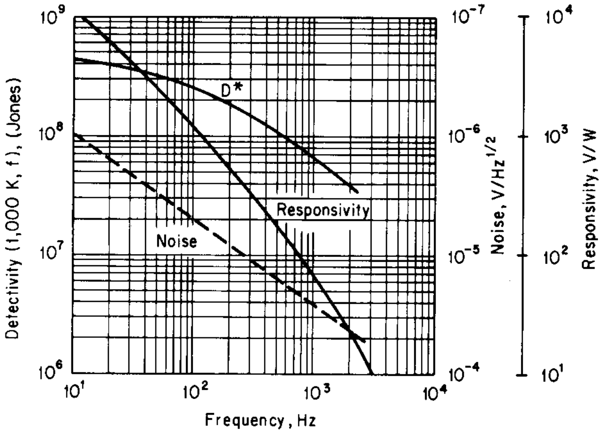

FIGURE 21 Typical D^*, responsivity, and noise vs. frequency ($A = 0.4 \times 0.4$ mm; $T = 296$ K). *(From Barnes Engineering, Bull. 2-220A.)*

Since $\mathcal{R} \propto 1/f$, use of an amplifier with $1/f$ noise and gain $\propto f$ is recommended. Then output signal and signal-to-noise ratio are independent of frequency.

spectral region. Because the mobility of the electrons varies as $T_e^{3/2}$ under these conditions, the conductivity of the material is modulated. This mechanism offers submicrosecond response and broad far-infrared coverage out to millimeter wavelengths but requires liquid-helium cooling and very sophisticated receiver design.

Technically, these devices may be classed as bolometers, since incident radiation power produces a heating effect which causes a change in free-charge mobility. In the normal bolometer, the crystal lattice absorbs energy and transfers it to the free carriers via collisions. However, in InSb bolometers incident radiation power is absorbed directly by free carriers, the crystal lattice temperature remaining essentially constant. Hence the name *electron bolometer.* Note that this mechanism differs from photoconductivity in that free-electron mobility rather than electron number is altered by incident light (hence there is no photoconductive gain).

Sensitivity: $D^*(2\text{ mm}, 900) = 4 \times 10^{11}$ Jones (see Fig. 28).

Noise: See Figs. 29 and 30.

Responsivity: ~1000 V/W.

Time constant: $\tau = 250$ ns.

Sensitive area: 5 × 5 mm typical.

Operating temperature: ~1.5–4.2 K.

Impedance: Without bias, 200 Ω; optimum bias, 150 Ω, depends on bias (see Fig. 29).

Recommended circuit: Optimum bias 0.5 mA (see Fig. 31).

Manufacturer: Infrared Laboratories.

Ge(Ga) Low-temperature Bolometer. The Ge(Ga) bolometer offers very high sensitivity and broad spectral coverage in the region 1.7 to 2000 μm. Liquid-helium cooling is

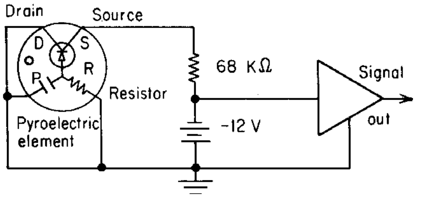

FIGURE 25 Pyroelectric detector-amplifier circuit. *(From Barnes Engineering, Bull. 2-220A.)*

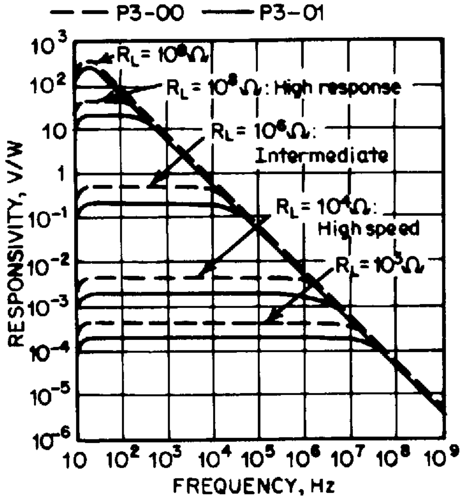

FIGURE 26 Responsivity vs. frequency for two pyroelectric detector models using various feedback resistors. *(From Molectron Detector, Inc.)*

required. A tradeoff exists between response time (seconds) and sensitivity (10^{-14} W NEP). Operation at 1000 Hz can be achieved still maintaining 2×10^{-13} W NEP.

Sensitivity: Depends on thermal conductance G (see Figs. 32 and 33). NEP(λ, 10 Hz) $= V_n/S = 3 \times 10^{-14}$ W for $G = 1\ \mu$W/K; $A = 1\ \text{mm}^2$, $D^*(\lambda, 10\ \text{Hz}) = 3 \times 10^{13}$ Jones ($\mathbf{Q} < 0.2\ \mu$W). For this detector, NEP $\approx 4T(kG)^{1/2}$ and does not vary with $A^{1/2}$(T is heat-sink temperature, and k is Boltzmann's constant). Thus D^* cannot be used as a valid means of comparison with other detectors; 300-K background-limited performance is achievable for 2π FOV when the bolometer is operated at 4.25 K with $G = 10^{-3}$ W/K. (For $A = 0.1\ \text{cm}^2$, the time constant is 50 s.)

Responsivity: Typically, responsivity $= 2.5 \times 10^5$ V/W $= 0.7(\mathbf{R}/TG)^{1/2}$, where $\mathbf{R} =$ resistance. Responsivity, and hence NEP, depends on thermal conductance G, which in turn is set by background power. G ranges from 0.4 to 1000 μW/K.

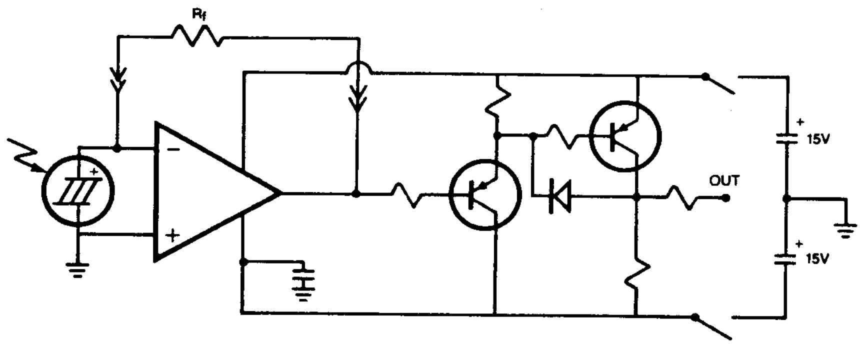

FIGURE 27 Resistive feedback circuit used with LiTaO_3 detectors. *(From Molectron Detector, Inc.)*

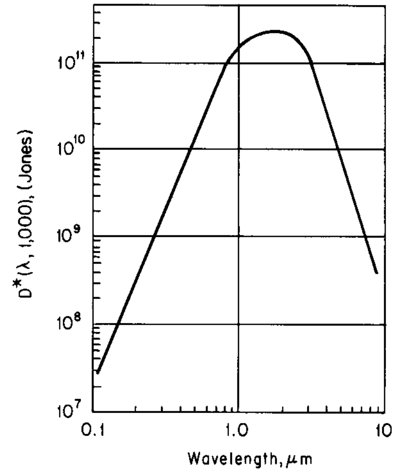

FIGURE 28 D^* vs. λ for InSb electron bolometer ($H = 0$). *(From Raytheon, IR Millimeter Wave Detector, 1967.)*

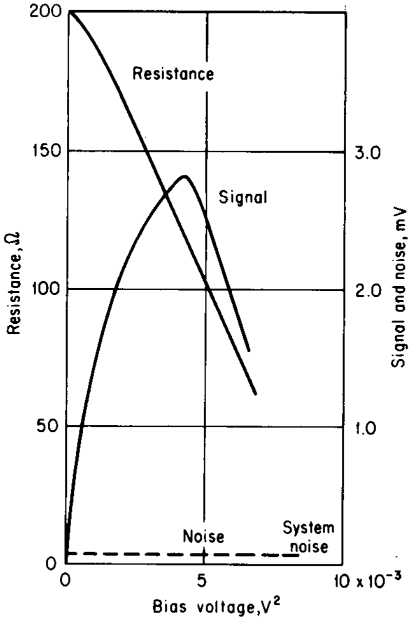

FIGURE 29 InSb electron bolometer, typical resistance, signal, and noise vs. bias voltage squared ($T = 5$ K; $\mathbf{R}_L = 200\ \Omega$; gain $= 2.4 \times 10^4$; $F = 1100$ Hz). *(From Santa Barbara Research Center, Prelim. Res. Rep., 1967.)*

Thermal conductance: Typically $G = 1\ \mu$W/K for background $\mathbf{Q} < 0.2\ \mu$W; note that $\mathbf{Q} < 1/2$ (optimum bias power P).

Sensitive area: 0.25×0.25–10×10 mm.

Resistance: 0.5 MΩ.

Operating temperature: 2 K (see Fig. 32). In applications where radiation noise can be

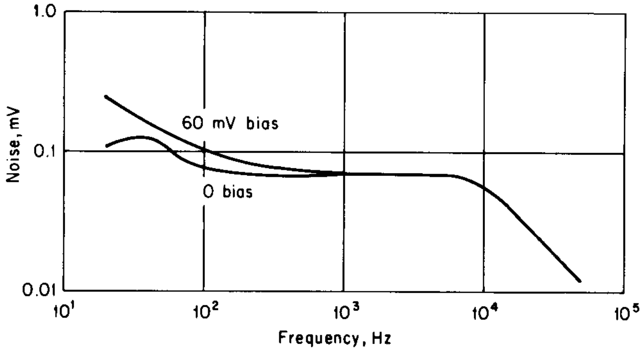

FIGURE 30 InSb electron bolometer, typical noise spectrum ($T = 5$ K, $\mathbf{R}_L = 200\ \Omega$; gain $= 2.4 \times 10^4$, $\Delta f = 5.6$ Hz). *(From Santa Barbara Research Center, Prelim. Res. Rep., 1967.)*

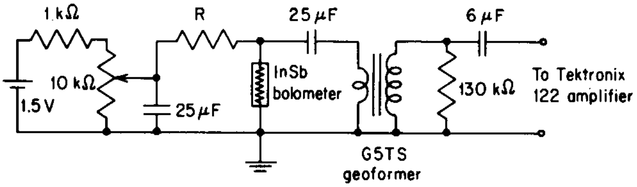

FIGURE 31 Electron-bolometer biasing circuit. *(From Santa Barbara Research Center, Prelim. Res. Rep., 1967.)*

eliminated there is much to be gained by operating at the lowest possible temperature. Figure 33 shows the theoretical NEP and time constant at 0.5 K, assuming that current noise remains unimportant.

Quantum efficiency: Depends on blackened coating and window. For $\lambda < 100\,\mu\text{m}$, absorptivity exceeds 95 percent. For $\lambda > 100\,\mu\text{m}$, efficiency varies with geometry.

Time constant: Response time constant is proportional to G^{-1}. Therefore, if G must be increased to accomodate larger background, the time constant is decreased proportionally. Responsivity and NEP, however, are degraded as $G^{-1/2}$.

Noise: $v_n = 1 \times 10^{-8}\,\text{V/Hz}^{1/2}$; thermal noise is due to **R** and $\mathbf{R}_L$.

Recommended circuit: Standard photoconductive circuit, with load resistor, grid resistor, and blocking capacitor at low temperature (see Fig. 34). See Fig. 35 for typical electrical characteristics. Bias power $P = 0.1TG$.

Manufacturer: Infrared Laboratories, Inc.

Photoemissive Detectors. Photoemissive detectors are generally the detector of choice in the UV, visible, and near-IR where high quantum efficiency is available. In the spectral region $\lambda < 600\,\text{nm}$, the photomultiplier, or multiplier phototube, has close to ideal

FIGURE 32 Germanium bolometer NEP vs. conductance. *(IR Labs, Inc.)*

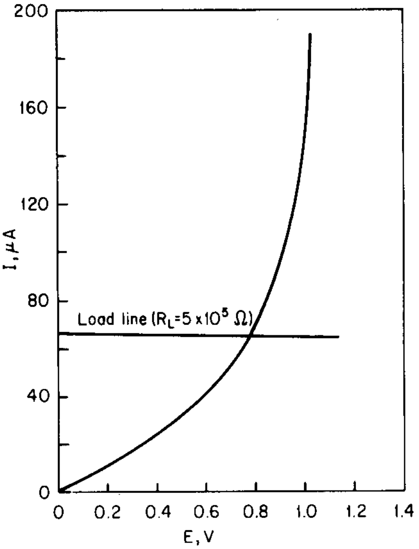

FIGURE 35 Load curve for a typical germanium bolometer ($T = 2.15$ K) with load line, showing optimum operating point. *(From Low, 1961.)*

sensitivity; i.e., selected photomultiplier tubes (PMT) are capable of detecting single photon arrivals (but at best only with about 30 percent quantum efficiency) and amplifying the photocurrent (pulse) enormously without seriously degrading the signal-to-noise ratio. Time resolution can be as short as 0.1 ns. Only very specialized limitations have precluded their use for $\lambda < 800\,\mathrm{nm}$, for example, cost, ruggedness, uniformity of manufacture, or need for still faster response. Recently these limitations have all been met individually but generally not collectively. Where adequate light is available, the simple phototube has advantages over the multiplier phototube in that high voltages are not required, the output level is not sensitive to applied voltage, and dynode fatigue is eliminated.

Microchannel plate tubes (MCPT) are a variant of the photomultiplier tube where the current amplifying dynode structure is replaced by an array of miniature tubes in which the photocathode current is amplified. MCP tubes are more compact than PMTs and are reliable in operating conditions of high environmental stress. The same range of photocathode materials is available in MCPTs as PMTs. MCPTs can provide a wide range of electron gain as available depending upon whether a single MCP or a stack of MCPs is used. The structure of a PMT and MCPT are compared in Fig. 36.

Sensitivity. In modern phototubes, shot noise due to the cathode dark current is by far the most important noise source. The most common descriptions of phototube sensitivity list both current responsivity (amperes per watt), dark current, and dark noise. Several useful measures of sensitivity are noise equivalent input (NEI) (see Sec. 15.4 "Definitions"), noise equivalent power (NEP), or its reciprocal $D \equiv 1/\mathrm{NEP}$. NEP and NEI in the range 10^{-14} to $10^{-17}\,\mathrm{W/Hz^{1/2}}$ are not uncommon.

Detectivity is generally limited by dark-current shot noise. Dark current depends on photocathode material, area, and temperature. Thus the best detectivity is obtained with small effective sensitive area. Cooling is especially useful for red-sensitive and near-IR tubes and is generally not worthwhile for others (see "Operating Temperature"). Special tube housings which can provide thermoelectric cooling are available.

The spectral response curves shown in Fig. 37 are for the combination of photocathode

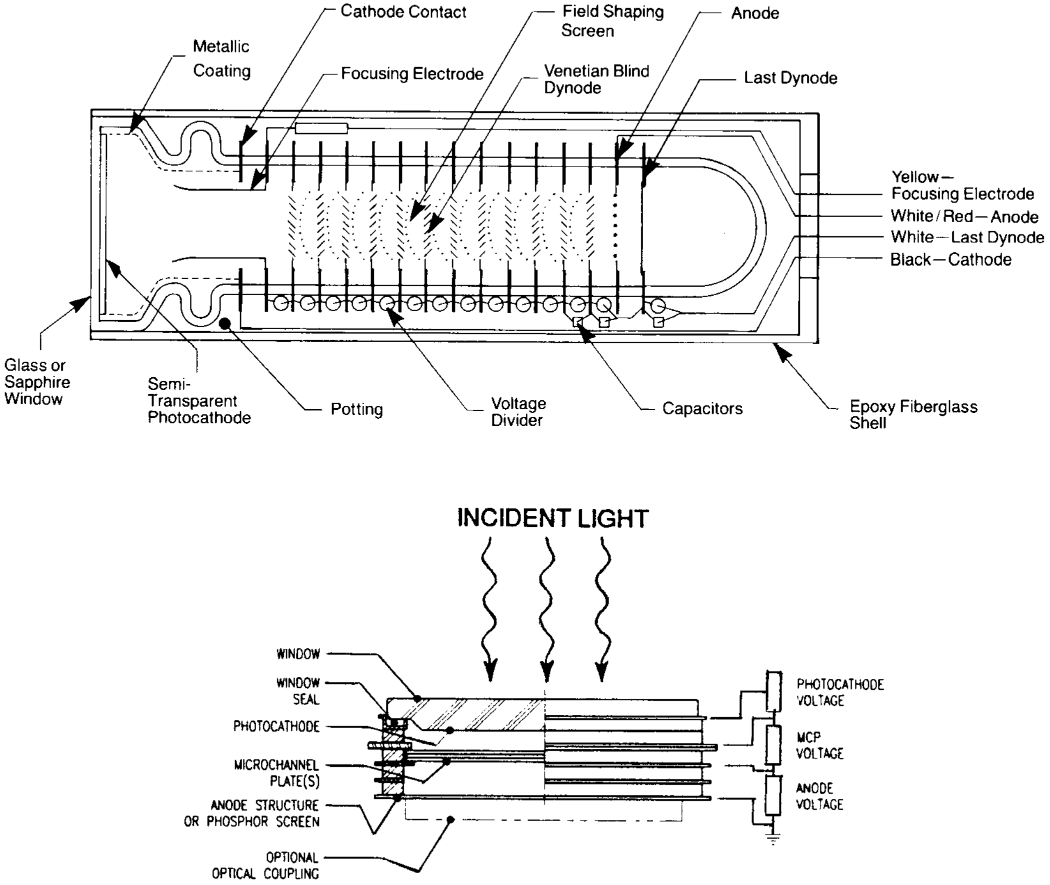

FIGURE 36 Comparison of photomultiplier tube (PMT) and microchannel plate tube (MCPT) construction. *(EMR Photoelectric.)*

and window. Historically, this method of description gave rise to the S-response designations, most of which are now obsolete. It is often desirable to separate photocathode response from window transmission. Thus, Fig. 38 shows the quantum efficiency (electrons per incident photon) of a number of photocathodes without window losses. For $\lambda < 400$ nm, each photocathode should maintain its peak quantum efficiency, up to photon energies where multiple photoemissions take place. In Fig. 39, the spectral dependence of quantum efficiency for a variety of modern photocathode/window combinations is illustrated.

D^* is a meaningful figure of merit for phototubes whose sensitivity is limited by dark noise (shot noise on the dark current) and whose emitting photocathode area is clearly defined, but D^* must be used with caution because, although modern phototubes are generally dark-noise-limited devices, they are often limited by noise in signal, i.e., the noise content of the signal itself (Eberhardt, 1967). Serious errors in predicting the detection capability of phototubes will arise if noise in signal is ignored and D^* is presumed to be the important limiting parameter (see Eqs. 6, 7, and 8). Very little reliable data are presently available on D^* for photoemitters. However D^* curves for S-1, S-20, and S-25 are shown in Figs. 40 (300 K) and 41 (PMT cooled to 200 K).

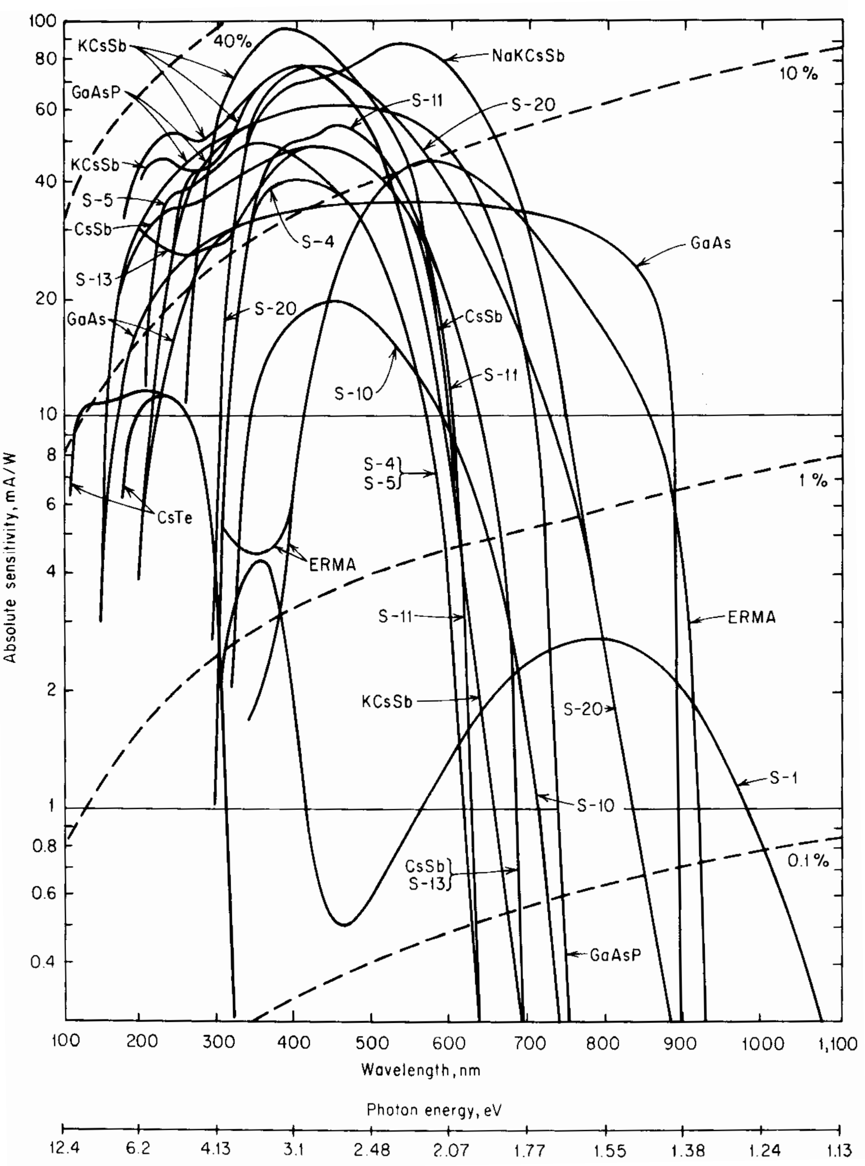

FIGURE 37 Spectral sensitivity of various photoemitters. Dotted lines indicate photocathode quantum efficiency. Chemical formulas are abbreviated to conserve space. S-1 = AgOCs with lime or borosilicate crown-glass window; S-4 = Cs_3Sb with lime or borosilicate crown-glass window (opaque photocathode); S-5 = Ss_3Sb with ultraviolet-transmitting glass window; S-8 = Cs_3Bi with lime or borosilicate crown-glass window; S-10 = AgBiOCs with lime or borosilicate crown-glass window; S-11 = Cs_3Sb with lime or borosilicate crown-glass window (semitransparent photocathode); S-13 = Cs_3Sb with fused-silica window (semitransparent photocathode); S-19 = Cs_3Sb with fused-silica window (opaque semicathode); S-20 = Na_2KCsSb with lime or borosilicate glass window. ERMA = extended red multialkali (RCA; ITT uses MA for multialkali). This curve is representative of several manufacturers' products. Many variations of this response are available, e.g., tradeoffs between short- and long-wavelength response. *(From RCA Electronic Components, chart. PIT-701B.)*

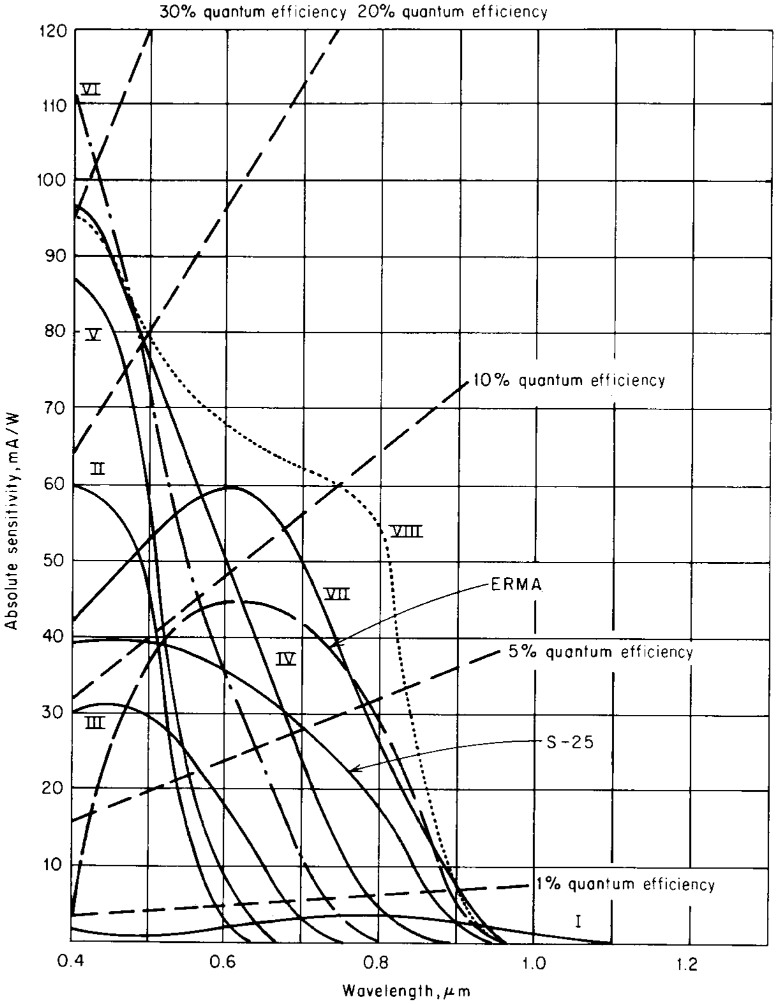

FIGURE 38 Photocathode responsivity and quantum efficiency vs. wavelength (no windows). For abbreviations, see Fig. 33. I = S-1, II = S-11, III = S-10, IV = S-20, V = K_2CsSb, VI = $K_2CsSb(O)$, VII = $NaKCsSb_3$, VIII = GaAs(Cs). *(Based on material from RCA.)*

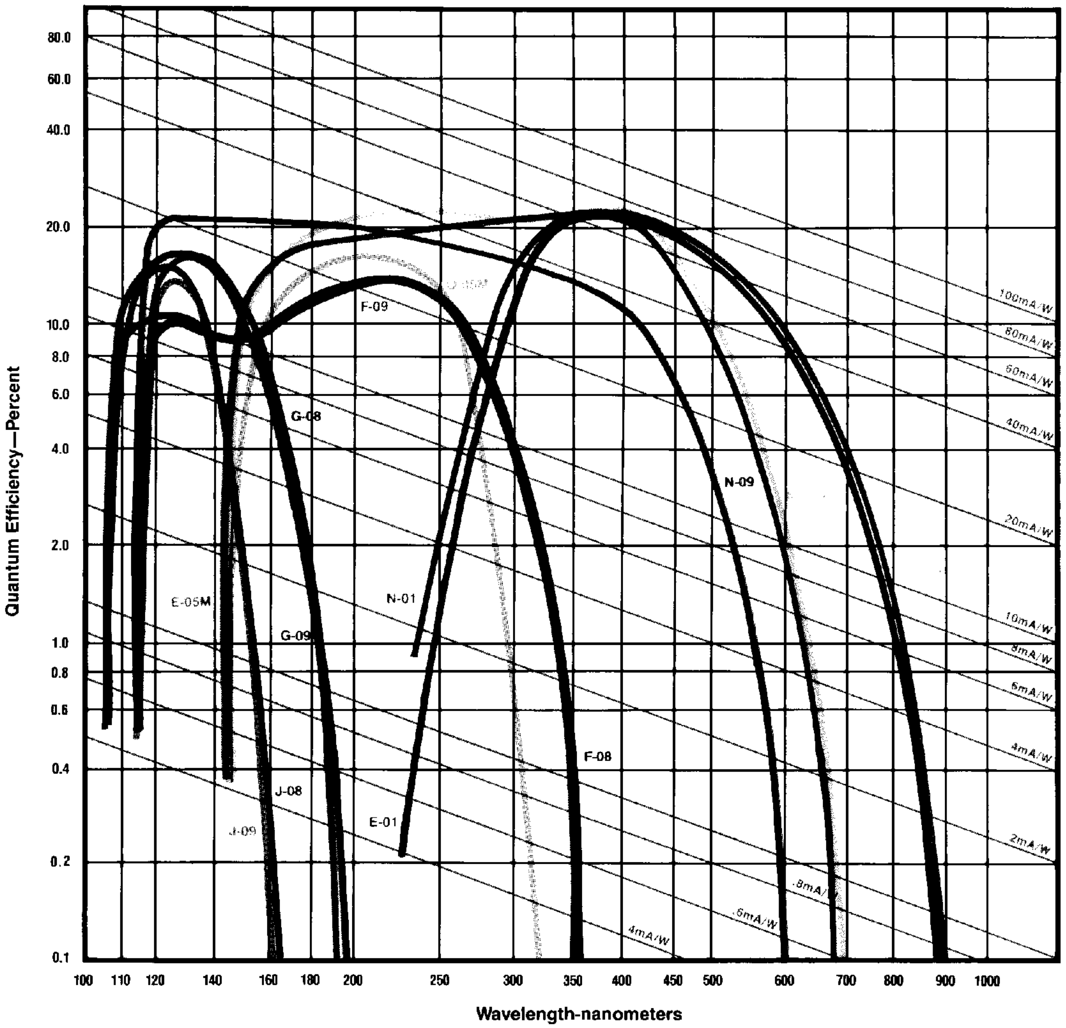
Short-wavelength Considerations. Window considerations are as follows:

For $\lambda > 200$ nm: Windows are essential, as all useful photocathode materials are oxidized and performance would otherwise be destroyed.

$200 \text{ nm} > \lambda > 105$ nm: Photocathode materials are not oxidized by dry air (moisture degrades performance). Windows are optional. LiF windows have shortest known cutoff, 105 nm. For $\lambda < 180$ nm, it is generally advisable to flush with dry nitrogen.

$\lambda < 105$ nm: No windows are available.



PHOTOCATHODE KEY

Key letter	Description	Long Wavelength Cutoff (Note 1)	Long Wavelength Sensitivity (Note 2)
E	Tri-Alkali (S-20)	850 nm	780 nm
F	Cesium Telluride	355 nm	340 nm
G	Cesium Iodide	195 nm	185 nm
J	Potassium Bromide	165 nm	150 nm
N	High Temperature Bi-Alkali	690 nm	640 nm
Q	Rubidium Telluride	320 nm	300 nm

FIGURE 39 Quantum efficiency of photocathode/window combinations as a function of wavelength. *(EMR Photoelectric.)*

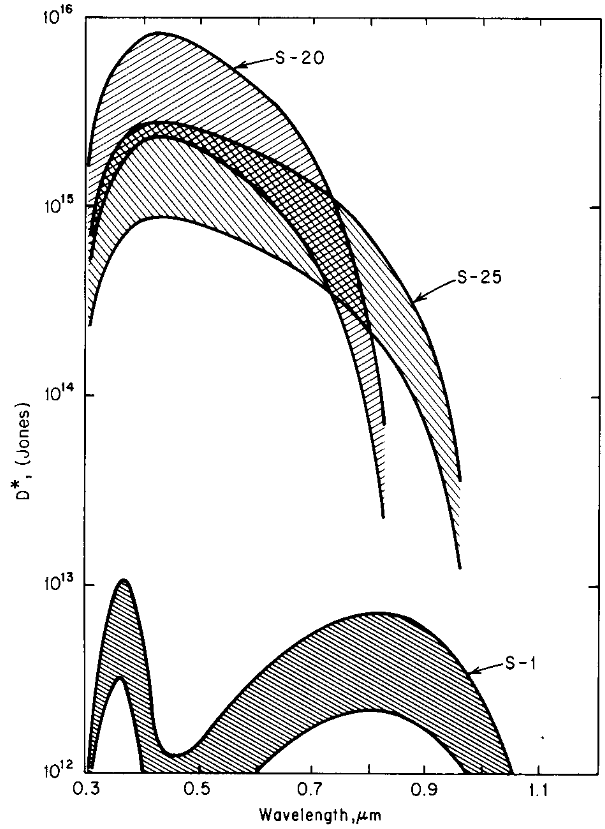

FIGURE 40 Range of D^* for uncooled photomultiplier tubes ($T = 300\,K$.) For abbreviations see Fig. 33. S-25 = same as S-20 but different physical processing. *(Based on material from RCA.)*

Since air absorbs radiation in the region 0.2 to 200 nm (ozone absorbs 200 to 300 nm), it is necessary to include the (windowless) detector in the vacuum with the source.

A useful technique for avoiding the far-ultraviolet window-absorption problem (provided $\lambda >$ vacuum ultraviolet) is to coat the outside of the window of a conventional PMT with an efficient fluorescent material, e.g., sodium salicylate, which absorbs in the ultraviolet and reemits in the blue, and is efficiently detected by most photocathodes (Samson, 1967).

Solar-blind considerations are as follows. Although most photocathodes have high quantum efficiency at short wavelengths, background-noise considerations often preclude their use at very short wavelengths, and very wide bandgap semiconductor photocathodes such as CsI, KBr, Cs_2Te, and Rb_2Te (having peak quantum efficiency a little greater than 10 percent) often give better signal-to-noise ratio. This sacrifice in quantum efficiency to obtain insensitivity to wavelengths greater than those of interest would not be necessary if suitable short-wavelength pass filters were readily available.

For applications where it is desirable that the detector not see much solar radiation, one can use photocathodes whose high work function precludes photoemission for photons of too low an energy. Figure 42 shows quantum efficiency vs. λ for three such photocathodes, tungsten, CsI, and Cs_2Te, compared with Cs_3Sb, and GaAs(Cs), which are not solar-blind.

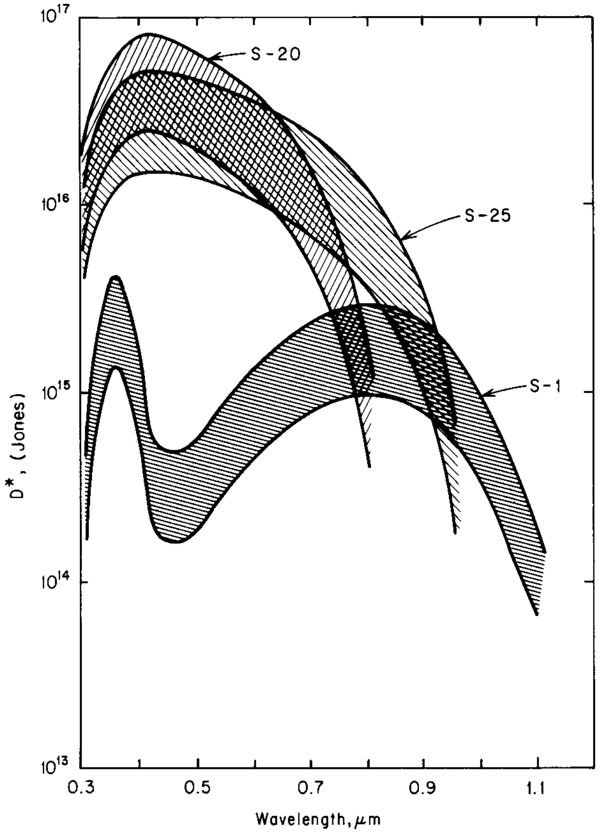

FIGURE 41 Range of D^* for cooled photomultiplier tubes ($T = 200\,\mathrm{K}$). S-25 = same as S-20 but different physical processing. *(Based on E. H. Eberhardt, "D* of Photomultiplier Tubes and Image Detectors," ITT Industrial Labs, 1969.)*

Quantum Efficiency. Figures 38, 39, and 42 show photocathode spectral quantum efficiency (probability that one photoelectron is emitted when a single photon is incident). Note that there are fairly few basic photocathode materials and that the window often determines effective quantum efficiency at short wavelengths.

For $\lambda < 40\,\mathrm{nm}$, a wide variety of photocathode materials are available at high quantum efficiency. Many of these materials, such as tungsten, are not destroyed by being subjected to air, so that open structures can be used, consisting of a photocathode multiplier chain without window. The complete windowless structure is then placed in the vacuum with the source of radiation.

The quantum efficiency at any wavelength can be calculated from the formula

$$\eta = \frac{\mathcal{R} \times 1239.5}{\lambda} \tag{22}$$

where $\mathcal{R}$ = photocathode response, A/W
λ = wavelength, nm

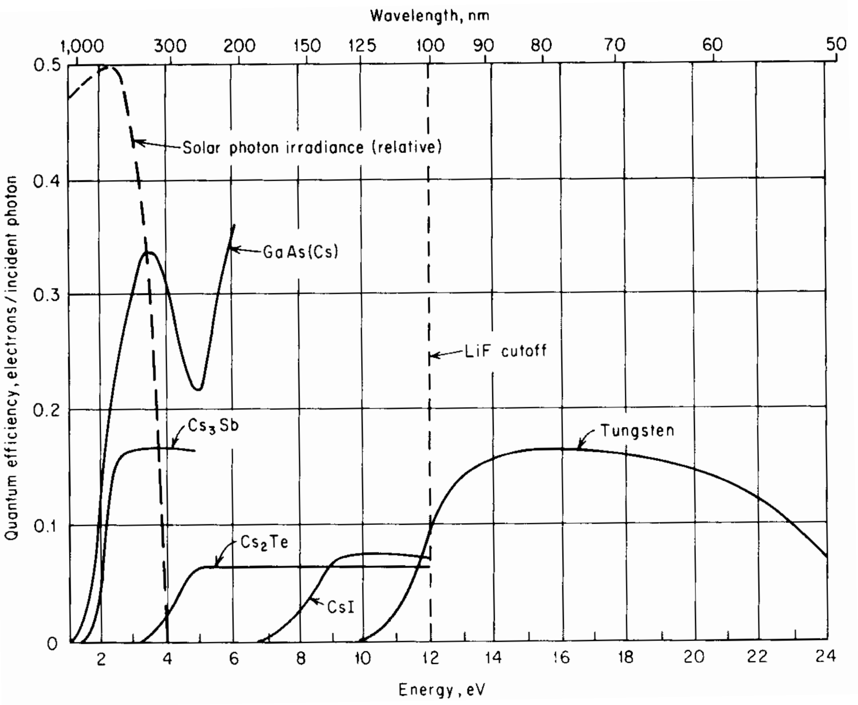

FIGURE 42 Quantum efficiency vs. wavelength (photon energy) for several photoemitters.

A useful technique for improving quantum efficiency, reported by Livingston (1966) and Gunter (1970), involves multipassing the photocathode by trapping the light inside the photocathode using a prism.

Responsivity. PMT responsivity depends upon photocathode quantum efficiency and subsequent dynode gain. For most purposes, the dynode gain in a well-designed PMT introduces no significant degradation in the photocathode signal-to-noise ratio. Figure 37 shows photocathode response expressed in photocurrent (amperes) per incident radiation power (watts).

Noise. The limiting noise in a PMT depends on the level of illumination. For low-level detection, limiting noise is the shot noise on the dark current,

$$i_n = (2ei_{\text{dark}}\Delta f)^{1/2} \tag{23}$$

For high illumination levels the shot noise on the signal photocurrent

$$i_n = (2ei_{\text{signal}}\Delta f)^{1/2} \tag{24}$$

far exceeds that on the dark current. Manufacturers usually express noise as photocathode dark current or anode dark current for given gain, which is therefore traceable to photocathode dark current.

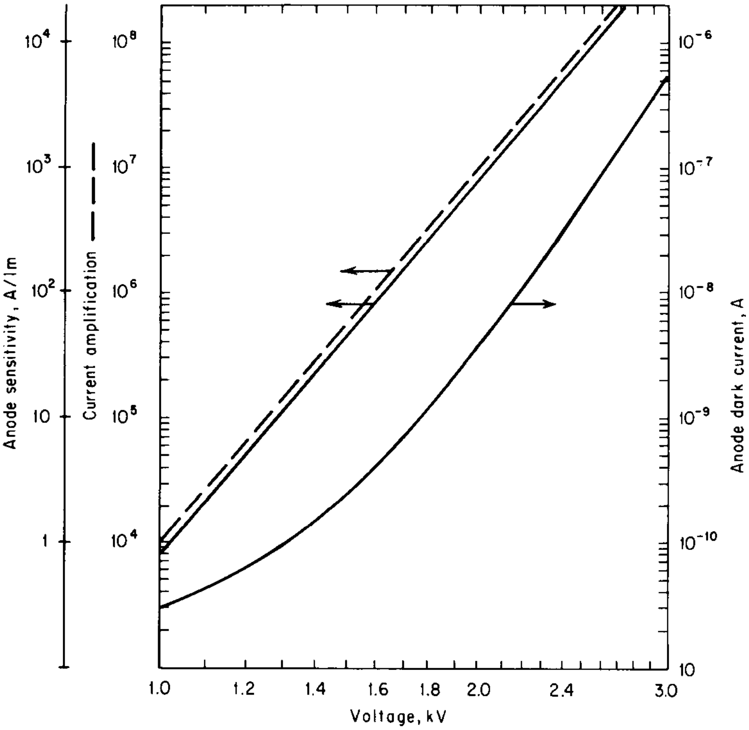

FIGURE 43 Typical current amplification and anode dark current as a function of applied voltage. *(Based on E. H. Eberhardt, "D* of Photomultiplier Tubes and Image Detectors," ITT Industrial Labs, 1969.)*

Photocathode dark current is approximately proportional to photocathode area so that small photocathode effective areas can be expected to have reduced noise. Figure 43 shows how anode dark current and gain increase with applied voltage for a typical PMT.

Minimum detectable power is related to limiting noise through responsivity via

$$\text{NEP} = \frac{i_n}{\mathscr{R}} \tag{25}$$

where $\mathscr{R}$ is in amperes per watt.

Operating Temperature. Dark current due to thermionic emission, usually greater in red-sensitive tubes, can be reduced by cooling (see Cole and Ryer (1972). The trialkali (S-20) performance does not benefit from cooling below 255 K. Maximum beneficial cooling (three to four dark counts per second) for AgOCs (S-1), (Cs)Na_2KSb (S-20), and Cs_3Sb (S-11) is 195, 255, and 239 K, respectively. Most photocathodes become noisier as temperature rises above ambient because of increased thermionic emission. Because its thermionic emission starts at a very low value, (Cs)Na_2KSb is a useful photocathode up to temperatures of approximately 373 K.

Response Time. The rise time of photomultiplier tubes depends chiefly on the spread in transit time during the multiplication process. For photomultiplier tubes, this spread is about 10 ns. Some tubes with specially designed electron optics can give spread as low as

1 ns. The crossed-field PMT makes possible a spread as small as 0.1 ns. Microchannel plate tubes have response times of a nanosecond or less.

For high-speed work (<1 ns rise time), good transmission-line technique must be used to obtain impedance match and to avoid reflection. The bandwidth of the output circuit will depend upon the total capacitance (PMT circuit plus stray capacitances) and the value of the load resistance.

Linearity. Photomultiplier tubes are nearly all linear to about 1 percent for cathode currents of 0.1 μA or less. Some tubes may be linear to better than 0.1 percent but must be individually selected (Bennett, 1966). Probably most of the nonlinearity results from the dynode structure.

Sensitive Area. No fundamental limitation. Only recently available with very small effective areas for extremely low dark current. Magnetic focusing has been used so that only a small fraction of the photocathode is used electron-optically.

Sensitivity Profile. Usually uniform within 20 to 50 percent. Microchannel plate detectors may have uniformity of ±5 percent.

Stability. PMTs are subject to short- and long-term drift which can depend upon anode current, changes in anode current, storage times, and aging or anode life. They are also subject to change if exposed to magnetic fields or changes in temperature. Vibration of the tube may modulate the signal (microphonic effect).

Recommended Circuit. See Fig. 44.

1. Since a PMT is a current generator, increasing output resistance $\mathbf{R}_1$ increases output voltage. An upper limit to $\mathbf{R}_1$ may be imposed either by the time-constant limitation or by nonlinearity, which results from a space charge produced near the anode when the anode is left nearly floating electrically.
2. The rated photocathode current (referred to anode current through gain) should not be exceeded.
3. Care should be taken not to destroy the photocathode with light (heating).
4. When large currents are drawn, it may affect later dynode interstage voltage and hence gain, causing nonlinearity; e.g., in Fig. 44, if the photocurrent from DY 10 to anode becomes comparable to the biasing current, through $\mathbf{R}_{11}$, the gain of the final stage is reduced. This can be avoided by biasing the dynodes with constant-voltage sources.
5. To avoid dynode damage, final dynode current must not exceed the value suggested by the manufacturer.

Photon Counting. At the photocathode, the shot-noise-limited signal-to-noise ratio (with negligible dark current) is

$$\frac{i_s}{i_n} = \frac{i_s}{(2ei_s\Delta f)^{1/2}} \left(\frac{i_s}{2e\Delta f}\right)^{1/2} = \left(\frac{N_s}{2\Delta f}\right)^{1/2} \tag{26}$$

where N_s is the photoelectron rate at the photocathode. Thus, for extremely low levels of illumination, the ideal signal-to-noise ratio becomes very poor. At this point there is much to be gained by abandoning attempts to measure the height of the fluctuating signal (Fig. 45*a*) in favor of digitally recording the presence or absence of individual pulses (Fig. 45*e*).

Single photoelectron counting can be achieved by using a pulse amplifier (see Fig. 46), which suppresses spurious dark-noise pulses not identical in amplitude and shape to those produced by photoelectrons.

An upper practical limit for (random) photon counting is set by convenient amplifier bandwidths at about $10^5\,\text{s}^{-1}$. For reasonable (1 percent) statistical accuracy, this implies a 10-MHz bandwidth.

Gallium Phosphide Dynodes. The development of GaP dynodes for increased

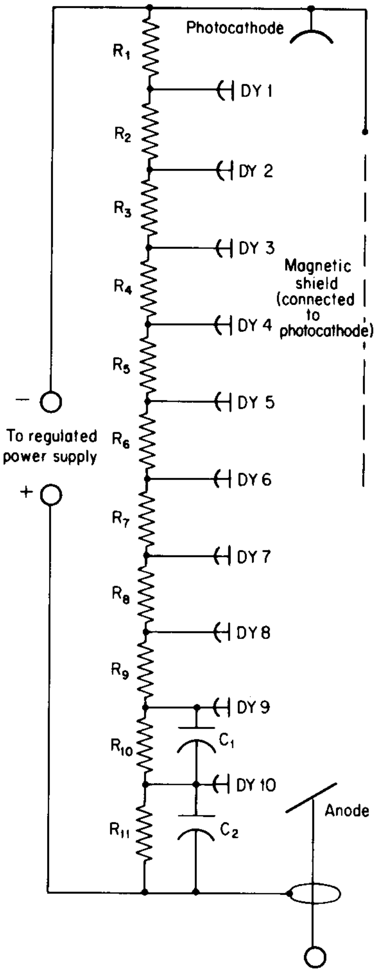

FIGURE 44 $C_1 = 68\,\text{pF} \pm 10$ percent, 500 V (dc working); $C_2 = 270\,\text{pF} \pm 10$ percent, 500 V (dc working); $\mathbf{R}_1 = 220\,\text{k}\Omega \pm 5$ percent, 1/4 W; $\mathbf{R}_2 = 240\,\text{k}\Omega \pm 5$ percent, 1/4 W; $\mathbf{R}_3 = 330\,\text{k}\Omega \pm 5$ percent, 1/4 W; $\mathbf{R}_4$ to $\mathbf{R}_{11} = 200\,\text{k}\Omega \pm 5$ percent, 1/4 W. *(Based on E. H. Eberhardt, "D* of Photomultiplier Tubes and Image Detectors," ITT Industrial Labs, 1969.)*

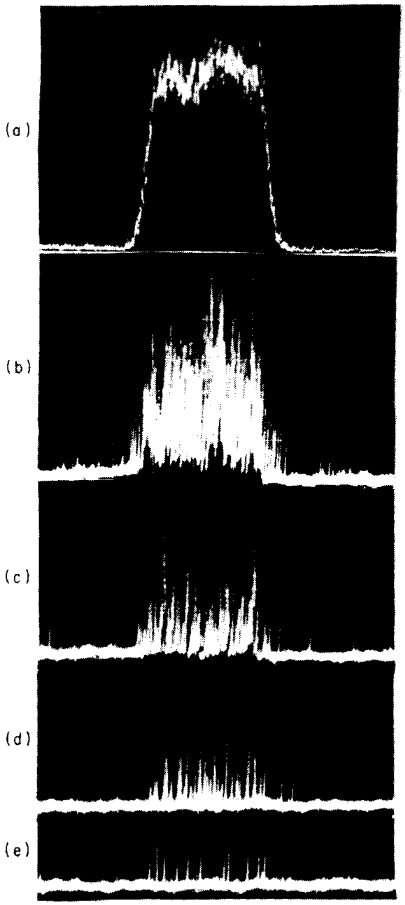

FIGURE 45 Oscilloscope presentation of PMT output when reviewing square-wave chopped light pulse. In (*a* to *e*) intensity is reduced and gain increased commensurately. *(Courtesy of E. H. Eberhardt.)*

secondary-electron production (Simon et al., 1968; Morton et al., 1968) makes possible unambiguous discrimination of small numbers of individual photoelectron counts which was not previously possible with lower dynode gains. This is shown in Fig. 47, where the spread in number of secondary electrons ($N \times \text{gain}$) is just $(N \times \text{gain})^{1/2}$.

In addition to the aforementioned fundamental advantage of high dynode gain, the large gain per stage in the first dynodes also helps discriminate against noise introduced by later stages of amplification. Also, fewer stages of amplification are required.

GaN. Gallium nitride photoconductive and photovoltaic detectors have spectral response in the ultraviolet (UV) from ≈200 to 365 nm as illustrated in Fig. 48. Response at visible wavelengths is absent, so that no special filtering is required to detect UV in the presence of visible lighting. These solid-state devices are potentially useful for operation at elevated temperatures, in high-vibration environments, and in other environments unsuitable for photomultiplier tubes. The photoconductive version of this device uses interdigitated contact electrodes because of the very high impedance of the GaN films.

Sensitivity: $D^* = 10^{13}$ Jones.

Response: Photoconductive 100–1000 A/W; photovoltaic 0.2 A/W.

Resistance: Photoconductor $1 \times 10^{11} \Omega$.

Dynamic range: Linear over five to six orders of magnitude.

Time constant: Photoconductive 0.2–1 ms; photovoltaic 0.16 μs.

Size: 1-mm (1 × 1 mm).

Manufacturer: APA Optics.

CdS and CdSe. Cadmium sulfide and cadmium selenide photoconductors are available for detection of visible light out to 700 to 800 nm. CdS and CdSe films have sheet resistivity in the range of 20 mΩ per square at an illumination level of 2 footcandles. The devices are typically made in a linear or serpentine configuration consisting of 2 to 500 squares to maximize the length-to-width ratio. A variety of material "types" are available, offering unique spectral curves for various applications, depending upon the source color. CdS and CdSe are typically slow detectors, with response times of 5 to 100 ms, with speed improving at higher light levels. These devices exhibit "memory" or "history" effects, where the response is dependent upon the storage condition preceding use—the length of storage and time in use, and differences between the storage light level and the light level during use. These history effects may amount to changes in resistance from less than 10 percent to over 500 percent. CdSe has comparably greater memory effect than CdS.

CdS and CdSe are useful for a variety of commercial applications, both analog and

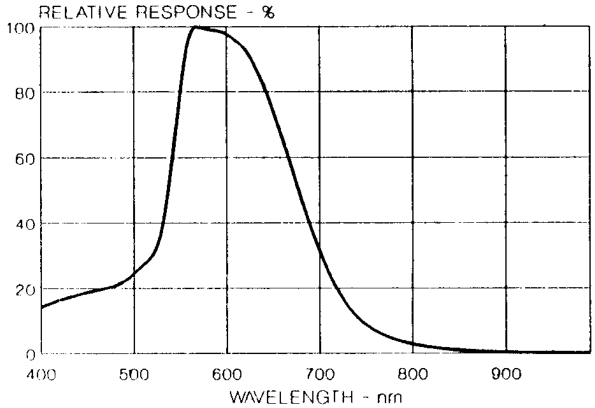

FIGURE 49 Relative spectral response for a "Type 0" CdS photoconductive cell. *(EG&G VACTEC,* Optoelectronics Data Book, *CdS Photoconductive Cells.)*

digital, such as camera exposure control, automatic focus and brightness controls, densitometers, night light controls, etc. They are comparatively inexpensive and are available in a wide range of packages and resistance values, including dual cell configurations.

Spectral response: See Figs. 49–54.

Resistance and sensitivity: See Figs. 55–60.

Temperature coefficient of resistance: See Figs. 61–66.

Light history effects: See Fig. 67.

Detector size: 4 × 4 mm to 12 × 12 mm approximate, dual elements available.

Manufacturers: EG&G VACTEK.

CdTe. Cadmium telluride and cadmium zinc telluride detectors are chemical group II-VI materials having an energy bandgap of about 1.6 eV, corresponding to a spectral cutoff in the vicinity of 775 nm. These devices, however, are principally used for gamma ray detection because of their high z number which translates into a high absorption coefficient for gamma rays. The principal advantage of CdTe in this application is its ability to operate at room temperature, in comparison with Ge gamma ray detectors which must typically be cooled to 77 K. Figure 68 illustrates the absorption of CdTe as a function of gamma ray energy out to 300 keV.

Sensitivity: See Fig. 68.

Standard sizes: Wafers in 10- and 16-mm dia.; rods 7 × 2 × 2 mm; cubes 2 × 2 × 2.

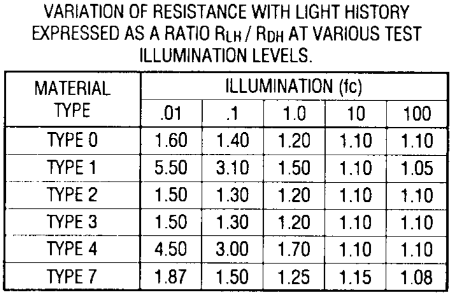
Standard thickness: 1 and 2 mm.

Bias voltage: 150–300 V/cm.

Operating temperature range: −10 + 55°C

Leakage current: 10–300 nA

Capacitance: 10 pF



VARIATION OF RESISTANCE WITH LIGHT HISTORY EXPRESSED AS A RATIO R_{LH} / R_{DH} AT VARIOUS TEST ILLUMINATION LEVELS.

Si. Silicon photovoltaic detectors are widely available. They are useful at wavelengths shorter than about 1.1 μm and can even be used for x-ray and gamma ray detection. There are four main silicon detector types:

- *pn* junction photodiodes, generally formed by diffusion, but ion implantation can also be used
- *pin* junctions, which have lower capacitance and hence higher speed, and because of a thicker active region have enhanced near-IR spectral response
- UV- and blue-enhanced photodiodes
- avalanche photodiodes with significant internal gain, combining high speed and sensitivity

The main parameters of interest are spectral response (see Fig. 69), time constant, and zero-bias resistance or reverse-bias leakage current. Silicon material has an indirect bandgap and hence the spectral cutoff is not very sharp near its long-wavelength limit as shown in Fig. 69. The effective time constant of *pn* junction silicon detectors is generally limited by RC considerations rather than by the inherent speed of the detection mechanism (drift and/or diffusion). High reverse bias may or may not shorten charge-collection time, but it generally reduces cell capacitance. Both result in faster response.

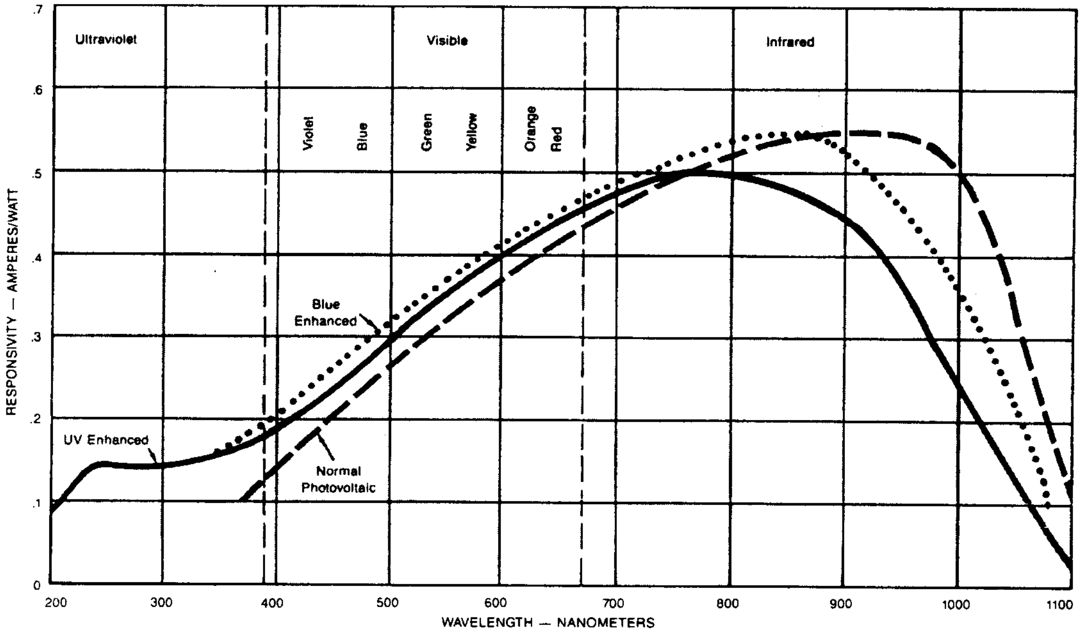

FIGURE 69 Typical spectral response for *pn* junction, blue-enhanced and UV-enhanced silicon photodiodes. *(UDT Sensors, Inc., Optoelectronic Components Catalog.)*

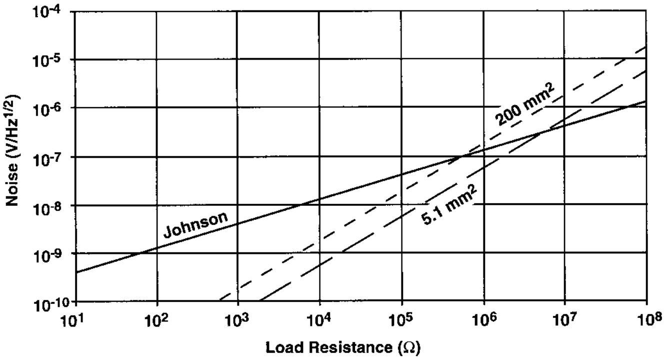

FIGURE 70 Output noise as a function of circuit load resistance for *pin* silicon photodiodes with areas of 5.1 and 200 mm^2, compared with the Johnson noise of the load resistor. Dark current measured at 10-V reverse bias for the detector with area of 5.1 mm^2 is 10 nA, and 100 nA for the detector with an area of 200 mm^2. Note that good preamplifiers have a noise level of about 1 nV/Hz$^{1/2}$, depending upon the bandwidth. *(Detector data from UDT Sensors, Optoelectronic Components Catalog.)*

On the other hand, increased reverse bias causes increased noise, so that a tradeoff exists between speed and sensitivity. For high-frequency applications, load resistance should be made small, although this makes Johnson (thermal) noise comparatively larger, which limits sensitivity (see Fig. 70). In order to keep sensitivity high when using these devices at high frequency, operational (current-mode) amplifiers, which can be built into the detector package, and avalanche photodiodes, which incorporate built-in gain before the load resistor is encountered, have been developed. Very careful regulation of the detector bias is required for stable operation of avalanche photodiodes.

Silicon pn Junction Photodiodes. These are general purpose when high sensitivity is required and time constants on the order of microsecond are permissible. The device construction is illustrated in Fig. 71. These devices are typically operated in a *photovoltaic mode* at zero bias, but can be used in a *photoconductive mode* in which the device is reversed biased.

Sensitivity: $D^*(\lambda_{\text{pk}}) \approx$ mid-10^{12} to 10^{13} Jones, $D^*(2800\text{ K}) \approx 2 \times 10^4$ Jones, becoming

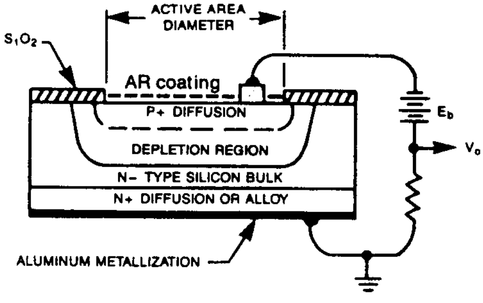

FIGURE 71 Planar diffused silicon photodiode construction. *(UDT Sensors, Optoelectronic Components Catalog.)*

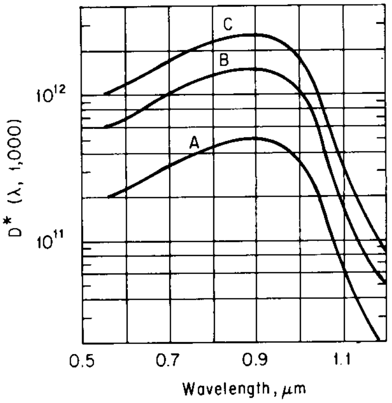

FIGURE 72 D^* vs. λ for small-area *pn* junction silicon photodiodes: curves *A, B,* and *C* correspond to areas of 0.02, 0.2, and 1 cm^2. The lower D^* for smaller-area detector performance is due to amplifier limitations rather than intrinsically poorer D^*, for small-area detectors. *(Texas Instruments, Infrared Devices, SC-8385-366. Reprinted by permission of Texas Instruments.)*

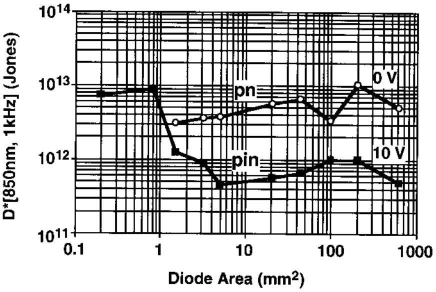

FIGURE 73 D^* as a function of diode area for *pn* junction silicon photodiodes operated in the photovoltaic mode (0 V) and *pin* junction diodes operated in the photoconductive or reverse-bias mode (10 V). *(UDT Sensors, Optoelectronic Components Catalog.)*

amplifier-limited for small-area detectors (see Figs 72 and 73). D^* can also be estimated from the $\mathbf{R}_0A$ product (detector zero-bias resistance or shunt resistance × diode area), which is illustrated in Fig. 74, in combination with Fig. 7, which illustrates the dependence of D^* on $\mathbf{R}_0A$ product.

Noise: See Figs. 75 (noise vs. bias) and 76 (noise vs. temperature); as T drops, impedance rises, so that decreasing noise current produces increasing noise voltage. However, the signal increases even faster, yielding an improved signal-to-noise ratio with cooling. Figure 77 (noise vs. frequency) shows the dependence on bias.

Capacitance: Capacitance is proportional to area and increases slightly with temperature (see Fig. 78).

Responsivity: See Figs. 69 and 75.

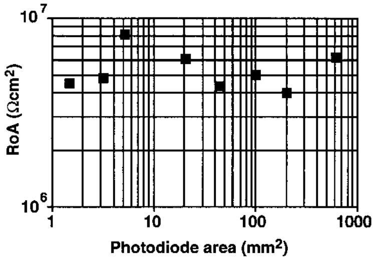

FIGURE 74 The resistance-area product at zero bias ($\mathbf{R}_0A$) and 295 K of silicon *pn* junction photodiodes. The lack of area dependence is evidence that the intrinsic properties of the junction are dominant in these devices.

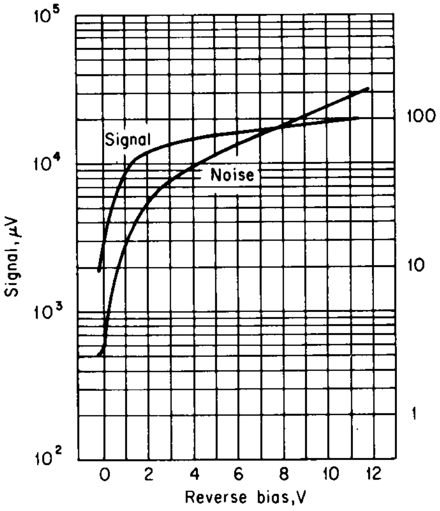

FIGURE 75 Typical *pn* junction signal and noise vs. reverse bias ($\mathbf{R}_L = 10\,\mathrm{M}\Omega$). *(Electronuclear Laboratories, Bull. 1053, 1966.)*

Quantum efficiency: >90 percent quantum efficiency achievable with antireflection coating.

Sensitive area: 0.2–600 mm^2 areas are readily available.

Time constant: Inherently slow for high-sensitivity applications, generally limited by

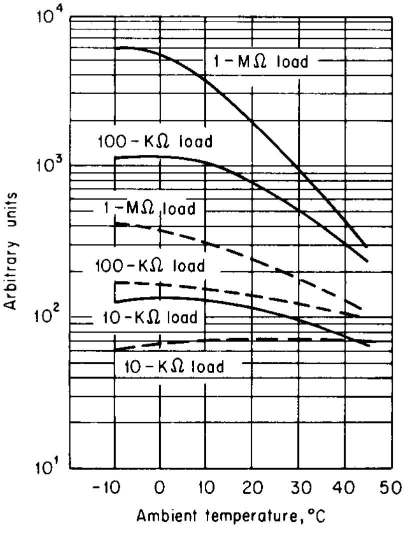

FIGURE 76 Relative signal and noise vs. temperature for *pn* junction silicon photodiode (zero bias); —— = signal; – – – – = noise. *(Electronuclear Laboratories, Bull. 1052, 1966.)*

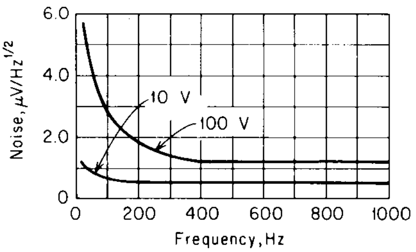

FIGURE 77 Typical *pn* junction and *pin* junction noise-frequency spectrum for different reverse bias ($A = 1 \times 1$ mm; $\mathbf{R}_L = 1\,\mathrm{M}\Omega$). *(Electronuclear Laboratories, Bull. 1078, 1968.)*

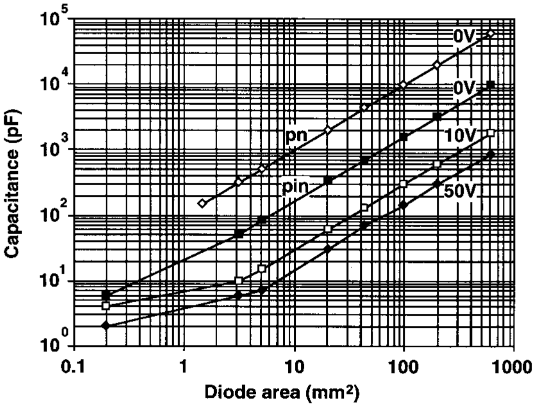

FIGURE 78 Capacitance as a function of detector area for *pn* junction silicon photodiodes operated in the photovoltaic mode (0 V) and *pin* junction photodiodes at 0-, 10-, and 50-V reverse bias. The larger depletion width, which is a consequence of the lightly doped "i" region in the *pin* device, gives *pin* diodes lower capacitance for the same device area. *(UDT Sensors, Optoelectronic Components Catalog.)*

RC (depends directly on device area), but can be limited by carrier diffusion outside the depletion region or by trapping of carriers in deep impurity centers. Typical data for a circuit using a 50-Ω load resistor is illustrated in Fig. 79.

Operating temperature: Ambient, but noise (leakage current) can be reduced by operating at lower temperatures (see Fig. 76 for typical signal and noise vs. temperature).

Uniformity: Typically ±8 percent across a diode area with a 40-μm focused light spot.

Linearity: 5 percent or better over 10 orders of magnitude flux from 10^{-13}–10^{-3} W/cm^2.

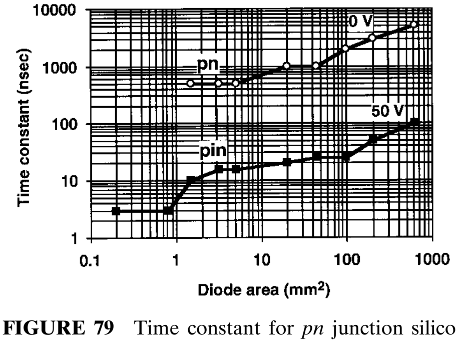

FIGURE 79 Time constant for *pn* junction silicon photodiodes operated in the photovoltaic mode (0 V) and a *pin* junction detector in the photoconductive or reverse-bias mode (50 V). A 50-Ω load was used in both cases, which limits sensitivity because of Johnson noise (see also Fig. 70). *(UDT Sensors, Optoelectronic Components Catalog.)*

Silicon pin Junction Photodiodes. The *pin* junction detector is faster but is also somewhat less sensitive than conventional *pn* junction detectors. *pin* photodiodes have slightly extended red response. In the normal *pn* junction, charge-collection time has a slow and a fast component. The fast component is due to photons absorbed in the depletion layer of the *pn* junction. Since the electric field in the depletion region is strong, carriers are quickly separated by drift. However, photons absorbed deeper in the material, beyond the depletion region, produce carriers which must diffuse to the junction before they are collected, and diffusion times are on the order of a microsecond. This component becomes more significant near the long-wavelength limit of the spectral response. Application of reverse bias in an ordinary *pn* junction detector reduces the capacitance, shortening the RC time constant, and increases the width of the depletion layer thereby increasing the fraction of photons absorbed within the high field region and proportionally increasing the fraction of the fast component of the response.

However, the doping level of the ordinary *pn* junction limits the extent of the depletion layer increase to only 5–10 μm at a reverse bias of 50 V (this assumes an abrupt junction with a concentration of $1 \times 10^{15}\,\mathrm{cm}^{-3}$). *pin* detectors incorporate a very lightly doped region between the *p* and *n* regions which allows a modest reverse bias to form a depletion region the full thickness of the material (~500 μm for a typical silicon wafer). Extended red response in a *pin* device is a consequence of the extended depletion layer width, since longer wavelength photons will be absorbed in the active device region. Unfortunately, the higher dark current collected from generation within the wider depletion layer results in

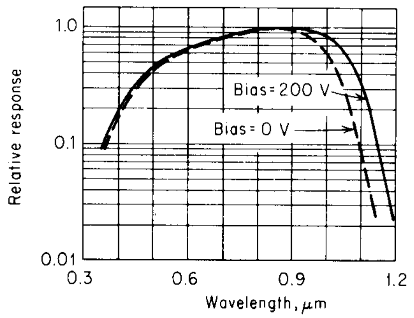

FIGURE 81 Dependence of spectral response on bias for silicon photodiodes. *(Electronuclear Laboratories, Bull. 1076, 1968.)*

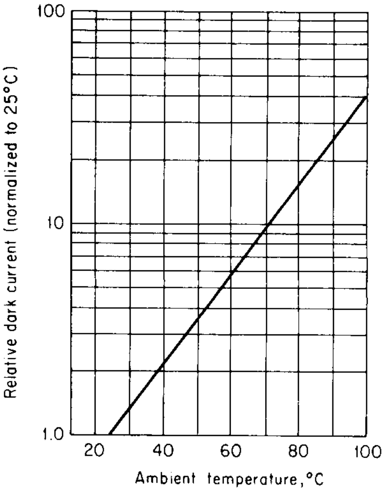

FIGURE 82 Relative dark current vs. temperature for *pin* junction silicon photodiode (bias—100 V). *(Electronuclear Laboratories, Bull. 1076, 1969.)*

lower sensitivity. Generation of carriers can be minimized by minimizing the concentration of deep-level impurity centers in the detector with careful manufacturing. Operation at lower temperature will also reduce the dark current.

Sensitivity: $D^*(\lambda_{pk}) = 1 \times 10^{12}$ Jones for 2 mm^2 area (depends slightly on bias, see Figs. 73 and 81). For high-speed operation, detectivity is lower (see Fig. 70).

Noise: Depends upon diode area and circuit load resistance. Johnson noise will dominate at low values of load resistance when circuit is optimized for fast response. Preamp noise may also limit. See Fig. 70.

Responsivity: Similar to *pn* junction. See Fig. 69.

Quantum efficiency: >90 percent quantum efficiency achievable with antireflection coating.

Capacitance: Proportional to detector area. See Fig. 78.

Operating temperature: See Fig. 82.

Time constant: Varies with capacitance (device area); see Fig. 79.

Sensitive area: 0.2–600 mm^2 readily available.

Recommended circuit: Same as for *pn* junction photodiodes. See Figs. 80 and 83.

Stability: See Fig. 8 and section relating to stability. Check with manufacturer.

Manufacturers: Same as for *pn* junction photodiodes.

UV- and Blue-enhanced Photodiodes. Blue- and UV-enhanced photodiodes may improve the quantum efficiency by 50 to 100 percent over standard photodiodes in the blue and UV spectral region. The quantum efficiency of ordinary *pn* and *pin* junction photodiodes degrades rapidly in the blue and UV spectral regions. This is because the high absorption coefficient of silicon at these wavelengths causes the photocarriers to be generated within the heavily doped $p+$ (or $n+$) contact surface where the lifetime is short due to the high doping and/or surface recombination. Blue- and UV-enhanced photodiodes optimize the response at short wavelengths by minimizing near-surface carrier

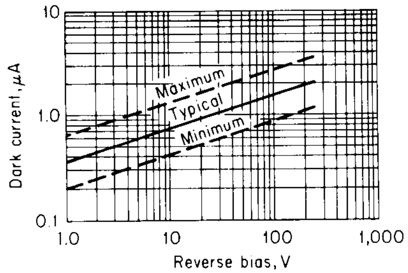

FIGURE 83 Typical dark current vs. bias for pin silicon photodiode ($A = 1 \times 1$ mm). *(Electronuclear Laboratories, Bull. 1078, 1968.)*

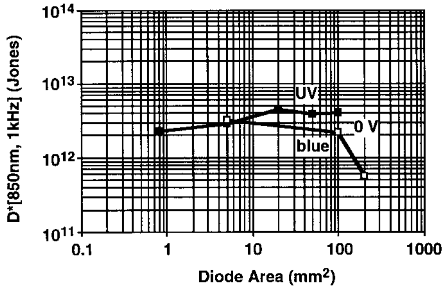

FIGURE 84 D^* as a function of diode area for blue- and UV-enhanced silicon photodiodes operated in the photovoltaic mode (0-V bias). *(UDT Sensors, Optoelectronic Components Catalog.)*

recombination. This can be achieved by using very thin and highly graded $p+$ (or $n+$ or metal Schottky) contacts, by using lateral collection to minimize the percentage of the surface area which is heavily doped, and/or passivating the surface with a fixed surface charge to repel minority carriers from the surface. These devices typically have quartz windows or UV-transmissive glass, compatible with good transmission into the UV spectrum. The user should be aware that UV and higher energy radiation in particular can alter the fixed charge conditions in the surface region of silicon and other detectors (typically in the surface oxide) which can cause the detector performance to drift and/or be unstable (see Fig. 8).

Sensitivity: See Figs. 69 and 84; $D^*(\lambda_{\text{pk}}) = 3\text{–}5 \times 10^{12}$ Jones for diodes with areas of 1–100 mm^2 at $V_R = 0$, $R_L = 40\ \text{M}\Omega$.

Quantum efficiency: Same as *pn* junction photodiodes, but enhanced in the UV and blue regions by 50 percent or more (see Fig. 69).

Responsivity: see Fig. 69.

Capacitance: Comparable to *pn* junction photodiodes (See Fig. 85).

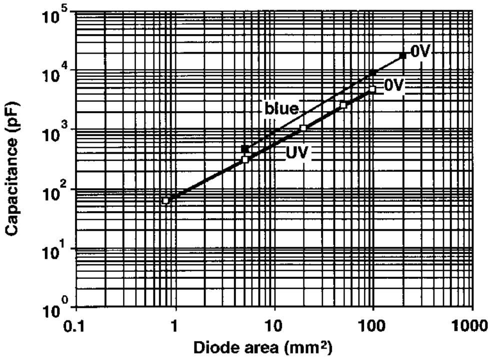

FIGURE 85 Capacitance as a function of detector area for blue- and UV-enhanced silicon photodiodes operated in the photovoltaic mode (0 V). The capacitance per unit area is close to that of *pn* junction photodiodes shown in Fig. 78. *(UDT Sensors, Optoelectronic Components Catalog.)*

Operating temperature: Ambient.

Time constant: Dependent upon device type. Increases with device area; 200 ns–6 μs for areas 1–100 mm^2 (see Fig. 86).

Sensitive area: 1–200 mm^2 readily available.

Recommended circuit: Same as *pn* junction photodiodes.

Stability: See Fig. 8 and section relating to stability. Check with manufacturer.

Manufacturers: See list for silicon *pn* junction photodiodes.

Silicon Avalanche Photodiodes (APDs). The avalanche photodiode, or APD, is especially useful where both fast response and high sensitivity are required. Whereas normal photodiodes become Johnson- or thermal-noise-limited when used with a low-impedance load resistor for fast response, avalanche photodiodes make use of internal multiplication, associated with reverse breakdown in the *pn* junction in order to keep the detector noise above the Johnson noise level. [Because the response time is usually RC-limited, small load resistors (often 50 Ω) are used to achieve fast signal response. However, as the load resistor is decreased, the detector noise voltage decreases in direct proportion, whereas the Johnson noise decreases only as the square root of the load resistor. Thus, the detector noise voltage can become lower than the Johnson noise for load resistance values smaller than a critical value. With an APD device, lower values of load resistors can be used without reaching the critical value because the internal gain boosts the detector noise voltage.]

Stable avalanche or multiplication is made possible by a guard-ring construction using n^+pp^+, Schottky-nn^+, or $n^+p\pi p^+$ structure; beveled *pin* structure (see Fig. 87); mesa structures; or other structures which prevent surface breakdown (Sze, 1981). However, very careful bias control is essential for stable performance. An optimum gain exists below which the system is limited by receiver noise and above which shot noise dominates receiver noise and the overall noise increases faster than the signal (Fig. 88).

In addition to fast-response applications, avalanche photodiodes are useful whenever amplifier noise is limiting, e.g., small-area devices. Signal-to-noise-ratio improvements of one to two orders of magnitude over a nonavalanche detector can be achieved.

APDs are sometimes used in combination with scintillator crystals such as CsI to detect high-energy radiation in the range of 10 to 1000 keV.

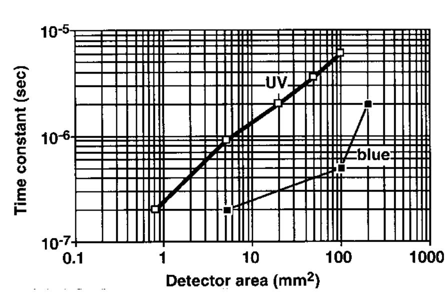

FIGURE 86 Time constant for UV- and blue-enhanced silicon photodiodes as a function of detector area at zero-volts bias. A 50-Ω load was used in both cases. *(UDT Sensors, Optoelectronic Components Catalog.)*

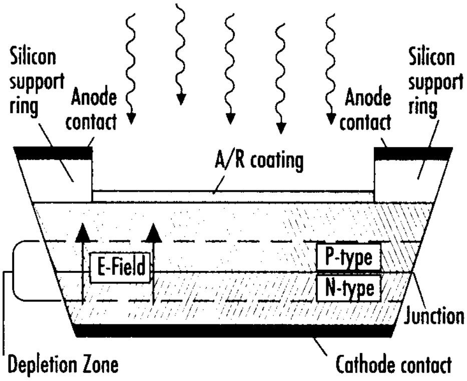

FIGURE 87 Cross section of a beveled-edge silicon avalanche photodiode. The beveled edge prevents early breakdown. *(Advanced Photonix, Avalanche Photodiode Catalog.)*

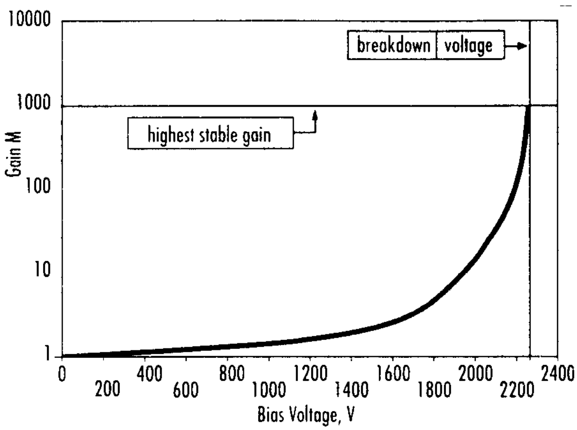

FIGURE 88 Gain as a function of reverse bias can reach 1000. This operating point is very close to breakdown and requires careful bias control. *(Advanced Photonix, Avalanche Photodiode Catalog.)*

Sensitivity: D^* 3–5 × 10^{13} Jones (see Fig. 89).

Noise: Function of detector area. As gain increases, noise increases (see Fig. 90). Optimum gain is where avalanche noise equals system noise. Thus, optimum gain is a function of system noise.

Responsivity: Photocurrent is the product of the incident optical power in watts, wavelength in micrometers, and quantum efficiency (η) divided by 1.24 and multiplied by the avalanche gain M. $I_{\text{photo}} = M(P\lambda\eta/1.24)$ (See Figs. 88 and 91).

Quantum efficiency: Typically 85 percent peak (see Fig. 91).

Capacitance: Depends on bias and area (see Fig. 92).

Sensitive area: 20–200 mm^2.

Series resistance: Depends on area; typical values are 40 Ω for 5-mm dia. to 5 Ω for 16-mm dia.

Time constant: See Fig. 93.

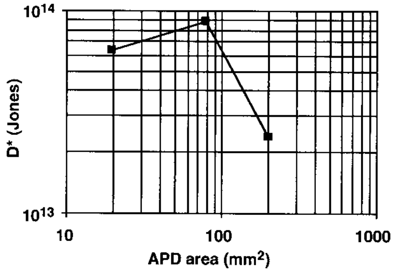

FIGURE 89 D^* for three silicon avalanche photodiodes (APDs) shown as a function of diode area. *(Advanced Photonix, Avalanche Photodiode Catalog.)*

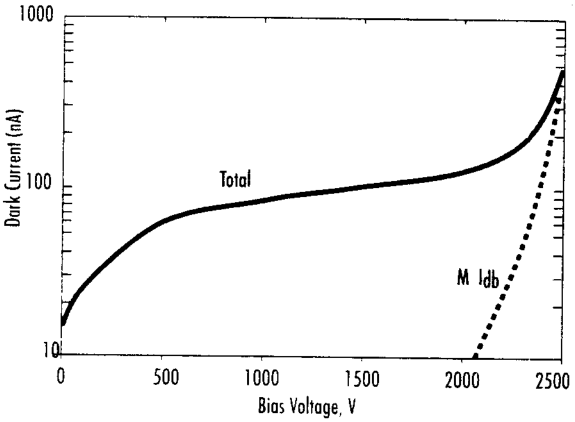

FIGURE 90 Dark current as a function of reverse bias for a 16-mm-diameter APD. At low-bias surface dark current dominates, but avalanche-multiplied bulk dark current increases rapidly as the gain increases. *(Advanced Photonix, Avalanche Photodiode Catalog.)*

Recommended circuit: Requires a filtered high-voltage dc supply that itself must have very low noise and a load resistor. The output may be ac- or dc-coupled. (See Fig. 94.)

Operating temperature: −40–+45°C.

Stability: Exposure to UV or high-energy radiation may affect dark current. See Fig. 8 and section relating to stability. Check with manufacturer.

InGaAs. Indium gallium arsenide detectors have been developed for optimum performance with fiber-optic communications at 1.3 and 1.55 μm. This detector material has a direct bandgap and represents one of several compound semiconductor alloy systems specially developed for photodetectors. In the case of this alloy of two group III-V chemical compound semiconductors, the ratio of InAs to GaAs controls the spectral cutoff, allowing the detector to be optimized for a particular wavelength. InGaAs detectors have generally been specialized for high-speed applications with optimum sensitivity since these performance factors can drive a fiber-optic system throughput and cost. For this reason, available devices include:

- *pin* photodiodes
- avalanche photodiodes (APDs)

The significance of these devices to fiber-optic applications is reflected in the number of vendors who sell integrated packages of InGaAs photodetectors combined with preamplifiers and fiber-optic pigtails.

The InGaAs alloy system allows the spectral response to be tailored to longer wavelengths than the quartz fiber-optic bands and devices with cutoffs of 2.2 and 2.6 μm are also available.

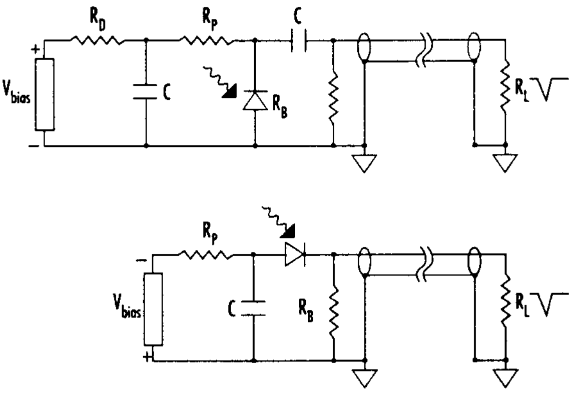

FIGURE 94 ac- and dc-coupled APD circuits with a filter following the power supply and a coaxial cable on the output. *(Advanced Photonix, Avalanche Photodiode Catalog.)*

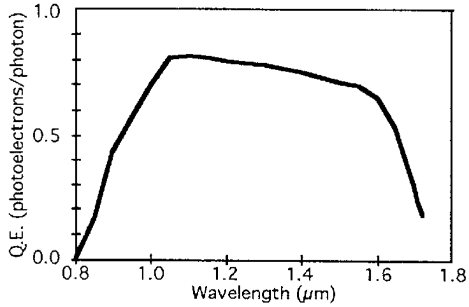

FIGURE 95 Spectral dependence of quantum efficiency for an InGaAs detector having a cutoff of 1.67 μm. *(Sensors Unlimited, data sheet.)*

InGaAs pin Photodiode

Sensitivity: D^* mid-10^{12} Jones for 1.67-μm cutoff; $D^* \approx 1 \times 10^{12}$ Jones for 2.2-μm cutoff, and $D^* \approx 5 \times 10^{11}$ Jones for 2.6-μm cutoff.

Responsivity: 0.85–0.95 A/W in the range of 1.3–1.55 μm.

Quantum efficiency: For 1.67-μm cutoff, see Fig. 95.

Dark current: See Fig. 96.

Capacitance: $0.7–1.2 \times 10^4$ pF/cm^2 for 1.7-μm cutoff; 2.5×10^4 pF/cm^2 for 1.85-μm cutoff; 3×10^4 pF/cm^2 for 2.15-μm cutoff; 5×10^4 pF/cm^2 for 2.65-μm cutoff. See also Fig. 97 for bias dependence.

Time constant: Varies with resistance-capacitance (RC) time (see Fig. 98). Since capacitance depends upon reverse bias, the time constant varies proportionally (see Fig. 97 for dependence of capacitance on bias).

Size: 0.05–3-mm dia.

Recommended circuit: Standard photodiode options; zero bias for best sensitivity, reverse bias for maximum speed.

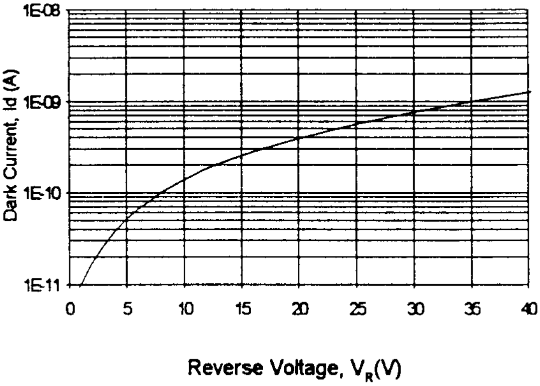

FIGURE 96 Dark current as a function of reverse-bias voltage for a 60-μm-diameter InGaAs detector having a cutoff of 1.67 μm. *(Fermionics, InGaAs Photodiodes.)*

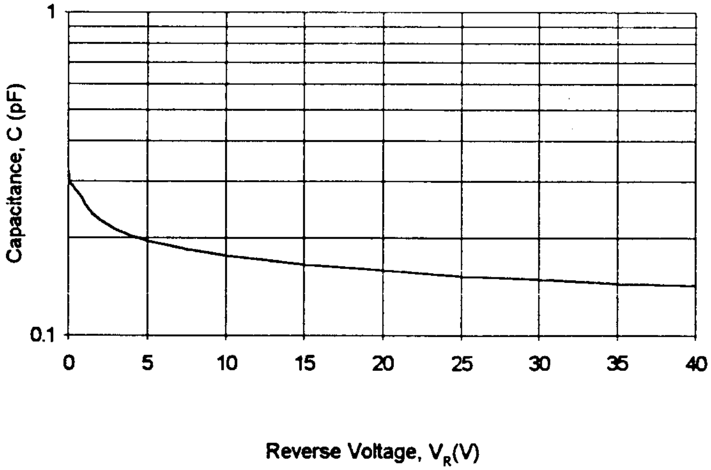

FIGURE 97 Capacitance as a function of reverse-bias voltage for a 60-μm-diameter InGaAs detector having a cutoff of 1.67 μm. *(Fermionics, InGaAs Photodiodes.)*

InGaAs Avalanche Photodiode

Sensitivity: $D^* \approx 5 \times 10^{11}$ Jones for 1.7-μm cutoff. In the fiber-optics industry, the sensitivity is also given in power units of dBm. Figure 99 compares InGaAs *pin,* APD, and Ge APD sensitivities.

Spectral response: 1.0–1.65 μm; see Fig. 100.

Responsivity: 8–10 A/W typical.

Avalanche gain: Critically depends upon reverse bias, see Fig. 101.

Capacitance: At gain of 12, 7.5×10^4 pF/cm^2.

Bandwidth: Up to 3 GHz; see Figs. 102 and 103.

Size: 0.04–0.5-mm dia.

Dark current: Dependent upon reverse bias, device structure, and temperature. See Figs. 104, 105, and 106.

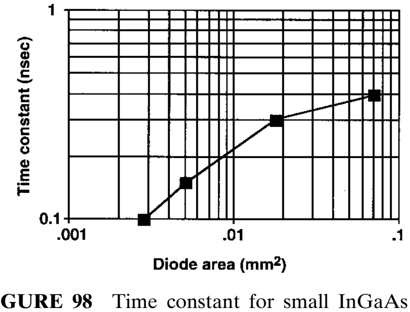

FIGURE 98 Time constant for small InGaAs *pin* photodiodes as a function of diode area measured with a 50-Ω load.

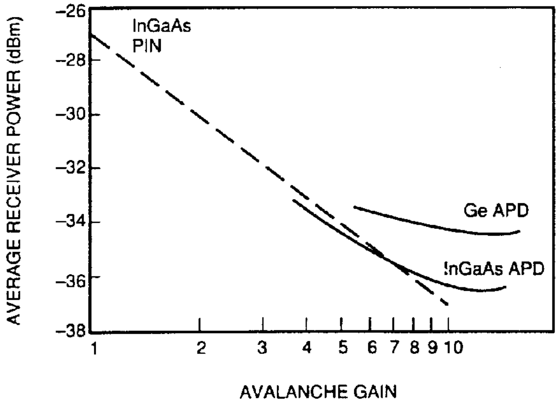

FIGURE 99 APD receiver sensitivity. Typical receiver sensitivity at a receiver rate of 1.7 Gbit/s and $\lambda = 1.3\ \mu m$ for an InGaAs *pin*, Ge APD, and InGaAs APD. *(AT&T, 126A/B,C ASTROTEC InGaAs.)*

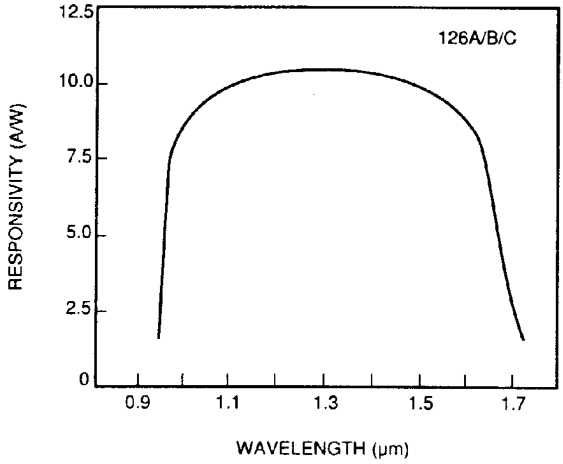
Recommended circuit: See Fig. 107.

Manufacturers: Advanced Photonix, Atomergic Chemetals, AT&T, BSA, EG&G Canada, Electro-Optical Systems, Electro-Optics Technology, Emcore, Epitaxx, Fermionics, GCA Electronics, Germanium Power Devices, Hamamatsu, New Focus, North Coast Scientific, Opto-Electronics, Ortel, Photonic Detectors, Sensors Unlimited, Spire, Swan Associates, Telcom Devices, UDT Sensors.



Note: Responsivity = (chip quantum efficiency) x gain x λ (μm)/1.24. The minimum chip quantum efficiency is 80%, and the minimum pigtail coupling efficiency is 90%.

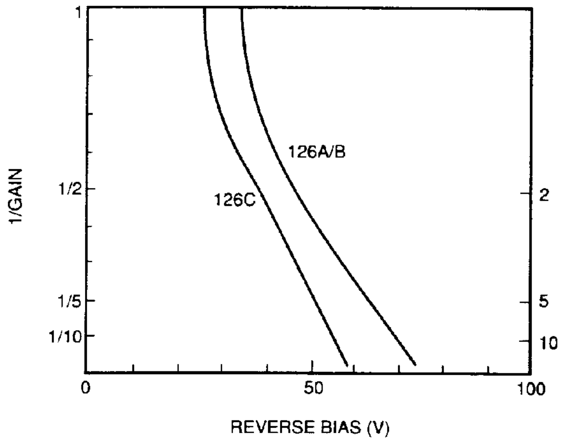

FIGURE 101 Inverse of avalanche gain for an InGaAs avalanche photodiode vs. reverse bias. *(AT&T, 126A/B,C ASTROTEC InGaAs.)*

Ge. Germanium intrinsic photodetectors are similar to intrinsic silicon detectors but offer spectral response out to 1.5 to 1.8 μm. *pn* junction photodiodes offer submicrosecond response or high sensitivity from the visible region to 1.8 μm. Zero bias is generally used for high sensitivity and large reverse bias for high speed. As in the case of silicon, germanium has an indirect bandgap and soft spectral cutoff. The previous discussion on silicon detectors applies in general, with the exception that blue- and UV-enhanced devices are not relevant to germanium detectors. Germanium detectors, because of their narrower bandgap, have higher leakage currents at room temperature, compared to silicon detectors. Detector impedance increases about an order of magnitude by cooling 20°C

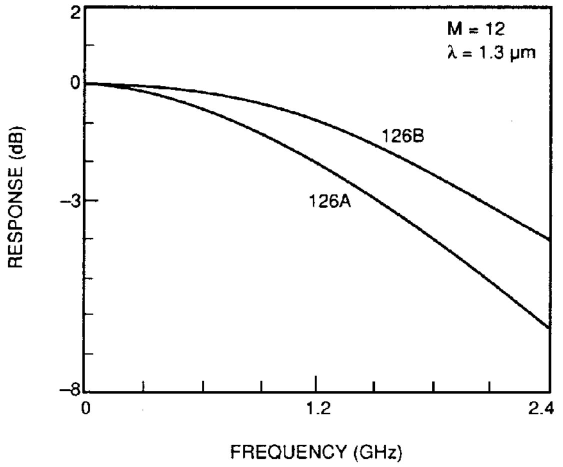

FIGURE 102 Frequency response of InGaAs APD (126A/B). *(AT&T, 126A/B,C ASTROTEC InGaAs.)*

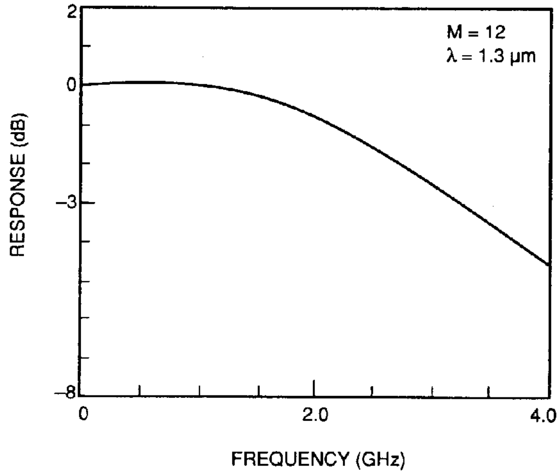

FIGURE 103 Frequency response of InGaAs APD (126C). *(AT&T, 126A/B,C ASTROTEC InGaAs.)*

below room temperature. Thus, performance can improve significantly with thermoelectric cooling or cooling to liquid nitrogen temperature.

As with silicon, the device structure and bias configuration can affect spectral response and rise time. Three detector types are available:

- *pn* junction
- *pin* junction
- avalanche photodiode (APD)

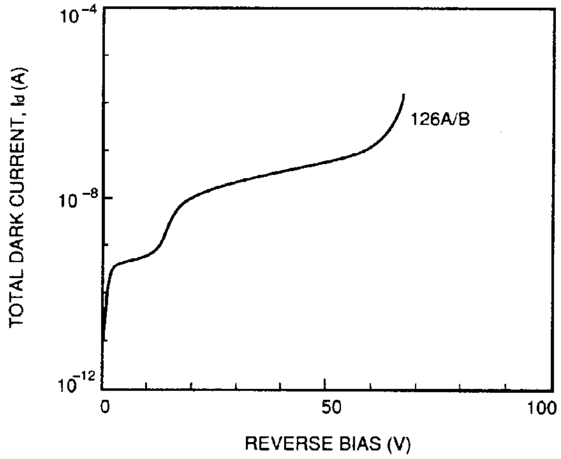

FIGURE 104 Dark current vs. reverse bias of InGaAs APD (126A/B). *(AT&T, 126A/B,C ASTROTEC InGaAs.)*

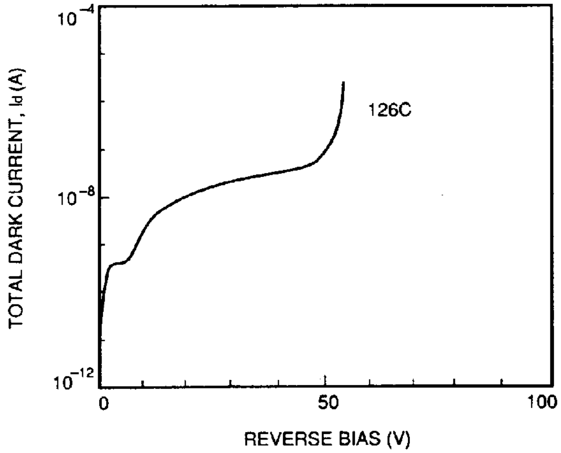

FIGURE 105 Dark current vs. reverse bias of InGaAs APD (126C). *(AT&T, 126A/B,C ASTROTEC InGaAs.)*

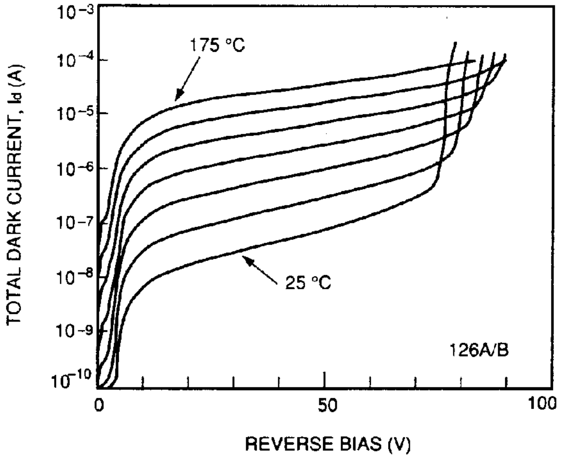
Germanium pn and pin

Sensitivity: $D^*(\lambda\text{peak}, 300\,\text{Hz}, \text{room temperature}) > 2 \times 10^{11}$ Jones, increases significantly with cooling by thermoelectric cooler or liquid nitrogen. (See Figs. 108, 109 and 110).

Quantum efficiency: >50 percent with antireflection coating.

Noise: See Figs. 111 and 112.



Note: The temperature dependence of the 126C dark current is the same as the 126A/B.

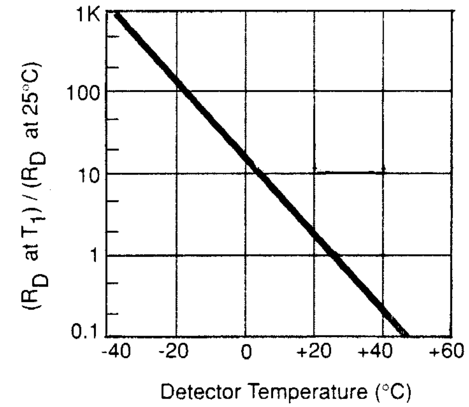

FIGURE 111 Ratio of resistance at temperature T to the resistance at 25°C for a germanium *pn* junction photodiode. *(EG&G Judson, Infrared Detectors, 1994.)*

Responsivity: 0.9 A/W at peak wavelength. see Fig. 108.

Capacitance: Lower for *pin* structure compared with *pn* diode. See Fig. 113.

Time constant: *pin* diodes provide faster response. See Fig. 114.

Sensitive area: 0.25–13-mm dia. standard.

Operating temperature: Ambient, TE-cooled, or liquid nitrogen.

Profile: ±2 percent across active area at 1.3 μm.

Linearity: Excellent over 10 orders of magnitude. See Fig. 115.

Recommended circuit: See previous section on silicon photodiodes.

Manufacturers: Atomergic Chemetals, Cincinnati Electronics, Edinburgh Instruments, EG&G Judson, Electro-Optical Systems, Fastpulse Technology, Germanium Power Devices, Graseby Infrared, Newport/Klinger, North Coast Scientific, Opto-Electronics, Oriel, Oxford Instruments, Scientific Instruments.

Germanium Avalanche Photodiode. The germanium avalanche photodiode (APD) is similar to the silicon APD but has lower optimum gain, longer cut-off wavelength (1.7 μm), and higher leakage current. Germanium APDs combine the sensitivity of a Ge *pn* photodiode and the speed of a *pin* Ge photodiode.

Sensitivity: D^* 2×10^{11} Jones at 30 MHz for a diode with area of 5×10^{-2} mm^2 or about the same as for a *pn* Ge diode with the same area, and about a factor of 4 higher than a *pin* Ge photodiode (compare with Fig. 109). D^* depends on gain.

Gain: See Fig. 116.

Dark current: See Fig. 117.

Capacitance: 2 pF at 20 V reverse bias for 100-μm diameter, 8 pF at 20 V reverse bias for 300 μm dia.

Quantum efficiency: 60–70 percent at 1.3 μm.

Responsivity: Photocurrent is the product of the incident optical power in watts, wavelength in micrometers, and quantum efficiency (η) divided by 1.24 and multiplied by the avalanche gain M. $I_{\text{photo}} = M(P\lambda\eta/1.24)$ (See Figs. 108 and 116).

Operating temperature: Ambient or TE-cooled.

Time constant: 0.2 ns for 100-μm diameter; 0.3 ns for 300-μm diameter; both at 1.3 μm, $M = 10$ and with $R_L = 50\,\Omega$. See Fig. 118.

Sensitive area: 100- and 300-μm dia. standard

Recommended circuit: See circuit recommended for Si APD.

Manufacturers: EG&G Judson, North Coast Scientific.

PbS. Photoconductive lead sulfide was one of the earliest and most successful infrared detectors. Even today it is one of the most sensitive uncooled detectors in the 1.3- to 3-μm

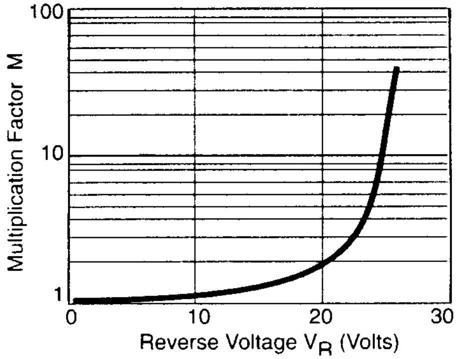

FIGURE 116 Gain as a function of reverse bias for a germanium avalanche photodiode. *(EG&G Judson, Infrared Detectors, 1994.)*

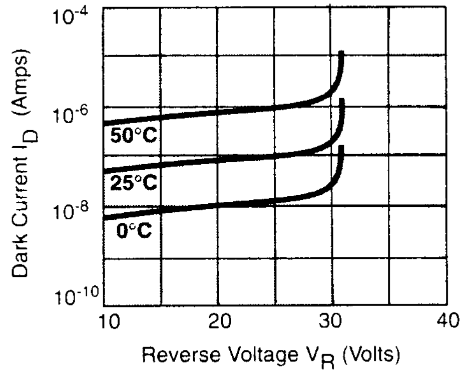

FIGURE 117 Dark current as a function of reverse bias for a germanium avalanche photodiode. *(EG&G Judson, Infrared Detectors, 1994.)*

spectral region. With cooling, PbS sensitivity is competitive with other detectors out to about 4.2 μm; however, its response time is slow.

Many PbS characteristics can be varied by adjusting the chemistry of the deposition process and/or the postdeposition heat treatment. These characteristics include spectral detectivity, time constant, resistance, and upper limit of operating temperature (Johnson, 1984). PbS is generally made by chemical reaction of Pb acetate and thiourea, except for high-temperature (373 K) applications, where evaporation is used. The material is deposited as a thin film (1 to 2 μm thick) on a variety of substrates, such as sapphire. With photolithographic processing, small sensitive areas can be made with comparatively high D^* values.

PbS may be tailored for ambient or room-temperature operation (ATO), intermediate or thermoelectrically cooled operation (ITO), and low-temperature or nitrogen-cooled operation (LTO). They are manufactured differently for particular temperature ranges, as shown in Table 2.

Sensitivity: $D^*1.5 \times 10^{11}$ Jones at 295 K. See Figs. 119–124.

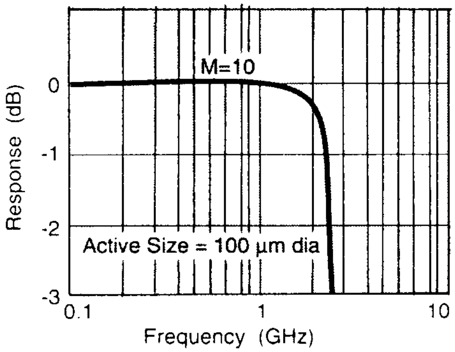

FIGURE 118 Frequency response of a germanium avalanche photodiode at two gain operating points. *(EG&G Judson, Infrared Detectors, 1994.)*

TABLE 2

	Typical operating temperature, K			
	350	273 (ATO)	193 (ITO)	77 (LTO)
Sensitivity	†	Figs. 119, 125	Figs. 120, 123, 125	Figs. 121, 125
$\frac{D^*(\lambda_{\max})}{D^*(500\,\text{K})}$		105	55	17
Noise, cm·Hz$^{1/2}$/W		Fig. 127	Fig. 127	Fig. 127
Dark resistance, MΩ/sq	<0.3	<2	<10	<20
Time constant, μs‡	50	100–500	5000	3000

† At 350 K, cutoff wavelength moves into ~2.4 μm, with $D^*(\lambda_{\max}) \approx 10^{10}$ Jones.

‡ These are typical values; the time constant can be adjusted over two orders of magnitude in fabrication, but D^* is affected.

Responsivity: Depends on detector area, bias, resistance, and operating temperature (see Figs. 125 and 126).

Quantum efficiency: Generally limited by incomplete absorption in the thin film to ≈30 percent as estimated from blip D^* values.

Noise: Dominated by $1/f$ noise at low frequencies. See Figs. 122, 126, and 127.

Time constant: Can be varied in manufacturing. Typical values are 0.2 ms at 295 K, 2–3 ms at 193 and 77 K. See Fig. 126.

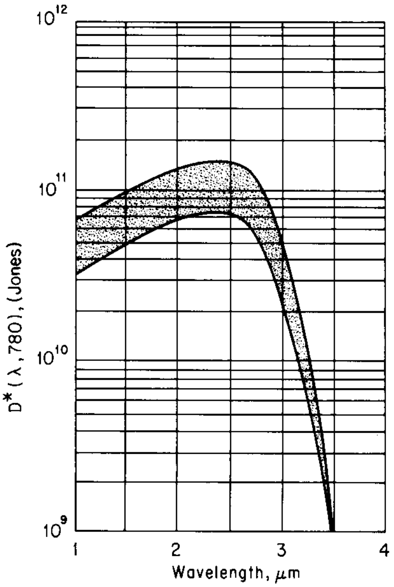

FIGURE 119 Range of spectral detectivities for PbS (ATO) at 295 K; 2π FOV, 295-K background. *(Santa Barbara Research Center.)*

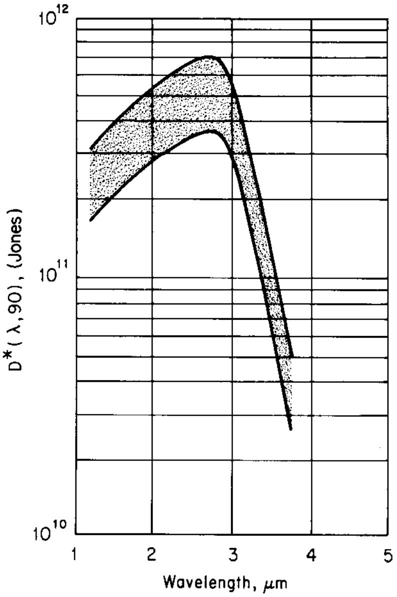

FIGURE 120 Range of spectral detectivities for PbS (ITO) at 193 K; 2π FOV, 295-K background. *(Santa Barbara Research Center.)*

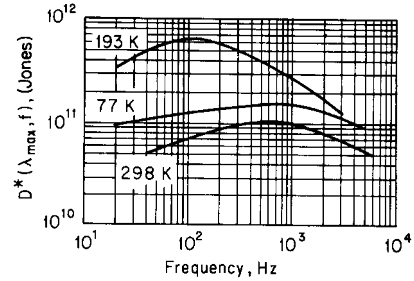

FIGURE 122 Example of detectivity vs. frequency for PbS detectors at various operating temperatures; 2π FOV, 296-K background. *(Santa Barbara Research Center.)*

Sensitive area: Typical commercial sizes are square elements with dimensions of 0.5, 1, 2, and 5 mm on a side.

Capacitance: <1 pF (limited by mounting configuration).

Recommended circuit: Standard photoconductor.

Stability: Exposure to visible and/or UV radiation can induce instability and drift. Stability will recover with storage in the dark, or by baking.

Sensitivity profile: Uniform within 10 percent.

Linearity: Excellent over broad range 10^{-8}–10^{-3} W.

Manufacturers: Alpha Omega Instruments, Atomergic Chemetals, Cal-Sensors,

InAs (Photovoltaic). InAs detectors are single-crystal, intrinsic, direct-bandgap photovoltaic devices for use in the 1- to 4-μm region (spectral cutoff varies with temperature). At room temperautre, InAs provides good sensitivity and submicrosecond response times. At 195 K, InAs performance equals or betters the sensitivity of any other detector in the 1- to 3.5-μm region. Devices with sapphire immersion lenses are available to increase signal responsivity for operation at higher temperatures where the detector is thermal-noise-limited.

Sensitivity: $D^*(\lambda\text{peak})$ varies from 1.2×10^9 Jones at 295 K to 6×10^{11} Jones at 77 K. See Fig. 128.

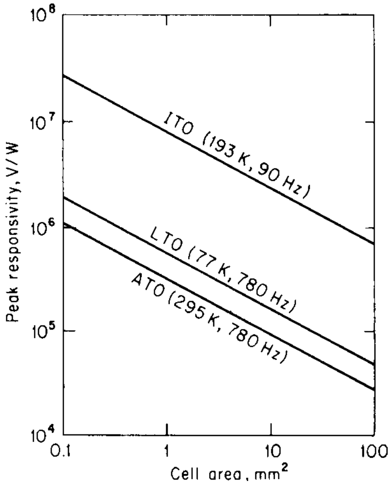

FIGURE 125 PbS typical peak responsivity vs. cell area (actual values range within a factor of two of these shown.)

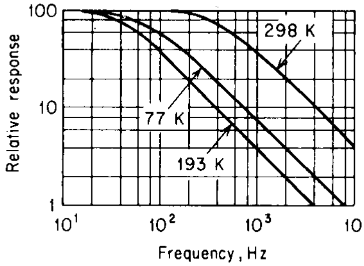

FIGURE 126 Example of signal vs. frequency for PbS detectors. *(Santa Barbara Research Center.)*

Quantum efficiency: Maximum of about 75 percent without antireflection coating.

Noise: Low impedance tends to make preamplifier noise dominate at room temperature; background limited (for 300 K background) at operating temperatures below ≈200 K.

Time constant: Less than 0.5 μs at all temperatures when low values of load resistor are used to lower the RC time constant.

Responsivity: 0.5–1.25 A/W at peak.

Dynamic resistance: See Fig. 129.

Diode capacitance: See Fig. 130.

Sensitive area: Standard sizes 0.25–2-mm dia.

Operating temperatures: 77–300 K.

Linearity: Anticipated to be very good over many decades.

Sensitivity profile: ±15 percent.

Recommended Circuits:

Open circuit: PV InAs detectors with areas less than 2×10^{-2} cm^2 require no bias when operated and can be connected directly into the input stage of amplifier (capacitor ensures elimination of dc bias from amplifier) (Fig. 131*a*).

Transformer: useful when using InAs at zero bias, particularly at room temperature where diode impedance is low (Fig. 131*b*).

Reversed bias: At temperatures greater than 225 K considerable gain in impedance and responsivity is achieved by reverse-biasing (Fig. 131*c*).

Fast response: To utilize the short intrinsic time constant, it is sometimes necessary to load the detector to lower the RC of the overall circuit (reverse bias will also lower detector capacitance) (Fig. 131*d*).

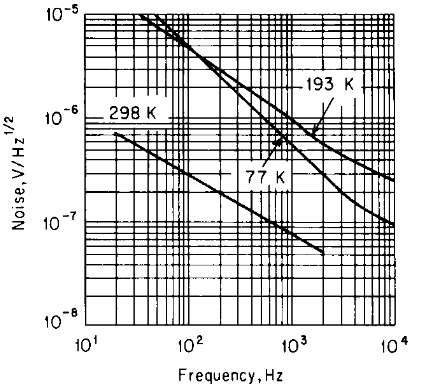

FIGURE 127 Example of noise vs. frequency for PbS detectors (1 × 1-mm area). *(Santa Barbara Research Center.)*

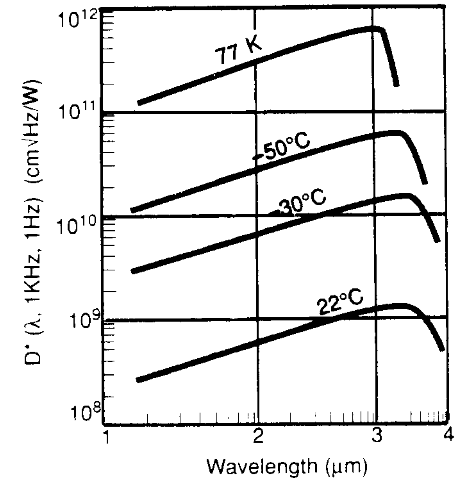

FIGURE 128 D^* vs. wavelength for InAs detector operating at temperatures ranging between 77 K and 295 K. *(EG&G Judson, Infrared Detectors, 1994.)*

Manufacturers: Atomergic Chemetals, Boston Electronics, BSA Technology, Cincinnati Electronics, EG&G Judson, MCP Wafer Technology.

PbSe. Lead selenide is an intrinsic, thin-film photoconductor, whose long-wavelength spectral response and speed of response exceeds that of PbS. At room temperature, PbSe has peak D^* which can exceed 1×10^{10} Jones with a spectral cutoff out to 4.4 μm. At liquid-nitrogen temperature, InSb offers twice the D^*, largely because PbSe offers response out to 7 μm at 77 K, considerably longer than InSb. However, for intermediate temperatures, from 180 K to room temperature, PbSe offers competitive D^* combined with moderately fast response (Johnson, 1984). PbSe technology has made a significant

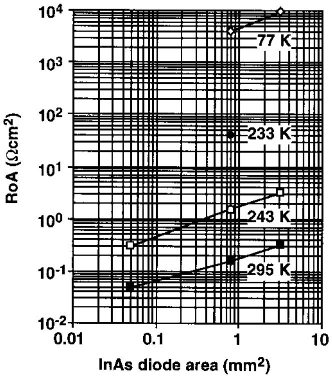

FIGURE 129 RoA of InAs photodiodes shown as a function of diode area. Lower impedance per unit area for smaller devices indicates that these devices are surface-leakage-limited. *(EG&G Judson, Infrared Detectors, 1994.)*

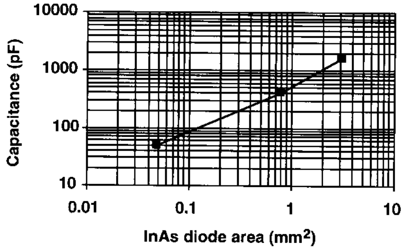

FIGURE 130 Capacitance of InAs photodiodes shown as a function of diode area. Capacitance will not change appreciably with temperature. *(EG&G Judson, Infrared Detectors, 1994.)*

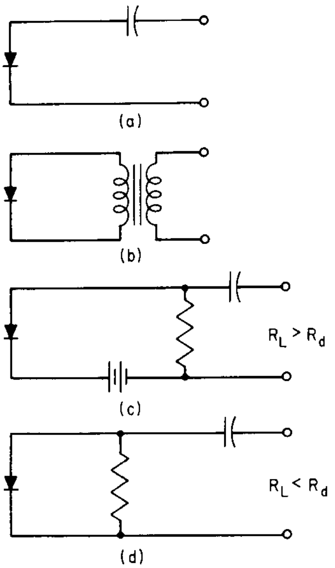

FIGURE 131 Recommended circuits for InAs detectors: (*a*) open circuit; (*b*) transformer; (*c*) reversed bias; (*d*) fast response.

advance in the past decade in some vendors being able to reproducibly make high-performance detectors.

Sensitivity: $D^* \approx 1 \times 10^{10}$ Jones at 300 K, increases with cooling (see Figs. 124 and 132). D^* is limited by $1/f$ noise at low frequencies (see Fig. 133).

Response: Figure 134 shows responsivity in amps per watt for a high-quality detector

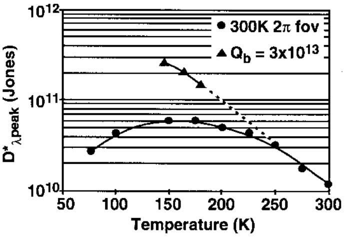

FIGURE 132 D^* of PbSe as a function of temperature for two background flux conditions: high background of 2π field of view and reduced background of 3×10^{13} photons/cm^2/sec. D^* at the higher background flux reaches a maximum around 160 K because the background noise increases at lower temperatures due to the increase in long-wavelength spectral response of the detector.

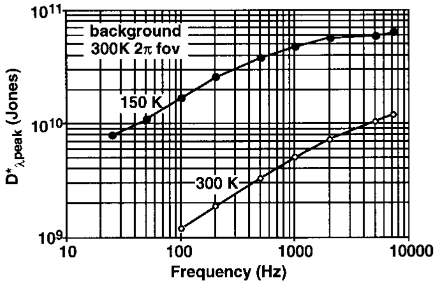

FIGURE 133 D^* of PbSe as a function of frequency for two temperatures. PbSe has considerable $1/f$ noise which reduces D^* at lower frequencies, especially at high temperatures.

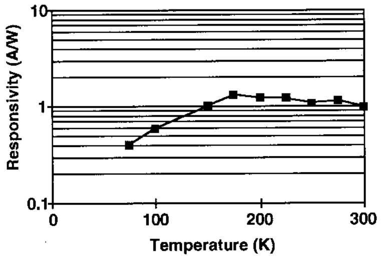

FIGURE 134 Responsivity in A/W of PbSe thin-film photoconductive detectors as a function of temperature for a high background flux level. Multiply by detector resistance to get V/W.

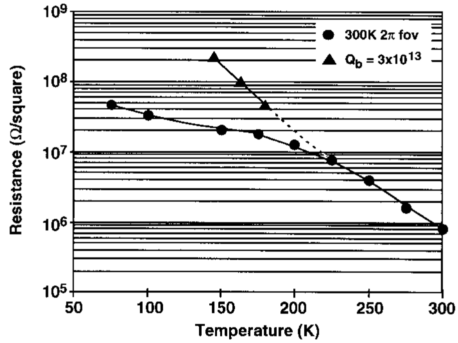

FIGURE 135 Resistance (Ω/square) of PbSe thin films as a function of temperature for two background flux levels. At any temperature, the absolute value can be varied by altering the manufacturing process in chemical deposition and/or heat treatment.

with a length of 0.016 cm and width of 0.024 cm. Responsivity in volts per watt is obtained by multiplying A/W data by resistance (see Fig. 135). Responsivity will vary inversely with detector length (see Figs. 136 and 137).

Noise: Figure 138 shows the noise as a function of temperature for a detector with a length of 0.016 cm and width of 0.024 cm. Noise as a function of frequency is shown in Fig. 139.

Resistance: Figure 135 shows the resistance as a function of temperature for a detector with a length of 0.016 cm and width of 0.024 cm.

Capacitance: 1 pF (limited by mounting configuration).

Time constant: See Figs. 140 and 141. Time constant will be longer when detector is operated in reduced background flux condition.

Stability: Exposure to visible and/or UV radiation can induce instability and drift. Stability will recover with storage in the dark at room temperature.

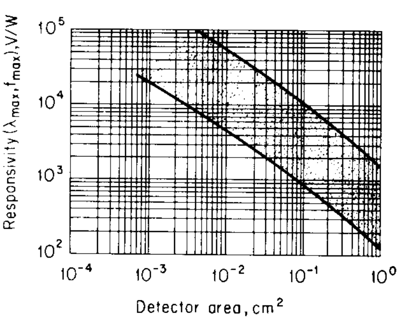

FIGURE 136 Expected range of peak responsivities vs. detector size, typical PbSe (ATO) infrared detectors. *(Santa Barbara Research Center.)*

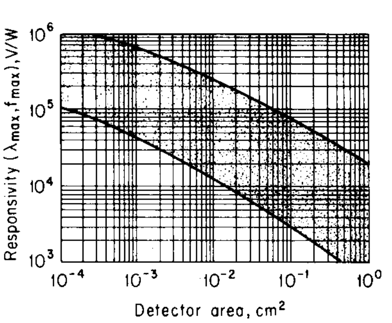

FIGURE 137 Expected range of peak responsivities vs. detector size, PbSe (ITO and LTO) infrared detectors. *(Santa Barbara Research Center.)*

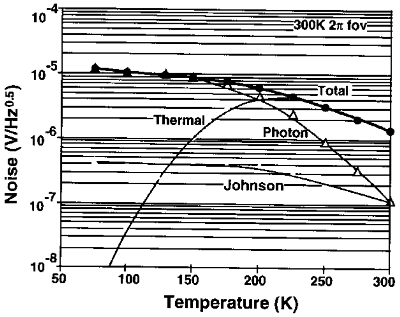

FIGURE 138 Noise voltage (per square root of bandwidth) of PbSe thin-film photoconductive detectors as a function of temperature for a high background flux level. Photon noise is dominant below 200 K. Thermal noise is dominant at higher temperatures. Total noise levels are well above typical preamplifier noise.

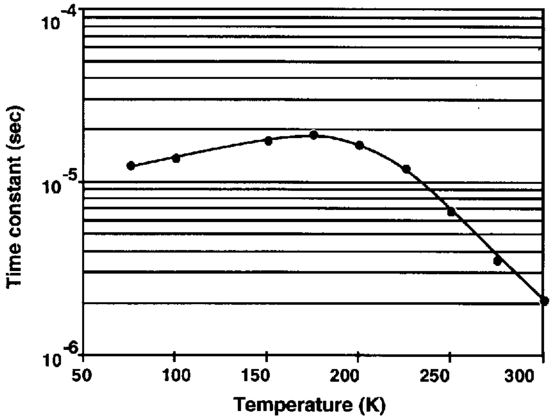

FIGURE 140 Time constant of PbSe thin films as a function of temperature.

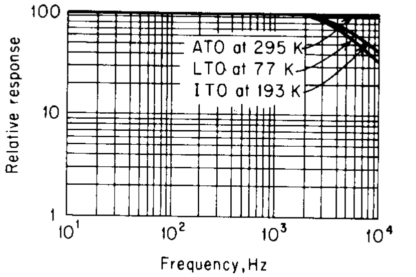

FIGURE 141 Example of signal vs. frequency for PbSe (ATO, ITO, and LTO). *(Santa Barbara Research Center.)*

Recommended circuit: Standard photoconductor.

Operating temperature: 77–300 K.

Manufacturers: Alpha Omega, Atomergic Chemetals, BSA Technology, Cal-Sensors, EDO/Barnes Engineering, Electro-Optical Systems, Graseby Infrared, Hamamatsu, Lambda Electronics, Oriel, Infrared Industries, OptoElectronics.

InSb. Historically, indium antimonide material has been used for at least four different radiation detectors, two of which, the photoconductive and photoelectromagnetic types, are no longer widely used. We discuss here the intrinsic photovoltaic device. [The very far infrared bolometer (InSb bolometer) was previously discussed in Sec. 15.7 on page 15.26.]

At 77 K, InSb photodiodes offer background limited sensitivity at medium to high background flux conditions in the 1- to 5.5-μm spectral range. At lower temperatures, they provide sensitive detectors at low background flux levels such as in astronomy applications, but with a slightly shortened long-wavelength cutoff. Operation is possible up to as much as 145 K, but because the spectral response increases with increasing temperature, the detector impedance drops rapidly leading to significant thermal noise.

Sensitivity: Spectral response out to 5.5 μm at 77 K (see Fig. 142). $D^* \approx 1 \times 10^{11}$ Jones, increases with reduced background flux (narrow field of view and/or cold filtering) as illustrated in Fig. 143.

Quantum efficiency: ~60–70 percent without antireflection coating. >90 percent with antireflection coating.

Noise: Background current limited over wide range of background flux at 77 K (see Fig. 144).

Time constant: <1 μs.

Responsivity: 3 A/W at 5 μm without antireflection coating.

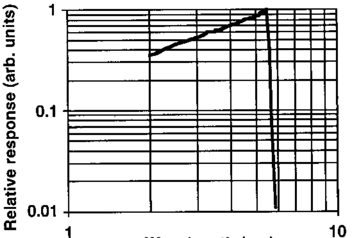

FIGURE 142 Relative spectral response per watt of an InSb photodiode without antireflection coating. The direct bandgap results in a sharp spectral cutoff.

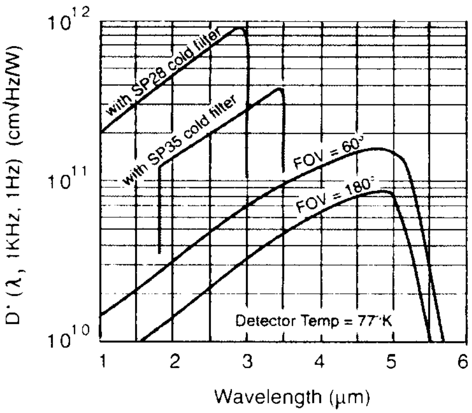

FIGURE 143 D^* as a function of wavelength for an InSb detector operating at 77 K. *(EG&G Judson, Infrared Detectors, 1994.)*

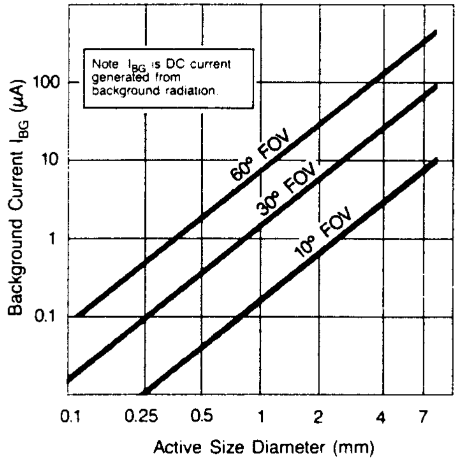

FIGURE 144 Background current as a function of photodiode area for InSb detectors operating at 77 K, shown at three values of the detector field of view. *(EG&G Judson, Infrared Detectors, 1994.)*

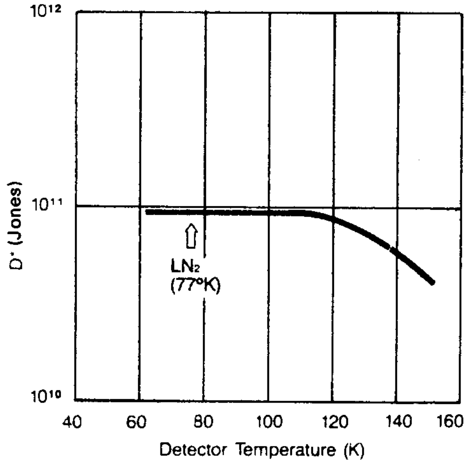

FIGURE 145 InSb photodiode D^* as a function of operating temperature between 77 K and 150 K, for a 2π (180° FOV). *(EG&G Judson, Infrared Detectors, 1994.)*

Capacitance: Typically 0.05 μF/cm^2.

Impedance: Top-grade detectors have 1–5 × 10^6 Ωcm^2 $\mathbf{R}_0A$ product at 77 K, at zero bias, and without background flux.

Sensitive area: 0.04 × 0.04-mm square to 1 × 5-mm rectangle; 0.25–10-mm dia.

Operating temperature: Normally 77 K; InSb can be used up to approximately 145 K (see Fig. 145).

Linearity: Linear to ~1 mW/cm^2.

Sensitivity profile: ±15 percent or better.

Stability: Devices from some vendors are subject to "flashing," where exposure to visible or UV flux causes a change in the insulating surface charge thereby causing a change in the diode impedance. The detector typically recovers at room temperature.

Recommended circuit: Same as for Si and Ge photodiodes; zero or reverse bias in combination with a load resistor and low noise preamplifier. Low-impedance load resistor can be used for obtaining fast response, with consequences of reduced sensitivity.

Manufacturers: Atomergic Chemetals, BSA Technology, Cincinnati Electronics, Edinburgh Instruments, EG&G Judson, Electro-Optical Systems, Graseby Infrared, Hamamatsu, MCP Wafer Technology, SAT, Vigo Sensor.

Ge:Au. Gold-doped germanium detectors are relatively fast single-crystal *p*-type impurity-doped photoconductors for the 2- to 9-μm region. Although not the most sensitive detector anywhere in its range of spectral sensitivity, Ge:Au offers respectable sensitivity over a broad spectral region using liquid nitrogen cooling. Sensitivity can be improved by a factor of 2.5 by operating at $T < 65$ K (pumped liquid nitrogen or other cryogen). At these temperatures, Ge:Au becomes background-limited.

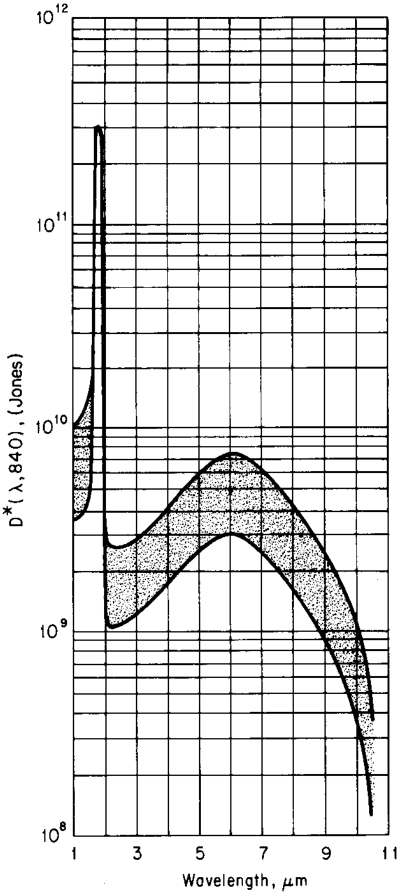

FIGURE 146 D^* vs. λ for Ge:Au; $T = 77$ K, 2π FOV; 295-K background. *(Santa Barbara Research Center.)*

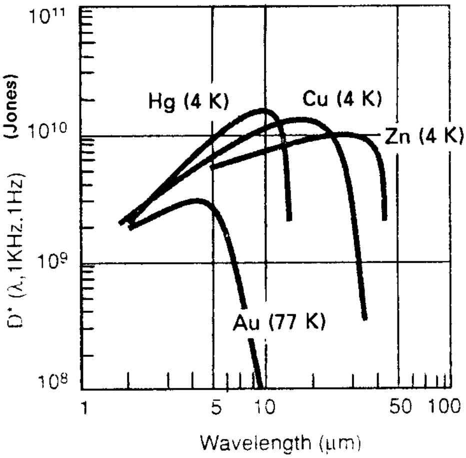

FIGURE 147 D^* as a function of wavelength for extrinsic germanium detectors doped with Au, Hg, Cu, and Zn, for a 300-K 2π (180° FOV) background flux. *(EG&G Judson, Infrared Detectors, 1994.)*

Sensitivity: See Figs. 146–149.

Quantum efficiency: Dependent on wavelength, detector geometry (absorption thickness), antireflection coating, and enclosure (integration chamber can increase absorption). $D^*(\lambda_{pk})/D^*(500\text{ K}) = 2.7$ (see Fig. 150).

Noise: See Fig. 151.

Time constant: <50 ns with full D^* [shorter response times (<2 ns) can be tailored by heavy concentration of compensating (n-type) dopant and suitable bias circuit (see circuit discussion to follow). Heavy compensation increases resistance, and hence the incoherent signal-to-noise ratio becomes limited by thermal noise of load (typically a factor of 2 degradation in the signal-to-noise ratio). Quantum efficiency, however, is not significantly altered, so that concentration does not hurt coherent-detection signal-to-noise ratio].

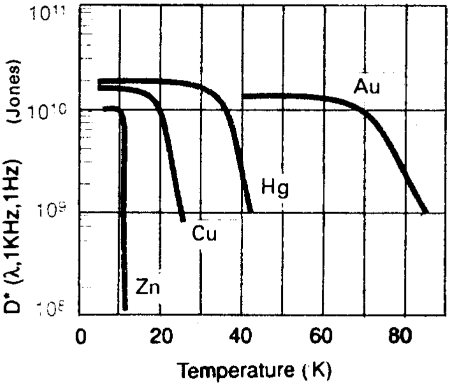

FIGURE 148 D^* as a function of operating temperature for extrinsic germanium detectors doped with Au, Hg, Cu, and Zn, for a 300-K 2π (180° FOV) background flux. *(EG&G Judson, Infrared Detectors, 1994.)*

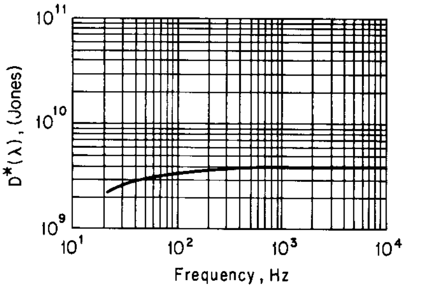

FIGURE 149 Typical D^* vs. frequency ($T = 77$ K). *(Santa Barbara Research Center.)*

Responsivity: Dependent upon bias and geometry, typical values are 0.1 to 0.2 A/W at 77 K. Multiply by detector resistance to get V/W.

Dark resistance: Varies with background flux and effective quantum efficiency (see previous quantum efficiency discussion), range may be 20 kΩ to 5 MΩ, or much greater under very low background flux conditions if adequately cooled to limit thermally activated conductivity. (Also see previous time-constant discussion.)

Capacitance: Depends on device geometry and mounting, typically <1 pF.

Sensitive area: 1–5-mm dia. standard.

Operating temperature: <85 K (normally 77 K, but see Fig. 148).

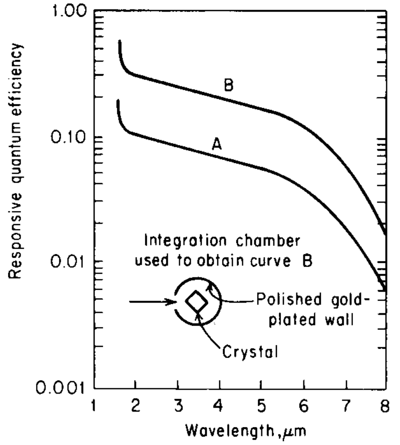

FIGURE 150 Quantum efficiency vs. λ for Ge:Au ($T = 78$ K). *(Santa Barbara Research Center, internal report.)*

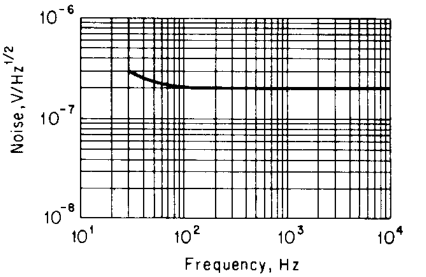

FIGURE 151 Typical noise spectrum for Ge:Au ($T = 77$ K; $A = 1 \times 1$ mm). *(Santa Barbara Research Center.)*

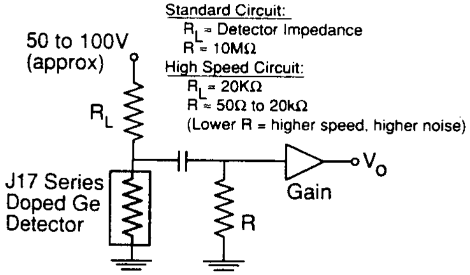

FIGURE 152 Basic operating circuit for extrinsic germanium detectors doped with Au, Hg, Cu, and Zn, for a 300-K 2π (180° FOV) high background flux. If the detector is operated in very low background flux conditions, the detector impedance can become very high. Cooled JFET ($T > \approx 50$ K) or PMOS buffer amplifiers can be helpful in impedance matching under these conditions. *(EG&G Judson, Infrared Detectors, 1994.)*

Recommended circuit: Standard photoconductive. See Fig. 152.

Manufacturers: EG&G Judson.

HgCdTe, HgZnTe, HgMnTe, etc. Mercury cadmium telluride is a direct-bandgap compound alloy semiconductor, made of chemical group II and VI elements, whose peak sensitivity at a particular temperature can be adjusted from 1 to 30 μm by varying the ratio of HgTe to CdTe (see Figs. 153 and 154). In addition to HgCdTe, other combinations of chemical groups II and VI elements can be used to produce similar variable spectral cutoff compound alloys, including HgZnTe, HgMnTe, HgCdZnTe, etc. For almost all purposes, HgCdTe will be as good as any other II-VI alloy detector, so we will speak here about it exclusively, but provide some data from the other alloys mentioned here. Both photoconductive (PC) and photovoltaic (PV) HgCdTe detectors are available for background-limited, high-speed, intrinsic photon detection in the SWIR, MWIR, and LWIR regions. Photoconductive devices with VLWIR response out to 25 μm are also available. HgCdTe detectors can be used at room temperature, with TE cooling, and at 77 K and lower temperatures. Sensitivity generally increases with cooling, depending upon

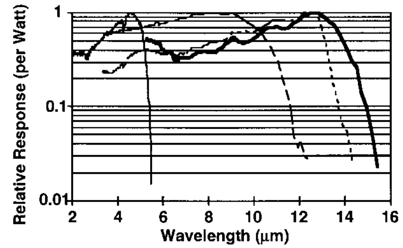

FIGURE 153 Relative spectral response per watt at 80 K for photoconductive HgCdTe detectors with antireflection coating. The curves are normalized to unity at peak value. The spectral cutoff can be adjusted by varying the ratio of HgTe to CdTe in the alloy.

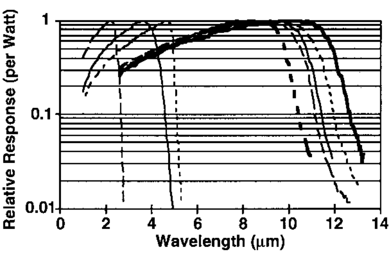

FIGURE 154 Relative spectral response per watt at 80 K for photovoltaic HgCdTe detectors without antireflection coating. The curves are normalized to unity at peak value. The spectral cutoff can be adjusted by varying the ratio of HgTe to CdTe in the alloy.

the spectral cutoff and background flux. MWIR, LWIR, and VLWIR spectral range devices are generally operated at 77 K or lower temperature for maximum sensitivity, depending upon the background flux. The photoconductive mode is advantageous when cooling is limited, since the thermal noise of a photoconductor increases less rapidly than a photodiode as the temperature is raised. Photoconductive devices with response out to 25 μm can be usefully operated at liquid nitrogen temperature and are popular for IR spectroscopy for this reason.

HgCdTe photoconductors are fabricated from thin (≈10-μm) single crystal-layers with metal contacts at each end of the element. They are low-impedance devices with 15 to 2000 Ω/square, depending upon the alloy composition, carrier concentration, operating temperature, background flux, and surface treatment. Photoconductor time constants at 77 K may be ≈2 μs for devices having a 12-μm cutoff, with longer time constants for shorter cutoffs, and shorter time constants for higher operating temperatures. In the case of small detector elements, the time constant may be reduced with increasing bias voltage because photoexcited carriers will be transported to the electrical contacts where they recombine. The spectral noise characteristics of PC HgCdTe typically exhibit $1/f$ noise out to a range of 50 Hz to 1 kHz or more, the value depending upon the detector quality, long-wavelength response, operating temperature, and background flux. The white noise levels range from less than 1 nV/√Hz (where preamplifier noise may then dominate), up to 20 nV/√Hz, depending upon detector quality, size, geometry, applied bias, temperature, and alloy composition. Photoconductive HgCdTe detectors are typically antireflection coated with a quarter-wave ZnS film, giving a peak quantum efficiency in the range of 85 to 90 percent, although this figure is only indirectly measured because the photoconductive gain can be much greater than unity. Without antireflection coating, the quantum efficiency is typically 70 percent, limited by the optical index of ≈4.

A class of HgCdTe detectors (mostly photoconductors) is offered for detection at TE-cooled and room temperature which are optically "immersed" with a hemispherical lens of Ge, CdTe, or other high-index material (see Fig. 155). The lens increases the effective area of the detector without increasing the detector noise, provided the noise is

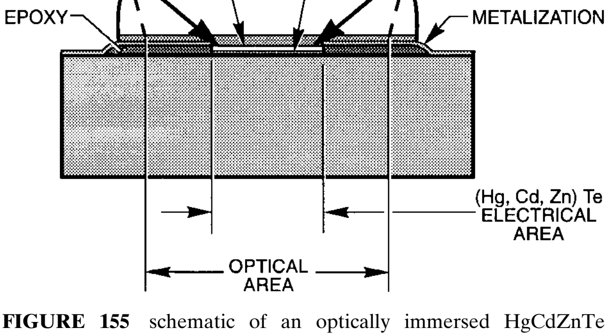

FIGURE 155 schematic of an optically immersed HgCdZnTe detector. *(Oriel Catalog Vol. II.)*

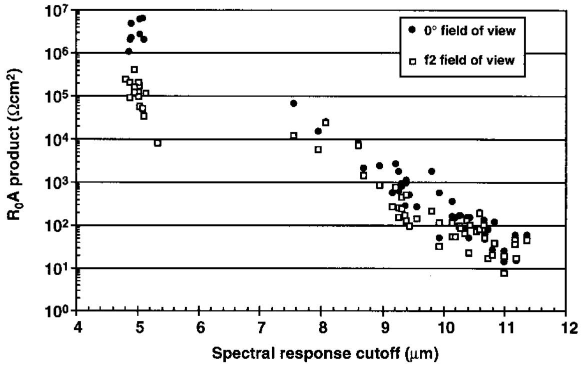

FIGURE 156 $\mathbf{R}_0A$ product "trendline" for small (25×25 to 100×100 µm) HgCdTe photodiodes at 77 K. Data is shown for devices with zero background flux (0° FOV) and with an F2 field of view (29°) of a 300-K background. For 5-µm spectral cutoff material, the $\mathbf{R}_0A$ product is higher at 0° FOV by about an order of magnitude, compared with an F2 background. At 10 µm, there is less of a difference between the two background conditions. Note that the $\mathbf{R}_0A$ product will generally be somewhat lower for larger area diodes.

dominated by thermal rather than photon noise as is the case for minimal cooling. The lens must be in intimate contact with the detector surface (<1 µm) to avoid total internal reflection of off-axis rays at the lens-detector interface. Immersed detectors offer up to a factor of 16 or greater increased detector signal, which can mean an increase in D^* by the same factor for a thermal-noise-limited device. Operation of LWIR PC detectors at TE-cooled and room temperature is generally accompanied by increased $1/f$ noise which dominates out to higher frequencies.

Photovoltaic HgCdTe detectors ideally offer $\sqrt{2}$ higher D^* than the photoconductive mode. Diodes are made in both n^+p and p^+n polarities, depending upon the manufacturer's capabilities. The $\mathbf{R}_0A$ product of HgCdTe photodiodes varies significantly with temperature, spectral cutoff, and device quality. It also varies with the amount of background flux incident on the device. The $\mathbf{R}_0A$ product defines the maximum D^* in the limit of reduced background flux (see Fig. 156 and Fig. 7). In addition to theoretically higher D^*, high-quality PV HgCdTe detectors have lower $1/f$ noise than PC HgCdTe devices, with $1/f$ knee frequencies as low as 1 Hz or less. However, the noise of PV detectors increases more rapidly with increasing temperature than for PC detectors, making photodiodes less attractive for applications where cooling is limited. Photodiodes of high quality are more difficult to make than good photoconductors and can be expected to warrant a premium price. Antireflection coating is available from some diode producers, but is not routinely offered.

Both PC and PV HgCdTe detectors are useful for infrared heterodyne detection. When sufficient local oscillator power is available, detector cooling becomes less important, since photon noise can dominate thermal noise at comparatively higher temperatures. Other things being equal, the photovoltaic detector has $\sqrt{2}$ sensitivity (signal-to-noise voltage) advantage over the photoconductor. For 10.6-µm heterodyne detection, 0.1×0.1-mm HgCdTe *pin* photodiodes with sensitivity near the quantum limit of $\approx 2 \times 10^{-20}$ W/Hz are available with bandwidths up to several GHz. Ordinary photodiodes of the same area have bandwidths of several hundred MHz. Photoconductors make better 10.6-µm heterodyne detectors when cooling is limited to TE-cooled temperatures of 180 K up to room temperature. At 180 K, TE-cooled photoconductors offer bandwidths of 50 to 100 MHz

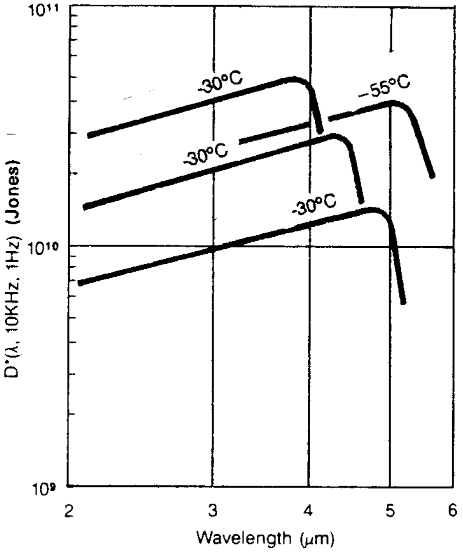

FIGURE 157 Typical D^* as a function of wavelength for a variety of MWIR HgCdTe photoconductors with thermoelectric cooling. *(EG&G Judson, Infrared Detectors, 1994.)*

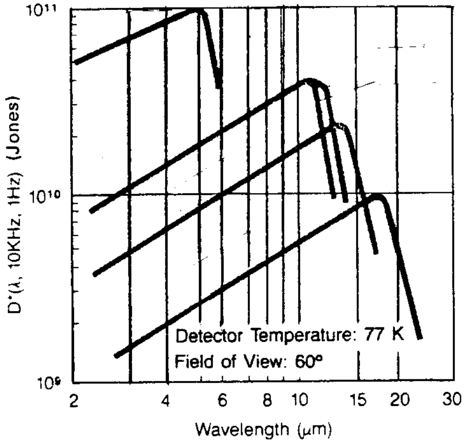

FIGURE 158 Typical D^* as a function of wavelength for a variety of LWIR and VLWIR HgCdTe photoconductors at 77 K. *(EG&G Judson, Infrared Detectors, 1994.)*

and heterodyne NEPs of 1 to 2×10^{-19} W/Hz. At room temperature, the NEP at 10.6 μm is limited to about 1×10^{-16} W/Hz. Immersion does not improve the performance of minimally cooled heterodyne detectors, since optical gain is already provided by the local oscillator.

Photoconductive HgCdTe

Sensitivity: Adjustable by varying alloy composition (see Figs. 153, 157–159).

Dark resistance: 15–2000 Ω/sq depending upon temperature, spectral cutoff, and surface passivation.

Responsivity: Varies with spectral cutoff, temperature, detector resistance, element length, and bias voltage or power. See Eq. (21) and Fig. 160 for detector elements with 50×50-μm dimensions.

Noise: $1/f$ noise is dominant at frequencies below 50–1000 Hz for LWIR detectors at 77 K (greater for LWIR at room temperature or TE-cooled). Generation-recombination (thermal or photon) white noise is present beyond the $1/f$ region at a level of less than 10^{-9} nV/$\sqrt{\text{Hz}}$ to 2×10^{-8} nV/$\sqrt{\text{Hz}}$, depending upon spectral cutoff, background flux, responsivity, and operating temperature. Noise and signal rolloff at high frequency determined by the time constant. See Fig. 161 for an example of the noise spectrum of an LWIR at 77 K.

Operating temperature: 77 K and below to 300 K and above for short spectral cutoffs and/or with significant D^* reduction for operation at higher temperatures.

Sensitive area: 0.025–4-mm linear dimensions.

Quantum efficiency: Typically > 70 percent, 85–90 percent with antireflection coating.

Capacitance: Low, limited by mounting configuration.

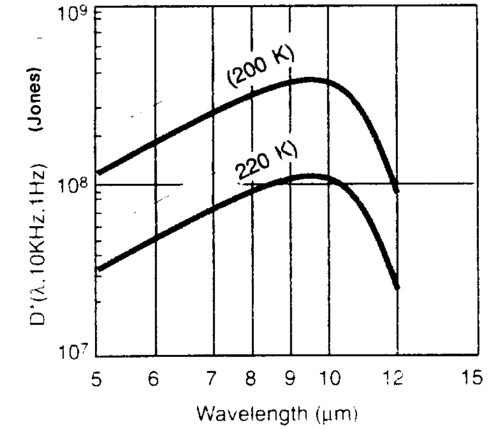

FIGURE 159 Typical D^* as a function of wavelength for LWIR HgCdTe photoconductors at 220 and 200 K. These units are cooled with three- or four-stage thermoelectric coolers. *(EG&G Judson, Infrared Detectors, 1994.)*

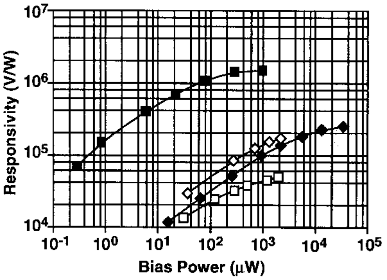

FIGURE 160 Range of peak responsivities for 12-μm cutoff HgCdTe photoconductors at 80 K. These devices have nominal dimensions of 50 × 50 μm, and resistance of 50 to 150 Ω/square.

Time constant: ~1–2 μs for LWIR at 77 K, depends on spectral cutoff, temperature, doping, and bias.

Circuit: Standard photoconductive.

Manufacturers: Belov Technology, Boston Electronics, Brimrose, Cincinnati Electronics, EG&G Judson, Graseby Infrared, Oriel, Phillips Infrared Defence Components, SAT, Spire.

Photovoltaic HgCdTe

Sensitivity: Adjustable by varying alloy composition (see Figs. 154, 156 and 162). Also compare Fig. 156 with Fig. 7 for an estimate of the extent to which D^* may increase (up to the $\mathbf{R}_0A$ or shunt resistance limit) as the background flux is reduced.

Time constant: Depends on diode capacitance (area); 10–20 ns without bias; ~0.5–

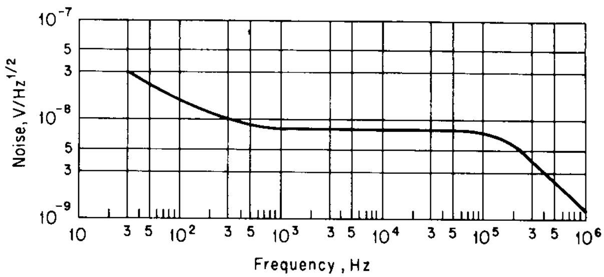

FIGURE 161 Variation of noise with frequencies for photoconductive HgCdTe at 77 K. *(GEC Marconi Infrared Ltd.)*

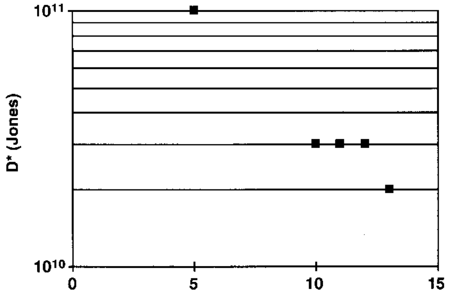

FIGURE 162 D^* specifications for small (50×50 to 250×250 μm) HgCdTe photodiodes at 77 K as a function of spectral cutoff. Data is shown for devices with 60° FOV background flux. *(Fermionics, Mercury Cadmium Telluride MWIR and LWIR Detector Series.)*

3 ns with reverse bias (some tradeoff of sensitivity). Low-capacitance *pin* devices with response out to several GHz (0.05–0.2-ns time constant) are also available for 10.6-μm CO_2 laser heterodyne detection.

Resistance: Refer to Fig. 156 for the $\mathbf{R}_0A$ product at zero bias corresponding to the detector cutoff wavelength (this figure shows very high quality diode impedances) and divide by the diode area. Large-area diodes will have somewhat lower $\mathbf{R}_0A$ product than shown in this figure. $\mathbf{R}_0A$ varies somewhat with background flux as can be noted from Fig. 156.

Operating temperature: Depends on spectral cutoff; 77 K and lower for LWIR and VLWIR detectors, up to room temperature for SWIR devices.

Noise: High-quality devices may have flat noise response from ~1 Hz out to the high-frequency limit of the time constant. $1/f$ noise may be present in lower quality devices and will vary with reverse bias.

Quantum efficiency: >50 percent (60–75 percent typical) without antireflection coating. Higher with antireflection coating.

Sensitive area: 0.01–0.25-mm square, 0.5- and 1-mm dia.

Capacitance: Depends on junction doping, area, and applied bias (very slightly dependent on spectral cutoff). For standard *pn* junction devices at zero bias and 10^{15} cm^{-3} doping, capacitance is approximately 3×10^4 pF/cm^2. Significantly lower for *pin* junction devices.

Circuit: Standard photovoltaic circuits, reverse-bias operation to enhance speed and zero bias to maximize D^* (see discussion under Si photodiodes).

Manufacturers: BSA, Fermionics, Kolmar, Oriel, Santa Barbara Research Center, SAT.

PbSnTe. PbSnTe offers an alternative semiconductor alloy system based upon the IV-VI chemical families to the II-VI (HgCdMnTeSe) families previously described for fabricating variable spectral cut-off detectors. Only photovoltaic detectors are available in PbSnTe. This technology has an advantage in the ease of material growth and in the fabrication of good quality photodiode junctions. It has a disadvantage in the very high dielectric constant of the material, combined with relatively high doping concentrations giving high-capacitance (comparatively slow) detectors. For low-frequency applications this is not a disadvantage.

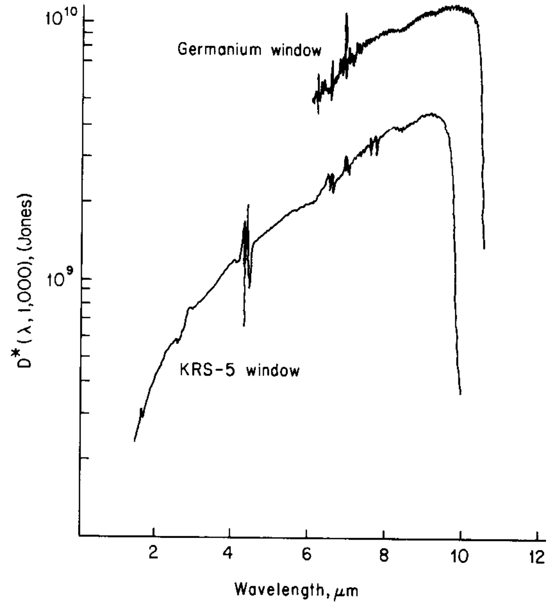

FIGURE 163 Photovoltaic (Pb,Sn)Te; 77 K, 60° FOV. *(Barnes Engineering Co.)*

Sensitivity: $D^*_{\text{peak}} > 10^{10}$ Jones (see Fig. 163).

Time constant: >50 ns.

Sensitive area: 1 × 1 mm.

Operating temperature: 77 K.

Circuit: Standard photovoltaic.

Manufacturers: Atomergic Chemetals, BSA Technology.

Ge:Hg. Mercury-doped germanium detectors are fast single-crystal impurity-doped photoconductors, sensitive out to 14 μm. Ge:Hg is especially well suited for detection through the 8- to 13-μm atmospheric window and for detection of near-ambient sources. Unfortunately, its operating temperature must be kept less than 40 K, where it becomes 300-K background-limited.

Sensitivity: See Figs. 147, 148, 164, and 165.

Quantum efficiency: 25–30 percent.

Noise: See Figs. 166 and 167.

Time constant: 100 ns with 50-Ω load for T < 28 K and electric fields < 30 V/cm. (Compensated material is available with ~5-ns time constant with a 50-Ω load. Responsivity then is reduced by 5–10× and detectivity is reduced by 2.)

Responsivity: Depends on concentration of compensating impurities, bias, area, and background flux. See Figs. 167–169, ~10^5 V/W.

Dark resistance: Depends on area and FOV: ~100 kΩ for 180° FOV (see Fig. 170).

Capacitance: <1 pF.

Sensitive area: 1–5-mm dia.

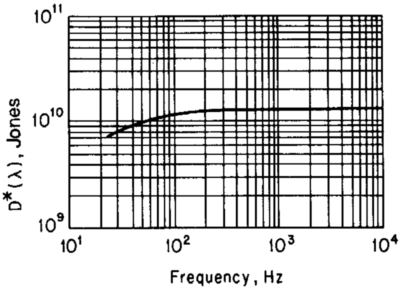

FIGURE 164 Typical D^* vs. frequency at 30 K for Ge:Hg; 1 × 1-mm area; essentially constant with temperature. *(Santa Barbara Research Center.)*

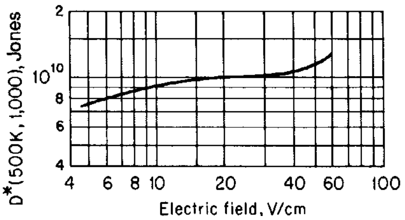

FIGURE 165 D^* vs. electric field for Ge:Hg; $T = 5$ K, 90° FOV; 300-K background; 6×10^{-4} cm^2 area; Irtran II window. *(Reprinted by permission of Texas Instruments.)*

Operating temperature: See Fig. 148.

Linearity: 10^{-3} to 10^{-8} W (size-dependent).

Sensitivity profile: ±15 percent.

Recommended circuit: Standard photoconductive (see Ge:Au). See Fig. 171 for current-voltage characteristics.

Manufacturer: EG&G Judson.

Si:Ga. (Gallium in silicon forms an acceptor level with a binding energy of ~72 meV which is the basis of an infrared detector with spectral response out to approximately 17 μm, as shown in Fig. 172. The exact spectral cutoff and quantum efficiency will vary slightly with the gallium doping concentration. Gallium-doped silicon requires cooling to 20 K or lower for optimum performance. Background-limited performance associated with

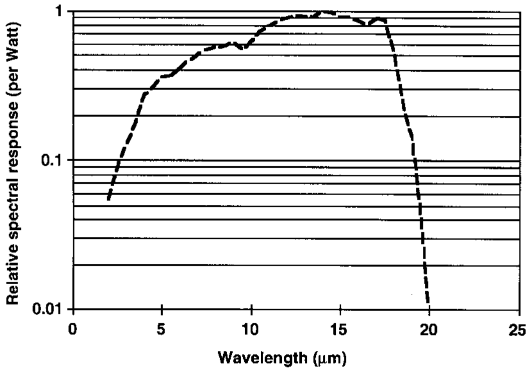

FIGURE 172 Relative spectral response per watt of Si:Ga as a function of wavelength. Data is normalized to unity at peak spectral response.

a quantum efficiency of about 15 percent is achievable over a wide range of background flux levels, provided the operating temperature is low enough to reduce thermal noise below the photon noise level.

Sensitivity: D^* is given by $D^* = 1.1 \times 10^{10} \times \sqrt{A\lambda\eta}/\sqrt{\mathbf{Q}}$ (Jones); where A is detector area, λ is the wavelength in μm, η is the quantum efficiency, and $\mathbf{Q}$ is the background flux in watts.

Responsivity: 0.9 A/W.

Time constant: <1 μs.

Resistance: Depends on background flux and detector bias (similar to Ge:Hg, see Fig. 170).

Capacitance: <1 pF (limited by mounting configuration).

Sensitive area: 0.2–2-mm square.

Operating temperature: <20 K.

Recommended circuit: Standard photoconductive.

Manufacturer: Infrared Laboratories.

Si:B. Boron in silicon forms an acceptor level with a binding energy of ~45 meV which is the basis of this infrared detector with spectral response out to approximately 30 μm. The exact spectral cutoff and quantum efficiency will vary slightly with the boron doping concentration. Boron-doped silicon requires cooling to about 15 K or lower for optimum performance. Background-limited performance associated with a quantum efficiency of about 10 percent is achievable over a wide range of background flux levels, provided the operating temperature is low enough to reduce thermal noise below the photon noise level.

Sensitivity: D^* is given by $D^* = 1.1 \times 10^{10} \times \sqrt{A\lambda\eta}/\sqrt{\mathbf{Q}}$ (Jones); where A is detector area, λ is the wavelength in μm, η is the quantum efficiency, and $\mathbf{Q}$ is the background flux in watts.

Responsivity: 2 A/W.

Time constant: <1 *μs.*

Resistance: Depends on background flux and detector bias (similar to Ge:Hg, see Fig. 170).

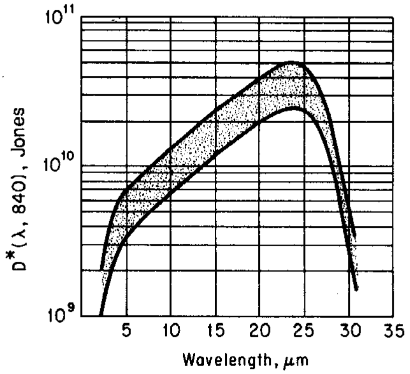

FIGURE 173 Range of spectral detectivities for Ge:Cu; 60° FOV. *(Santa Barbara Research Center.)*

Capacitance: <1 pF (limited by mounting configuration).

Sensitive area: 0.2–2-mm square.

Operating temperature: <15 K.

Recommended circuit: Standard photoconductive (see Ge:Au).

Manufacturer: Infrared Laboratories.

Ge:Cu. Copper-doped germanium detectors are fast, single-crystal, impurity-doped photoconductors, with high sensitivity in the broad region 2 to 30 μm. Operating temperature must be maintained below 20 K (ideally <14 K). Ge:Cu is then 300-K background-limited, and response time <50 ns.

Sensitivity: See Figs 147, 148, 173, and 174.

Noise: See Figs. 175 and 176.

Time constant: ~100 ns (can be doped to be faster, ~5 ns). (See discussion of time constant under Ge:Au).

Responsivity: 10^5 V/W (see Figs. 176–178).

Dark resistance: Depends on FOV (~100 kΩ for 180° FOV).

Capacitance: <1 pF.

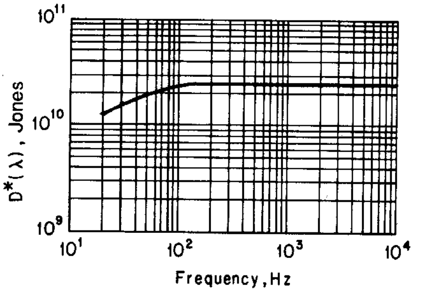

FIGURE 174 Typical D^* vs. frequency for Ge:Cu at 4.2 K. *(Santa Barbara Research Center.)*

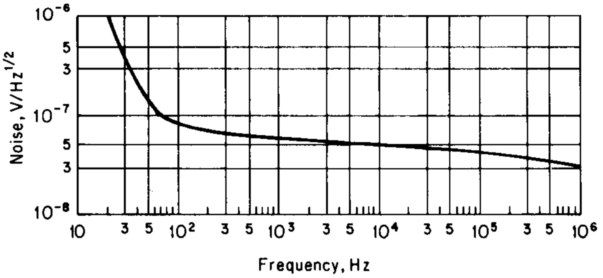

FIGURE 175 typical noise frequency spectrum for Ge:Cu. *(GEC Marconi Infra Red Ltd.)*

Sensitive area: 1–5-mm dia.

Operating temperature: See Figs. 148 and 178.

Linearity: 10^{-3}–10^{-8} W/cm^2 (depends on size).

Sensitivity profile: ±15 percent.

Stability: Stable in all ambient storage environments tested.

Recommended circuit: See Figs. 152 and 179.

Manufacturer: EG&G Judson.

Ge:Zn. Very similar to Ge:Cu except that cutoff wavelength moves out to 42 μm and operating temperature should be <10 K. A relatively low field breakdown limits the responsivity.

Sensitivity: See Figs 147, 148, and 180.

Noise: See Fig. 181.

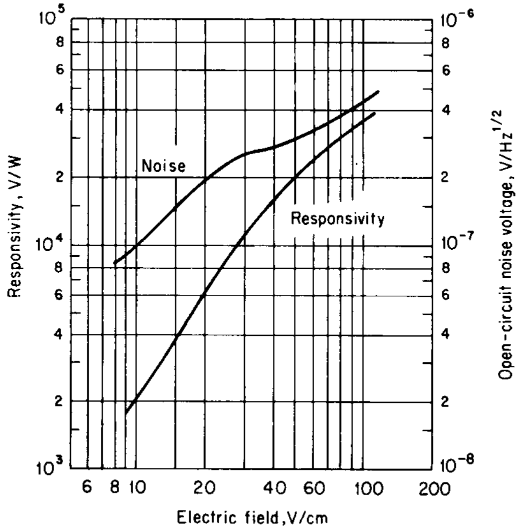

FIGURE 176 Typical noise and responsivity vs. biasing field for Ge:Cu; 5 K, 60° FOV; 300-K background, $A = 10^{-2}$ cm^2, 500-K blackbody. *(Reprinted by permission of Texas Instruments.)*

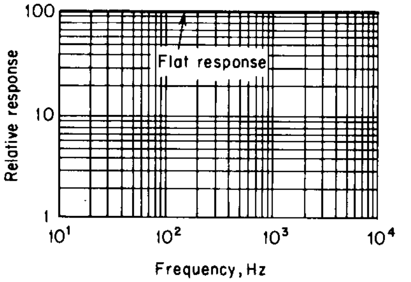

FIGURE 177 Relative response vs. frequency for Ge:Cu at 4.2 K. *(Santa Barbara Research Center.)*

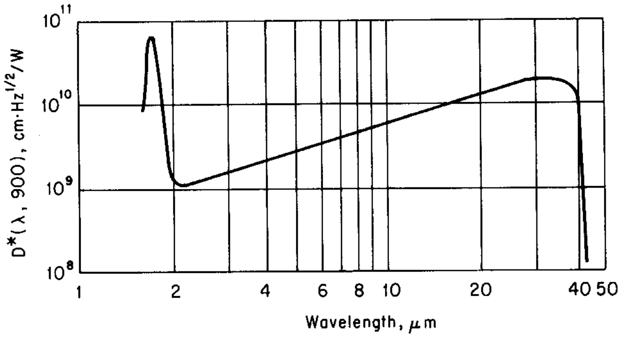

FIGURE 180 D^* vs. wavelength for Ge:Zn.

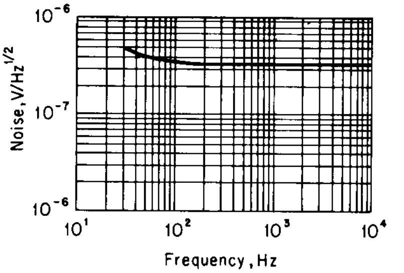

FIGURE 181 Typical noise-frequency spectrum at $T = 4.2$ K for Ge:Zn; $A = 1 \times 1$ mm. *(Santa Barbara Research Center.)*

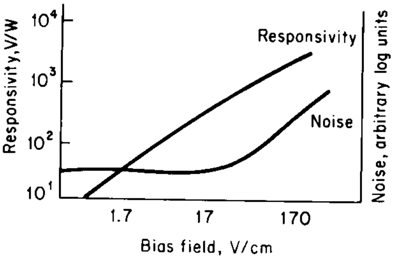

FIGURE 182 Signal and noise for Ge:Zn.

Time constant: <50 ns. (See discussion of time constant under Ge:Au.)

Responsivity: 10^3 V/W (see Fig. 182).

Dark resistance: 0.5–5 MΩ/sq (60°-FOV ambient background).

Capacitance: <1 pF (limited by mounting configuration).

Sensitive area: 1-, 2-, 3-, and 5-mm dia.

Operating temperature: <10 K.

Recommended circuit: Standard photoconductive.

Manufacturer: EG&G Judson.

Ge:Ga. The elements of B, Al, Ga, In, and Tl from chemical group III form shallow acceptor states (~10 meV) in germanium which are the basis of infrared detectors with spectral response out to approximately 120 μm. Currently, gallium-doped germanium is commercially available, but germanium doped with other group III elements (Ge:B, Ge:Al, Ge:In, Ge:Tl) will give similar detector performance. The small binding energies associated with this detector require cooling to liquid helium temperatures (4.2 K) or lower for optimum performance. Background-limited performance associated with a quantum efficiency of about 7 percent is achievable over a wide range of background flux levels, provided the operating temperature is low enough to reduce thermal noise below the photon noise level.

Sensitivity: D^* is given by $D^* = 1.1 \times 10^{10} \times \sqrt{A\lambda\eta}/\sqrt{\mathbf{Q}}$ (Jones); where A is detector area, λ is the wavelength in μm, η is the quantum efficiency, and **Q** is the background flux in watts.

Responsivity: 4 A/W.

Time constant: <1 μs.

Resistance: Depends on background flux and detector bias.

Capacitance: <1 pF (limited by mounting configuration).

Sensitive area: 0.5-, 1-, and 2-mm square.

Operating temperature: <4.2 K, best below 3 K.

Recommended circuit: Standard photoconductive.

Manufacturer: Infrared Laboratories.

Photographic. In this paragraph we present only the spectral sensitivity of some typical photographic emulsions. See Chap. 20, Photographic Films, in Vol. I of this Handbook, for a more extensive coverage.

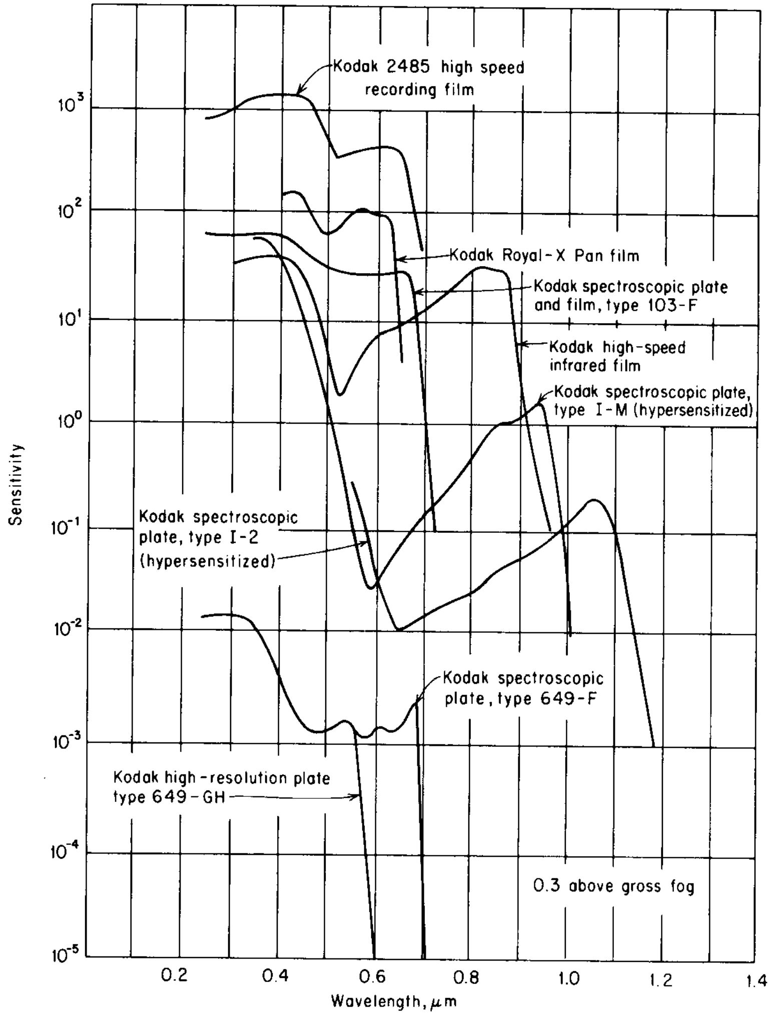

FIGURE 183 Sensitivity vs. λ for typical photographic emulsions. *(Eastman Kodak.)*

The term spectral sensitivity generally has a different meaning when applied to photographic detectors than it does when applied to the other detectors described in this chapter. It comes closer to responsivity than to minimum detectable power or energy.* In Fig. 183 sensitivity is the reciprocal of exposure, expressed in ergs/cm^2, required to produce

$$\text{Density} \equiv \log \frac{1}{\text{transmittance}} = 0.3$$

above gross fog in the emulsion when processed as recommended.

Manufacturers: AGFA, Eastman Kodak, Fuji, Polaroid.

* Work is in progress to evaluate photographic materials in terms of minimum detectable energy, a concept involving the average number of photons necessary to produce a change in density (signal) equal to that of the fog-density fluctuations (noise); see Marchant (1964), Jones (1958), Bird et al. (1969).

Sensors Unlimited, Inc.
Princeton, New Jersey

16.1 GLOSSARY

A	photodetector active area
A_0	incident photon flux
B	bandwidth of the photodetector
C	capacitance of the photodetector
D^*	detectivity
E	applied electric field
E_a	activation energy
E_g	bandgap of the semiconductor
E_i	impurity energy state
f	frequency
I_{diff}	diffusion current
$I_{g\text{-}r}$	generation-recombination current
IR_0	unity gain current
IR_1	reverse current generated by avalanche action
I_{tun}	tunneling current
k	Boltzmann's constant
L	distance traveled by a charge carrier
M	photocurrent gain
m	effective mass of electrons
N_A	acceptor impurity concentration on p side
N_D	donor impurity concentration on n side
n	refractive index of the AR coating
q	electron charge

R	sum of the detector series resistance and load resistance
R_o	detector shunt impedance
T	temperature in degrees Kelvin
t_n	transit time of electrons
t_p	transit time of holes
t_r	transit time of charge carriers (holes or electrons)
V	applied reverse bias in volts
V_B	breakdown voltage
V_{bi}	built-in potential of a *p*-*n* junction
W	depletion width of a *p*-*n* junction
α	absorption coefficient of the photodetector's absorption layer
ε_s	semiconductor permittivity
η	quantum efficiency of photodetector
θ	tunneling constant
λ	wavelength of incident photons (nm)
λ_{co}	detector cutoff wavelength (10 percent of peak response, nm)
μ	mobility of charge carriers (holes or electrons)
μ_n	mobility of electrons
μ_p	mobility of holes

16.2 INTRODUCTION

The approach of this chapter will be descriptive and tutorial rather than encyclopedic. It is assumed that the reader is primarily interested in an overview of how things work. Among the many excellent references to be consulted for further details are Sze's book,[1] and the article by Forrest.[2] For the latest in photodetector developments, consult recent proceedings of the Society of Photo-optical and Instrumentation Engineers (SPIE) conference or the IEEE Optical Fiber Conference.

A photodetector is a solid-state sensor that converts light energy into electrical energy. According to Isaac Newton, light energy consists of small packets or bundles of particles called *photons.* Albert Einstein, who won a Nobel prize for the discovery of the photoelectric effect, showed that when these photons hit a metal they could excite electrons in it. The minimum photo energy required to generate (excite) an electron is defined as the *work function* and the number of electrons generated is proportional to the intensity of the light. The semiconductor photodetectors are made from different semiconductor materials such as silicon, germanium, indium gallium arsenide, indium antimonide, and mercury cadmium telluride, to name a few. Each material has a characteristic bandgap energy (E_g) which determines its light-absorbing capabilities. Light is a form of electromagnetic radiation comprised of different wavelengths (λ). The range of light spectrum is split approximately as: ultraviolet (0–400 nm); visible (400–1000 nm); near infrared (1000–3000 nm); medium infrared (3000–6000 nm); far infrared (6000–40,000 nm); extreme infrared (40,000–100,000 nm). The equation between bandgap energy (E_g) and cutoff wavelength (λ_c) is

$$\lambda_c = \frac{1.24 \times 10^3 \text{ nm}}{E_g(\text{eV})} \tag{1}$$

TABLE 1 Important Photodetector Materials

Type	E_g (eV)	λ_c (nm)	Band
Silicon	1.12	1100	Visible
Gallium arsenide	1.42	875	Visible
Germanium	0.66	1800	Near-infrared
Indium gallium arsenide*	0.73–0.47	1700–2600	Near-infrared
Indium arsenide	0.36	3400	Near-infrared
Indium antimonide	0.17	5700	Medium-infrared
Mercury cadmium	0.7–0.1	1700–12500	Near-to-far-infrared

* The alloy composition of indium gallium arsenide and mercury cadmium telluride can be changed to alter the bandgap (E_g).

The smaller the bandgap (eV), the farther the photodetector "sees" into the infrared. Table 1 lists some prominent photodetector materials, their bandgaps, and cutoff wavelengths (λ_c) at room temperature (300 K).

Photodetectors find various applications in fiber-optic communications (800–1600 nm), spectroscopy (400 nm–6000 nm), laser range finding (400 nm–10,600 nm), photon counting (400 nm–1800 nm), and satellite imaging (200 nm–1200 nm), to name only a few topics. We will discuss three kinds of photodetectors: (1) Photoconductors, (2) *p-i-n* photodetectors (including avalanche diodes), and (3) photogates. Frequently, such detectors need to have high sensitivity, low noise, and high reliability. For fiber-optic applications, the frequency response and the cost can be a critical issue, whereas for infrared applications, many times it is the area of the photodetector. Large area (1-in diameter), high-sensitivity silicon avalanche photodetectors are now competing aggressively with conventional photomultiplier tubes for low light sensing applications in the visible. They offer the advantage of compact size and more rugged construction. We will also discuss reliability issues concerning photodetectors and take notice of a few novel photodetector structures.

16.3 PRINCIPLE OF OPERATION

When an electron in the valence band receives external energy in the form of light, the electron may overcome the nuclear attraction and become a "free electron." When light energy creates this transformation, it is termed *photonic excitation* (see Fig. 1*a*). The range of energies acquired by these free electrons is termed the *conduction band.* The energy difference between the bottom of this conduction band and the top of the valence band is

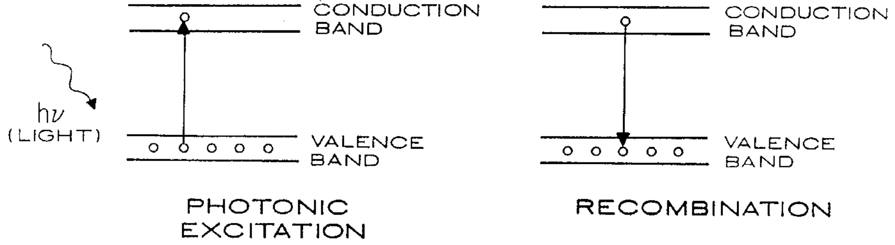

FIGURE 1 Photonic excitation and recombination in a semiconductor.

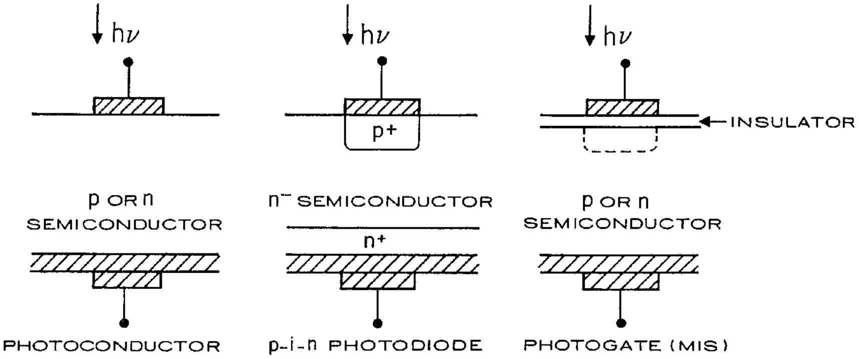

FIGURE 2 Types of photodetectors.

termed the *energy bandgap* (E_g) and represents the minimum energy of light that the material can absorb.

However, under the influence of even a small external electric field, the free electrons can "drift" in a specific direction. This is the fundamental principle of a photodetector. Figure 2 shows the three kinds of photodetectors discussed in this chapter. A brief explanation of each kind follows.

All photodetectors can be characterized by their quantum efficiency, detectivity (sensitivity), and response time.[1] Quantum efficiency (QE) is perhaps the most fundamental property, as it determines just how efficiently the device converts incoming photons into conduction electrons. Usually expressed in percentage, quantum efficiency can range from under 1 percent for PtSi Schottky barrier infrared detectors to well over 90 percent for InGaAs *p-i-n* fiber-optic photodetectors. Responsivity (R) is a related term expressed in amps/watt, which determines how much photocurrent is produced by optical power of a given wavelength. Detectivity measures how *sensitive* a detector is: that is, not only its light conversion efficiency, but also its ability to detect low-level light signals. It is limited by the various noise currents (shot, 1/f, etc.) introduced by the detector. Finally, response time describes how rapidly a detector can respond to a changing light signal. This ranges from milliseconds for certain types of PbS photoconductors to picoseconds for GaAs-like metal-insulator-semiconductor detectors.

These three parameters are frequently traded off. A large-area detector captures more light signal and thus might have greater detectivity. However, its larger capacitance would slow down the device. Similarly, response time in *p-i-n* detectors can be improved by thinning the absorbing region of the detector. However, this in turn cuts down quantum efficiency by reducing the total number of photons absorbed.

Photoconductor

A photoconductor, as the name implies, is a device whose conductivity increases with illumination. It acts as an open switch under dark (or no illumination) and as a closed switch under illumination. The simple equivalent electric circuit is shown in Fig. 3. This basic principle of a photoconductor finds numerous applications in relays and control circuits. An ideal switch should have low resistance in the closed position and, therefore, a pair of ohmic (not-rectifying) contacts are formed to the photoconductor. These ohmic contacts form the electrodes and usually have contact resistance of less than 10 ohms.

Types of Photoconductors. The two principle photoconductors are (1) intrinsic and (2)

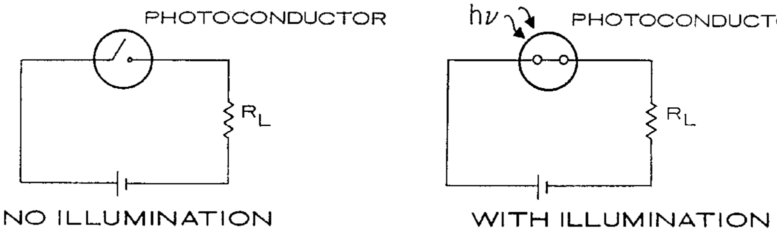

FIGURE 3 Equivalent circuit diagram of a photoconductor.

extrinsic. In an intrinsic device there is no external impurity atom. However, when an external impurity (dopant) is added to a material, it is termed *extrinsic.* This impurity atom occupies an energy state between the valence band and the conduction band. The functional difference between the intrinsic and extrinsic photoconductor is seen in Fig. 4. For an intrinsic device, the photo excitation (hv) needs to have energy greater than the bandgap energy (E_g) and its cutoff wavelength (λ_c) is given by Eq. (1). But, for an extrinsic one, the photon excitation (hv) should exceed the impurity energy state (E_i) and its cutoff wavelength λ_{co} is

$$\lambda_{co} = \frac{1.24 \times 10^3 \text{ nm}}{E_i(\text{eV})} \tag{2}$$

For intrinsic photoconductors, it is extremely difficult to achieve bandgap energies (E_g) less than 0.1 eV (refer to Table 1). This limits its capability to see in the far infrared and extreme infrared (13,000 nm–100,000 nm) and beyond. This is overcome by extrinsic devices whose E_i is less than 0.1 eV and is normally done by doping germanium or silicon. However, the extrinsic photoconductor suffers from very low absorption coefficients and, hence, poor quantum efficiencies. Also, since ambient thermal energy can excite carriers, they have to be cooled to liquid nitrogen temperature (77 K) and below, whereas most intrinsic photoconductors can operate at room temperature (300 K).

Photo Gain. The sensitivity of a photoconductor is determined by its gain. Photo gain is defined as the ratio of the output signal to the input optical signal. When photons impinge on a photoconductor, they generate electron-hole pairs and, under the influence of external fields, they are attracted toward the anode and cathode. A typical

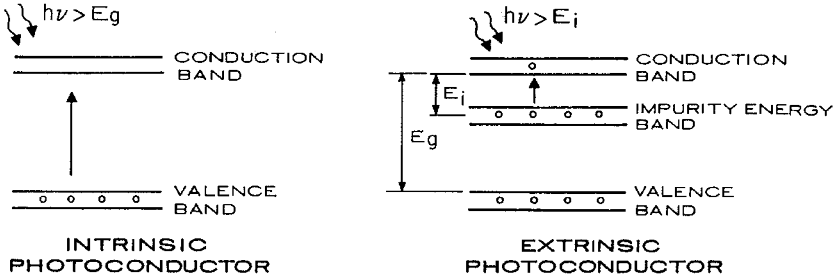

FIGURE 4 Functional diagram of an intrinsic and extrinsic photoconductor.

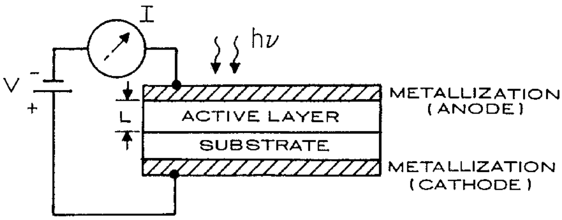

FIGURE 5 A typical photoconductor.

photoconductor is illustrated in Fig. 5 with L being the thickness of the active layer. The transit time (t_r) requires for a charge carrier to travel a distance L is given by:

$$t_r = \frac{L^2}{\mu V} \tag{3}$$

where V = applied bias and μ = mobility.

The mobility of electrons (μ_n) and that of holes (μ_p) is different, with (μ_n) being usually far higher than (μ_p). This causes a difference in the transit time of electrons and holes. Hence, photon-generated electrons are swept away more quickly than holes which result in a positive charge in the active layer. To maintain the charge neutrality, new electrons are supplied by the external voltage source. Therefore, for one incident photon, more than one electron is circulated in the electric circuit. This results in an "effective gain." Thus, photoconductor gain can be defined as the ratio of slower transit time (t_p) to faster transit time (t_n).

$$M = \frac{t_p}{t_n} \quad \text{or} \quad \frac{\mu_n}{\mu_p} \tag{4}$$

The slower the transit time, the higher the gain; however, the bandwidth of the device is reduced. Hence, high-gain photoconductors will result in slow devices and vice versa. Such "high-gain, slow devices" can be best utilized for imaging applications.[3] For high-speed optical communication applications in the 1000–1700-nm spectrum, InGaAs is the material of choice due to its high mobility. Several reports have been published on high-speed InGaAs photoconductors that find practical applications in optical receivers.[4–9] (Also see Chap. 17, "High-Speed Photodetectors," by J. Bowers.)

p-i-n Photodiode

Unlike photoconductors, a photodiode has a *p-n* junction, usually formed by diffusion or epitaxy. In a photoconductor, metal contacts are made to either *n-* or *p*-type material. However, a photodiode consists of both *n-* and *p*-type materials across which a natural electric field is generated. This field is known as the *built-in potential* (V_{bi}) and its value depends on the bandgap of its material. A silicon *p-n* junction has V_{bi} of 0.7 V whereas in germanium it is 0.3 V. The higher the bandgap (E_g), the larger the built-in potential (V_{bi}). An important physical phenomenon called *depletion* occurs when a *p*-type semiconductor is merged with an *n*-type semiconductor. After an initial exchange of charge, a potential is built up to prevent further flow of charge. This built-in field creates the depletion width (W), which is a region free of any charge carriers and is given by[10]

$$W = \sqrt{\frac{2\varepsilon_s(N_A + N_D)}{q(N_A N_D)}(V_{bi} - V)} \tag{5}$$

where N_A and N_D are impurity concentrations of p side and n side, respectively, q is the

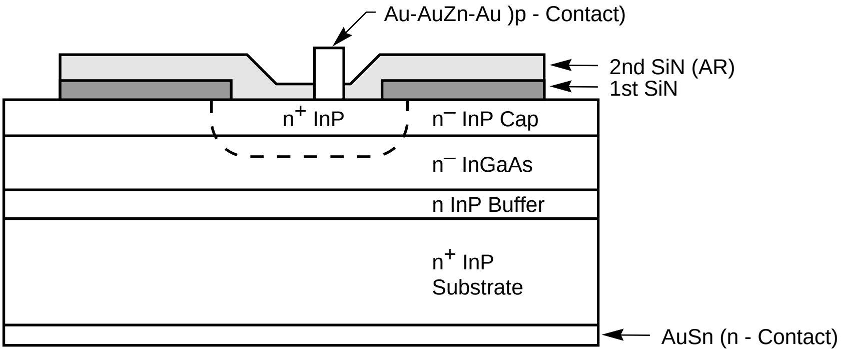

FIGURE 6 A typical InGaAs *p-i-n* photodiode.

electron charge, V_{bi} is the built-in potential and ε_s is the semiconductor permittivity, V is the applied bias and is negative for reverse-bias operation. As seen from Eq. (5), under reverse bias the depletion width (W) increases causing a decrease in the capacitance of the photodiode. A *p-i-n* photodiode is similar to a parallel plate capacitor with the anode-cathode being the two plates and the depletion width (W) being the separating medium. A typical InGaAs *p-i-n* photodiode is shown in Fig. 6 and its capacitance is termed as[1]

$$C = \frac{\varepsilon_s A}{W} \tag{6}$$

where ε_s is the semiconductor permittivity and A is the active area of the photodiode. From first principles, a decrease in capacitance improves the bandwidth (B) of the photodetector since

$$B = \frac{0.35}{2.2RC} \tag{7}$$

where, R is the sum of the detector series resistance and load resistance. For a detailed analysis on high-speed photodetectors, see Chap. 17 by John Bowers.

Dark Current. For applications ranging from optical communications (III-V compound semiconductors) to infrared sensing (Si, Ge, III-IV, and II-IV compound semiconductors), a *p-i-n* photodiode must have high sensitivity and low noise. These are largely determined by the dark currents originating in the device. Several authors have published papers on dark currents in InGaAs[11–13] and HgCdTe.[14,15] The three major components of dark current are (1) diffusion current, (2) generation-recombination current, and (3) tunneling current.

Diffusion Current. In the nondepleted region of the photodiode, electron-hole pairs are formed by the ambient temperature. These thermally generated carriers diffuse toward the depletion region and produce the diffusion current.

$$I_{\text{diff}} \propto e^{-E_g/kT} \tag{8}$$

where E_g is the bandgap of the photodiode material, k is Boltzmann's constant, and T is the ambient temperature in degrees Kelvin. From Eq. (8), clearly diffusion current is higher in low-bandgap material. Therefore, InSb ($E_g = 0.17$ eV) has far higher diffusion current than silicon ($E_g = 1.12\,\text{eV}$) and in fact this makes InSb almost useless at room temperature. To overcome this excessive diffusion current, InSb photodiodes are cooled to liquid nitrogen temperature (77 K).

Generation-Recombination Current. The current generated in the depletion region of the photodiode is called the *generation-recombination current.* When impurity trap levels are present within the forbidden gap (E_g), trapped carriers can be elevated to the conduction band with less energy than for diffusion current. This ‘‘trap-assisted’’ current is given by

$$I_{g-r} \alpha \sqrt{(V_{bi} - V)}\, e^{-Eg/2kT} \tag{9}$$

From Eq. (5), the depletion width W is proportional to $V_{bi} - V$. Hence,

$$I_{g-r} \alpha W e^{-Eg/2kT} \tag{10}$$

Generation-recombination current is proportional to the volume of the depletion width and, hence, is reverse-bias-dependent, whereas the diffusion current in Eq. (8) is bias-independent. For high-bandgap semiconductors with bandgaps above 1.0 eV (e.g., silicon), the generation current usually dominates over the diffusion current at room temperature. However, for low-bandgap material such as indium antimonide, the diffusion current is dominant over generation current at room temperature.

Tunneling Current. When the electric field in a reverse-biased *p-n* junction exceeds 10^5 V/cm, a valence band electron can jump to the conduction band due to the quantum mechanical effect[10] called *tunneling* which occurs at high field and with geometrically narrow energy barriers. The tunneling current is given by

$$I_{\text{tun}} \alpha E V \exp\left(\frac{-\theta\sqrt{m}}{E} E_g^{3/2}\right) \tag{11}$$

where E is the applied electric field, m is the effective mass of electrons, and θ is a dimensionless constant whose value depends on the tunneling barrier height. Higher doping levels at the *p-n* junction lead to a narrower depletion width which causes higher electric fields, thus increasing the amount of tunneling current. Low-bandgap photodiodes exhibit much more tunneling than do higher-bandgap diodes. Tunneling shows a weak dependence on temperature, the only minor change being caused by the temperature dependence of the bandgap (E_g). This leads to a *decreasing* breakdown voltage with increasing temperature as opposed to an *increasing* breakdown voltage exhibited by the avalanche effect.

Quantum Efficiency, Responsivity, and Absorption Coefficient. Quantum efficiency (η) is defined as the ratio of electron-hole pairs generated for each incident photon. In a nonavalanche *p-i-n* photodiode, quantum efficiency is less than unity. Responsivity (R) is a measured quality in amps/watt or volts/watt and is related to quantum efficiency by

$$Q \cdot E(\eta) = \frac{(1240) \cdot R(A/W)}{\lambda} \tag{12}$$

where λ is the wavelength in nm of incident photons and R is the responsivity in

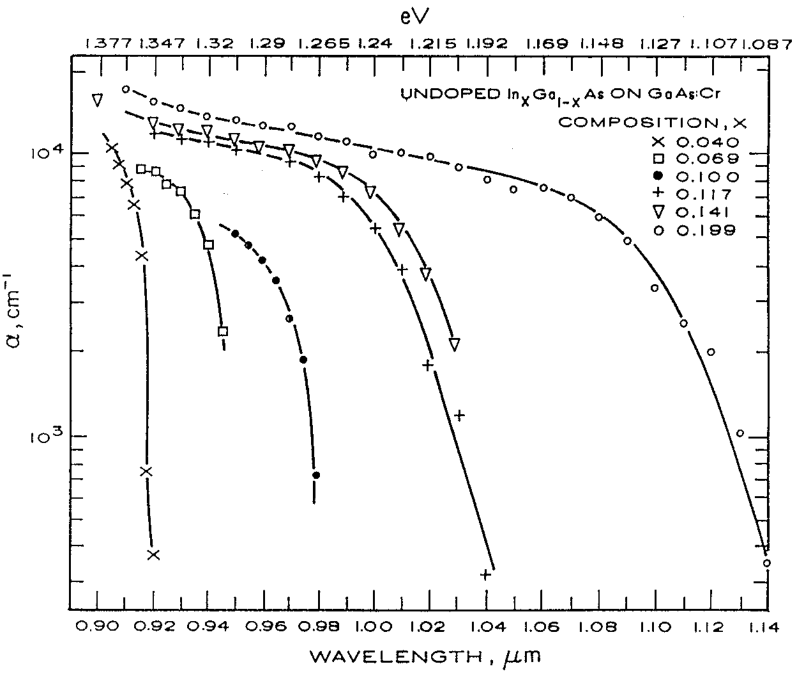

FIGURE 7 Absorption coefficients for 1-μm thick undoped $In_xGa_{1-x}As$, $0 < x < 0.25$.[16]

amps/watt. The value of η is determined by the absorption coefficient (α) of the semiconductor material and the penetration distance (x) in the absorbing layer. The light flux (A) at a distance x with the absorption layer is

$$A = A_0 e^{-\alpha x} \tag{13}$$

where, A_0 is the incident photon flux and α is a strong function of wavelength (λ). Figure 7 shows its typical values for a 1-μm thick undoped $In_xGa_{1-x}As$, $0 < x < 0.25$.[16] For optimized η, the reflectivity at the semiconductor surface has to be minimized. Hence, an antireflection (AR) coating of proper thickness is deposited on the photodiode surface. For single-layer AR coatings, the proper "quarter-wave" thickness (L) of the AR coating is:

$$L = \frac{\lambda}{4n} \tag{14}$$

where n is the refractive index of the coating. With good AR coatings, InGaAs photodiodes can achieve quantum efficiencies above 95 percent at 1300–1500 nm. For the visible region, silicon photodiodes show high η (90 percent) in the 800-nm range, and the mid-infrared InSb has a typical η of 80 percent at 5000 nm.

Avalanche Photodiodes. Avalanche photodiodes (APDs) will be briefly discussed here. For a detailed treatment, see Chap. 17 on high-speed photodetectors by John Bowers in this book. An avalanche photodiode is a *p-i-n* diode with a net efficiency or gain greater than unity. This is obtained through the process of "impact ionization" by operating the photodiode at a sufficiently high reverse bias. The typical operating voltage for an InGaAs APD is 75 V, while that for silicon can be as high as 400 V. The impact ionization process

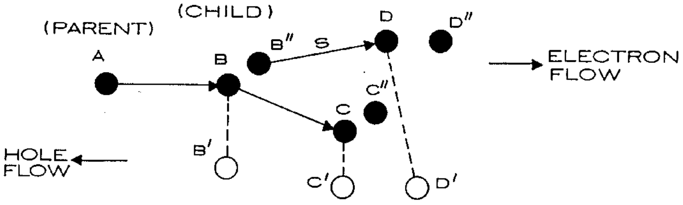

FIGURE 8 Impact ionization process.

is described in Fig. 8. Under the influence of a high electric field (>5×10^5 V/cm), electron *A* gains sufficient kinetic energy to hit atom *B* with a tremendous force and knock out an electron hole pair *B′*-*B″*. *A* is called the "parent" and *B′*-*B″* the "child" charge carriers. The child electron *B″* moves through a critical distance *S* and acquires enough kinetic energy to create its own child particles *D′*-*D″*. The sum effect of the impact ionization of a number of electrons is termed *avalanche multiplication.* Because of this avalanche action, the gain in an APD exceeds unity, reaching useful values above 10 for InGaAs and several hundred for silicon before the multiplied noise begins to exceed the multiplied signal. A solid-state APD is a fast device with gain-bandwidth products than can exceed 20 GHz.[17,18] In spite of high operating bias, an APD can be designed for low noise operation[19] and used for numerous applications such as photon-counting, laser pulse detection,[20] and fiber-optic communication. The gain or avalanche multiplication (M) of an APD is given by

$$M = \frac{IR_1}{IR_0} \tag{15}$$

where IR_1 is the reverse current generated by avalanche action and IR_0 is the unity gain current. At voltage breakdown of the APD, the multiplication factor M tends to infinity. An empirical relation between the multiplication factor (M) and reverse bias (V) is given by[21,22]

$$M = \frac{1}{1 - (V/V_B)^n} \tag{16}$$

where V is the applied reverse bias and V_B is the breakdown voltage. The factor n varies between 3 to 6, depending on the semiconductor material and its substrate type. Typical gains are on the order of 10 to 20 for germanium and InGaAs APDs, and above 100 for silicon APDs. Due to their lower noise, InGaAs and silicon APDs have better sensitivity than their germanium counterparts.

Extended Wavelength (1000–3000 nm) Photodetectors

Detector materials used for the 1000–3000 nm spectrum include InSb, InAs, PbS, HgCdTe, and recently InGaAs. PbS is an inexpensive, reasonably sensitive detector that can operate at relatively high temperatures, even room temperature. Its major drawback is its slow (typically milliseconds) response time. InAs has higher sensitivity over the 1000–3500 nm spectrum and fast response time, but must be cooled thermoelectrically (to 230 K) or cryogenically (to 77 K). InSb has similar properties out to 5500 nm but must definitely be cryogenically cooled. HgCdTe has high sensitivity and speed and can be operated at room temperature. However, a new competitor has come on the scene recently: indium gallium arsenide. This material was originally developed for fiber-optic applications out to 1.7 μm (using $In_{0.53}Ga_{0.47}As$) and can now be used out to 2500 nm by increasing its indium content to $In_{0.8}Ga_{0.2}As$. InGaAs appears to be the *best* detector material for high-temperature

TABLE 2 Comparison of R_0A Values in HgCdTe and InGaAs (Ω-cm^2)

	$R_0A(T)$	
λ_{co} (nm)	HgCdTe	InGaAs
1400	4×10^4 (292 K)	2.5×10^5 (300 K)
	7×10^6 (230 K)	1.3×10^8 (220 K)
1700	2×10^2 (300 K)	2.5×10^5 (300 K)
	2×10^5 (220 K)	1.3×10^8 (220 K)
2100	7×10^1 (300 K)	2.5×10^3 (300 K)
	7×10^3 (220 K)	6.5×10^5 (220 K)
2500	1×10^1 (300 K)	1.3×10^2 (300 K)
	1×10^3 (210 K)	1.0×10^5 (210 K)

operation in the 1000–3000 nm spectrum. It has a 10–100× advantage in shunt resistance at room temperature compared to HgCdTe—the previously used material for this wavelength.

Table 2 contains a summary of the available data. It is extremely difficult to find data at exactly the same cutoff wavelengths and temperature with the same area device. R_0A was determined (in cases where it was given as such) by simply multiplying two numbers, where, R_0 is the shunt impedance of the detector, and A is the active area of the photodetector.

Photogate (Metal-Insulator-Semiconductor Detector)

The advent of silicon charge coupled devices (CCDs) has revolutionized the television industry and introduced one of the most popular consumer items to millions of people around the world—the CCD camcorder. From the sandy shores of Hawaii to the ski slopes of Colorado, people have captured life's best moments with a CCD camcorder. With its superior imaging quality and noise performance of a few electrons/per pixel (<20), a CCD has diverse uses from space imaging to chemical analysis spectroscopy. A CCD is a matrix of metal oxide semiconductor (MOS) devices operated in the "depletion" mode. Each individual MOS device is called a *photogate* and its schematic diagram is shown in Fig. 9. Consider an n-type semiconductor with a negative potential applied to its gate. This will repel the negatively charged electrons and create a depletion layer. As the negative potential on the gate is further increased, the volume of the depletion region increases further into the bulk. However, the surface potential at the semiconductor-insulator

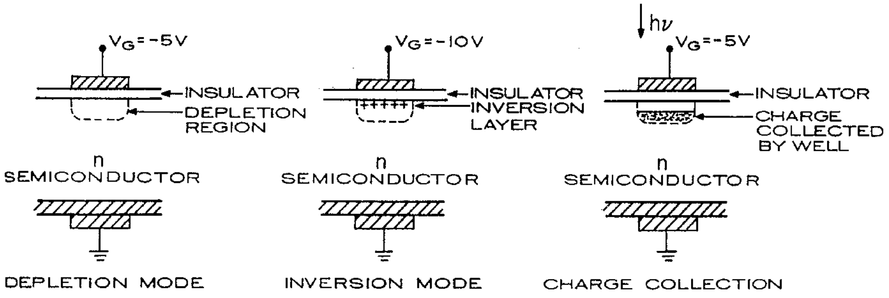

FIGURE 9 Schematic diagram of a photogate.

interface also becomes more negative. Finally, with increased gate bias, the surface potential becomes sufficiently high to attract minority carriers (holes). This creates a positive charge at the semiconductor-insulator interface and is termed the *inversion layer.* In an MOS transistor, the inversion layer forms a conducting channel between the source and the drain, and the gate bias needed to achieve inversion is termed the *threshold voltage.* Usually a photogate is operated in depletion at a gate bias lower than the threshold voltage. When incident photons create hole-electron pairs, the minority carriers drift away to the depletion region and the volume of the depletion region shrinks. The total amount of charge that a photogate can collect is defined as its *well capacity.* The total well capacity is decided by the gate bias, the insulator thickness, the area of the electrodes, and the background doping of the semiconductor. Numerous such photogates with proper clocking sequence form a CCD imaging array. For in-depth understanding of CCDs, we refer to Chap. 22 ‘‘Visible Array Detectors,’’ by T. J. Tredwell.

16.4 APPLICATIONS

The main commercial uses for photodetectors include optical communications and infrared sensing. Although these applications often overlap, optical communication typically involves transmitting data over an optical fiber at higher rates. The format is increasingly digital (telecommunications and data links) at rates from 1 Mbit/s to over 2 Gbit/s.

However, one growing application is cable TV (CATV) where analog data rates from 1 to beyond 1000 MHz are most often found. Infrared sensing mostly involves nonfiber applications at sub-MHz analog rates. The property to be detected is usually the amplitude (in watts) and wavelength of the incoming radiation. In digital applications, the wavelength and individual pulse amplitude are relatively fixed, and successful communication occurs simply by distinguishing when the pulse is ‘‘on’’ or ‘‘off.’’ Although very weak pulses must sometimes be detected, the actual amplitude of the pulse is irrelevant. The ultimate ‘‘resolving power’’ of the detector is when a weak pulse can no longer be distinguished from background noise, i.e., when the incoming signal strength (S) equals the background noise strength (N) or when the ‘‘signal-to-noise’’ ratio $S/N = 1$. Thus, the strengths of individual pulses are unimportant as long as the presence of a pulse can be detected. Information is conveyed by the timing sequence of the pulses rather than by the amplitude of the individual pulse. Analog applications, on the other hand, depend critically on the frequency content and amplitude of the transmitted signal. In an AM cable TV transmission system, the detector must be able to linearly reproduce the incoming optical signal as an electrical current of the same frequency content and amplitude, and to minimize intermodulation and harmonic distortion that is invariably produced in the detection of an AM signal.

Infrared applications often involve spectroscopy whereby the detected electrical signal depends on both the optical wavelength and strength of the incoming infrared signal. Thus, the detector must be carefully calibrated in terms of ‘‘responsivity’’ (electrical amps/optical watt) versus wavelength in order to accurately identify the nature of the incoming signal. Identification of gases (e.g., methane, which absorbs light near 1650 nm) depends on these properties. Other ‘‘infrared’’ applications include spectroscopy, remote sensing from satellite, and general laboratory detection. Not *all* infrared applications are analog, however. One notable digital application is LIDAR (LIght Detection And Ranging), which essentially is a form of laser radar. High-intensity light pulses are emitted into the atmosphere (or a gas) which absorbs, scatters, and reemits the laser pulse. The character of light pulses detected back near the source can be used to determine the nature of the gas particles that interacted with the light: the absorbing wavelength, the gas density (velocity), and the amount present. Applications include remote pollution monitoring and ‘‘windshear detection,’’ whereby the presence of abrupt changes in wind velocity can be instantly detected at distances of several miles. This application[42] has been demonstrated with laser wavelengths of 2060 and 10,600 nm for use on aircraft and may be required on all commercial aircraft by the year 1995. The 2060-nm system works better in severe storms and does not require a cryogenically cooled detector (as does the 10,600-nm system). However, the CO_2 gas laser used for 10,600 nm, although bulky and costly, is more highly developed and more readily available than the more recent HO:YAG solid-state lasers used for 2060 nm.[42] Further developments will undoubtedly occur here over the next several years.

One important noise source in infrared applications is the so-called 1/f noise which becomes noticeable at frequencies below 10 MHz. Although poorly understood, this noise is thought to originate at heterointerfaces such as semiconductor-metal contacts and heteroepitaxial interfaces. Photodiode arrays are often required to detect low-light-level signals of a few hundred photons, and they must integrate the signal for 1 second or more. However, with longer integration times, 1/f noise may become noticeable and can degrade the S/N ratio and thus, impose an upper limit on the effectiveness of longer integration times. Limiting 1/f noise becomes critical for numerous infrared sensing applications and research indicates that surface depletion width at the semiconductor-insulator interface to be a major source of 1/f noise in the InGaAs photodiodes.[44]

One important area for detectors is the array configuration used both for spectroscopy (linear) and imaging (two-dimensional). Linear arrays are used in so-called multichannel analyzers whereby the detector is placed behind a fixed grating and the instrument functions as ‘‘motionless’’ or ‘‘instant’’ spectrometer with each pixel corresponding to a narrow band of wavelengths. The resolution of the instrument is determined by the number and spacing of pixels, so *narrow* pixel geometries are demanded along one direction whereas *tall* pixel geometries are demanded along the perpendicular direction to enhance the light collection.

One ‘‘mixed’’ infrared/fiber-optic application is the use of large-area (typically 3-mm diameter) detectors for optical power meters: the optical equivalent of a voltmeter which accurately measures the amount of optical power in watts or dBm (number of decibels above or below 1 mW contained in an incoming beam). The large area ensures large collection efficiency. The most important parameter here is the responsivity and the uniformity of response across the detector.

A ‘‘figure-of-merit’’ for infrared detectors is D^* (deestar), whereby detectors of differing area can be compared. It is related to the noise equivalent power (NEP) in watts, the lowest power a detector can detect at a signal-to-noise ratio of 1 as

$$D^*(\lambda, f, B) = (AB)^{1/2}/\mathrm{NEP} \tag{17}$$

where A is the detector area. The optical bandwidth B (often taken to be 1 Hz), frequency of signal modulation (f), and operating wavelength (λ) must be stated.

16.5 RELIABILITY

In today’s global economy of severe competitiveness, new product development and innovation is incomplete without quality assurance and reliability. Reliability is the assurance that a device will perform its stated functions for a certain period of time under stated conditions, and considerable research has been done to improve the reliability of photodetectors.[23–26] The two major industrial standards for testing semiconductor device reliability are: (1) test methods and procedures for microelectronics (MIL. STD. 883C), and (2) Bellcore technical advisory (TA-TSY-00468). The former standard is generic to the semiconductor industry, while the latter is specifically developed for fiber-optic optoelectronic devices.

The tests performed under MIL. STD. 883C comprise of the following major groups:

TABLE 3 Electrical and Optical Testing of Photodetectors

Tests or measurement	Parameter	Symbol	References
Optical response	Responsivity	R	Bellcore Technology
	Gain	G	Advisory
Electrical performance	Dark current	I_d	TA-TSY-00468
	Breakdown voltage	V_{br}	Issue 2, July 1988

(1) *environmental tests,* e.g., moisture resistance, burn-in, seal, dew point, thermal shock, (2) *mechanical tests,* e.g., constant acceleration, mechanical shock, vibration, solderability, and bond strength, and (3) *electrical tests,* e.g., breakdown voltage, transition time measurements, input currents, terminal capacitance, and electrostatic discharge (ESD) sensitivity classification. Under the Bellcore Technical Advisory, each photodetector lot undergoes visual inspection, optical and electrical characterization, and screening. Visual inspection removes any photodiodes with faulty wire bonds or cracks in the glass window or in the insulating films. Table 3 lists the electrical and optical testing performed on every photodiode. After testing, all the devices are sent for screening (burn-in), e.g., some $In_{0.53}Ga_{0.47}As$ photodiodes are burned-in at 200°C for 20 hours at -20 V reverse bias to weed out any infant mortality.

Photodetector Life Test (Accelerated Aging)

To predict the lifetime or *mean-time-to-failure* (MTTF), accelerated aging tests are carried out on groups of diodes at several elevated temperatures. For example, the MTTF for 300-μm diameter InGaAs photodiodes was determined on groups of 20 screened devices at elevated temperatures of 200, 230, and 250°C. The failure criterion was a 25 percent increase in the room temperature dark current value.[26,27] The total lifetest extended over a time period of several years, and every week the samples were cooled to room temperature to check their dark current. Failed devices were removed from the sample population and the remaining good ones put back at the elevated temperature.

From the temperature-dependence of the data, it was observed that the failure mechanism is thermally activated. The Arrhenius relationship calculates the activation energy (E_a) for thermally activated failure[27] as

$$\mathrm{MTTF(T)} = Ce^{(E_a/kT)} \tag{18}$$

where, C is a constant, k is Boltzmann's constant (8.63×10^5 eV/K), and T is the temperature in Kelvin. Figure 10 shows the MTTF for three batches of 300-μm diameter $In_{0.53}Ga_{0.47}As/InP$ photodiodes. Using least-squares fit to the data, the calculated activation energy (E_a) is 1.31 eV with a correlation coefficient (r^2) of 0.99. From Eq. (18) and an experimentally determined activation energy of 1.31 eV, the MTTF at 25°C is calculated to be 1.34×10^{14} hours. Such a "geological" lifetime may seem to be an overkill, even for the electronics industry. However, when thousands of these devices are working together in a single system (e.g., telephones), the net MTTF of all these devices chained together may be on the order of only a few years. Thus, continuing improvements in reliability must be an ongoing process. Reliability in most photodetectors is determined by a number of factors including: (1) material quality, (2) processing procedures, (3) planar technology versus mesa technology, and (4) amount of leakage current. Poor material quality can

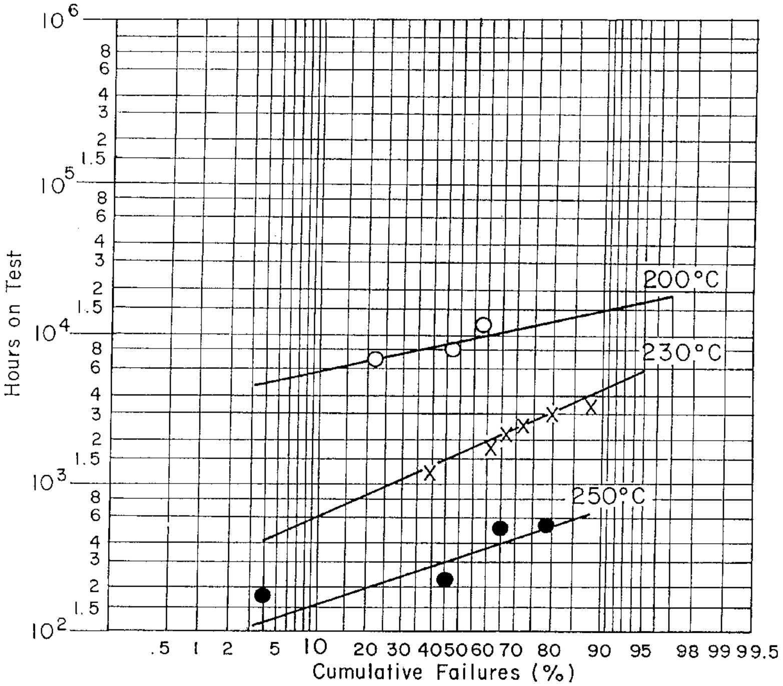

FIGURE 10 Time versus cumulative percent failure of InGaAs diodes at 200, 230, and 250°C lifetest.

introduce crystal defects such as vacancies and dislocations which can increase the dark current. Higher dark current has been directly linked to lower MTTF.[26] Device processing is probably the most crucial item in photodetector reliability. The dielectric (typically silicon nitride) used in planar detector processing serves as a diffusion mask in *p*-*n*-junction formation and a passivant (termination) for the junction so produced. Any surface states or impurities introduced here can directly increase leakage current and degrade reliability.

An important milestone in detector reliability was the changeover mesa to planar structures.[2,28] Just as the transistors in the 1950s were first made in mesa form, so were the optical photodetectors of the 1980s, due to their simplicity and ease of fabrication. However, in both cases, reliability issues forced the introduction of the more complex planar structure. A sketch of a mesa and planar photodiode is illustrated in Fig. 11. A mesa photodiode typically is formed by wet chemical etching of an epitaxially grown *p*-*n*

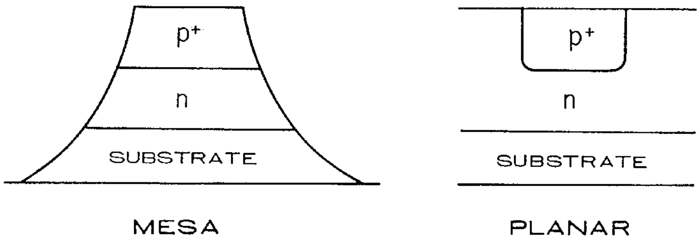

FIGURE 11 Sketch of a mesa and planar photodetector.

crystal structure, while in a planar process, a *p*-*n* junction is formed by diffusing a suitable *p* or *n* dopant in an *n*- or *p*-type crystal. Research shows a planar structure to be more reliable than a mesa one[28] because a *p*-*n* junction is never exposed to ambient conditions in a well-designed planar process. Exposure of the *p*-*n* junction can cause surface corrosion leading to increased leakage current and, in effect, poorer reliability.[29]

16.6 FUTURE PHOTODETECTORS

In the near future, a lateral *p*-*i*-*n* photodiode and a quantum well infrared photodetector (QWIP) may find increased commercial applications. Both these structures have already been developed in the research laboratories and show promising characteristics compared to the current photodetector structures that they may well replace. A long wavelength QWIP in the 8000–12000-nm band[30–33] has posed a severe challenge to the present favorite mercury cadmium telluride photodetectors, while a medium wavelength QWIP in the 3000–5000-nm band[34] may compete with indium antimonide and platinum silicide photodetectors. A QWIP made from GaAs/AlGaAs heterosystems promises to have higher detectivity (D^*), higher yield due to well established 3-in wafer GaAs technology, and easier monolithic integration with circuit electronics. A lateral *p*-*i*-*n* diode, as the name implies, has charge carrier flow in a lateral direction compared to the vertical direction in a conventional (vertical) photodiode structure. Because of its process compatibility and simple fabrication, a lateral *p*-*i*-*n* photodiode can be suitably integrated on an optoelectronic integrated circuit (OEIC) chip[35,36] having numerous field-effect transistors. An OEIC has a lower noise floor due to the reduced stray capacitances and inductances compared to that of hybrid detector-amplifier packages and finds applications in high-speed digital data communication.

Lateral *p-i-n* Photodetector

The vertical *p*-*i*-*n* structure in Fig. 6 has high sensitivity, low noise, low capacitance, better reliability, and an easy manufacturing process. However, such a vertical structure is nonplanar and therefore harder to integrate on an OEIC. The nonplanarity is also an issue with lasers and LEDs, and optical integration demands surface-emitting LEDs and lasers (SLEDs and SLASERs) over the conventional edge-emitting sources (ELED and ELASER). The future low-cost OEICs will probably have surface-emitting sources with lateral photodetectors in the same plane with integrating transistor amplifiers. The cross section of an AlGaAs/GaAs lateral *p*-*i*-*n* photodiode is shown in Fig. 12.

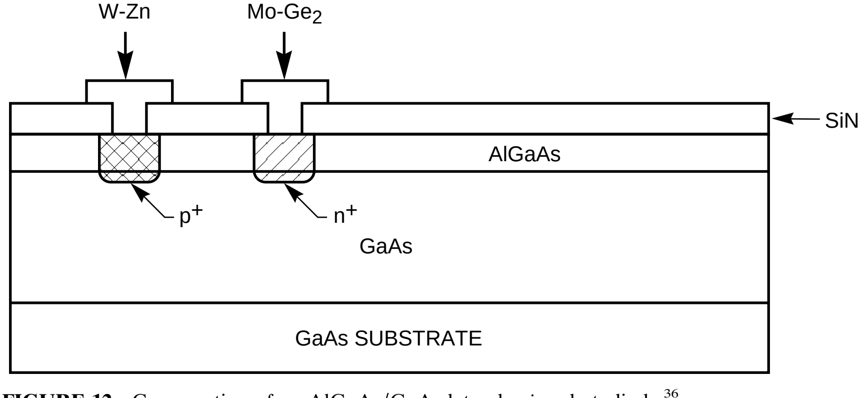

FIGURE 12 Cross section of an AlGaAs/GaAs lateral *p*-*i*-*n* photodiode.[36]

The higher-bandgap AlGaAs layer acts as a surface barrier, reducing the leakage currents. The low-bandgap GaAs layer absorbs the incoming light, and the generated carriers flow to the W-Zn and Mo-Ge_2 ohmic contacts which act as the *p* region and *n* region, respectively. The diffusion of zinc and germanium in the ohmic contacts forms a compositionally graded barrier at the AlGaAs/GaAs interface, rather than an abrupt interface. This smooth barrier helps the lateral *p-i-n* photodiode to have better speed than a lateral metal-semiconductor-metal photodetector. A comfortable spacing of 3 to 5 μm between the *p* and *n* regions gives high quantum efficiency and low capacitance, thus providing all the desirable properties of a vertical *p-i-n* structure and yet being easier to integrate.

Quantum Well Infrared Photodetector (QWIP)

QWIPs offer the possibility of achieving *long* wavelength (5000–10,000 nm) infrared detection by using materials whose bandgap normally allows them only to absorb light in the *short* wavelength (~10,000 nm) region, e.g., GaAs/AlGaAs. The use of thin (<500 Å) layers allows the absorbing wavelength to be controlled by material *geometry* rather than material *chemistry.*[37]

Before discussing the QWIPs, we take the liberty of explaining a few basic terms and concepts of quantum physics. Superlattices or quantum well structures consist of a stack of ultrathin semiconductor layers normally 50 to 500 Å in thickness. Molecular beam epitaxy (MBE) techniques are frequently employed to grow these structures because their characteristically slow growth rate of a few Angstroms/sec which helps achieve abrupt heterointerfaces. Two semiconductors of different compositions, when stacked together, form a heterointerface. Type III-V compound semiconductors such as AlGaAs/GaAs and InAlAs/InGaAs are the best candidates for growing quantum well structures, as they can be easily doped and their alloy composition readily changed to form semiconductor layers of different bandgaps. Tailoring the bandgap can alter the heterobarriers, creating exciting device results. When quantum well layers have thicknesses less than the electron mean free path (typically 50 to 100 Å), electron and holes cannot have their normal three-dimensional motion. This restricts carriers to move in two dimensions in the plane of the layer.[2,37] Because of this quantized motion, a new band of discrete energy levels is generated. Carriers no longer obey Boltzmann's statistics[1] and optical absorption becomes more complicated than the conventional band-to-band absorption given by Eq. (1). The absorption of light energy by a quantum well structure can cause an electron to jump from "multiple valence subbands" to "multiple conduction subbands," thereby enabling it to absorb light wavelengths not decided by the *material* properties (bandgap) of the semiconductor layers alone, but by its *geometrical* properties as well.

In QWIPs, the light energy transfers an electron in a bound state to an excited state in the continuum.[38] Figure 13 shows an AlGaAs/GaAs quantum well structure with L being the width of the well and V_1, V_2 being the barrier heights. The electron excited by the IR radiation is swept out of the doped GaAs well by applying an external electrical field. By controlling the barrier heights V_1, V_2, and quantum well width L, the spectral response of a QWIP can be changed for the desired IR window of 3000–5000 or 8000–12,000 nm.[38] A multiple period quantum well infrared photodetector is illustrated in Fig. 14.[32] The n^+-doped (2×10^{18} cm^{-3}) GaAs quantum wells are 40–100 Å and the undoped AlGaAs barriers are of 500-Å thickness. The multiple period stack is sandwiched between two n^+ GaAs-doped contacts. This photodetector has exhibited a blackbody D^* of 1×10^{10} cm/(Hz/W)$^{1/2}$ at 68 K for a cutoff wavelength of 10,700 nm. InGaAs/AlInAs superlattices have exhibited blackbody D^* of 2×10^{10} cm/(Hz/W)$^{1/2}$ at 120 K with peak responsivity at 4000 nm.[34]

In summary, QWIPs promise higher detectivity, good uniformity, high yield, multiple

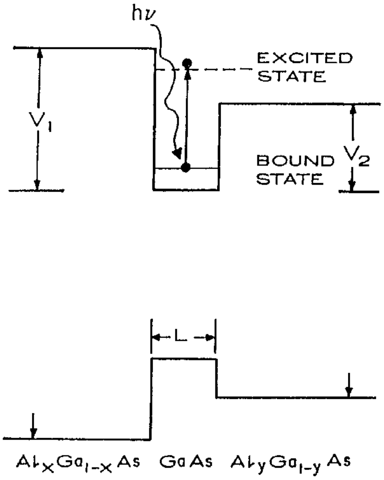

FIGURE 13 Infrared detection with an AlGaAs/GaAs quantum well.[38]

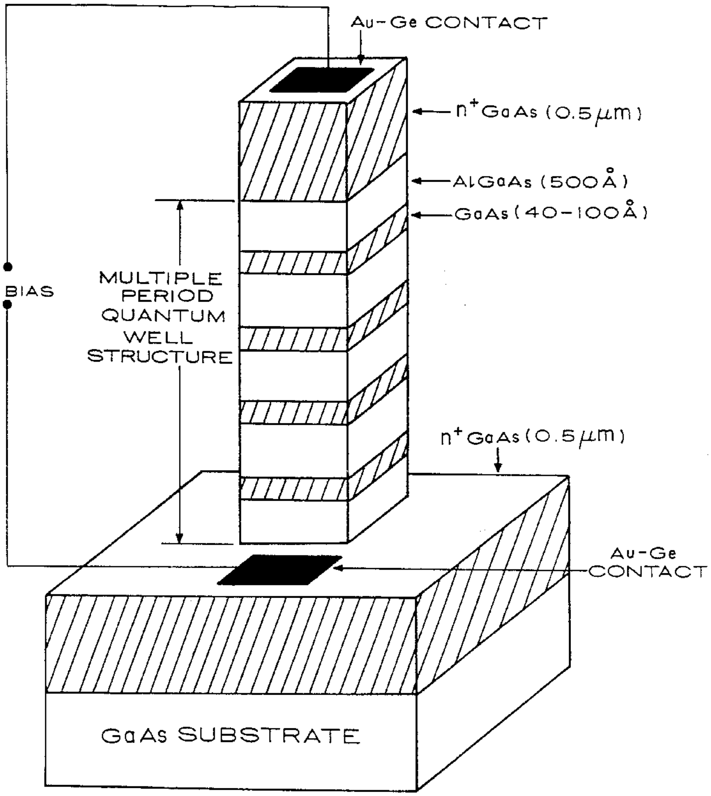

FIGURE 14 Multiple period AlGaAs/GaAs quantum well infrared photodetectors.

spectral windows, and intrinsic radiation hardness, thereby making them attractive for numerous imaging and spectroscopy applications.[39]

16.7 ACKNOWLEDGMENT

We sincerely acknowledge the support of EPITAXX, Inc., Amy Vasger, and Jennifer Romano (Sensors Unlimited) for preparing the manuscript, and Jim Rue for his technical discussions.

CHAPTER 17
HIGH-SPEED PHOTODETECTORS

J. E. Bowers
Y. G. Wey
Department of Electrical and Computer Engineering
University of California
Santa Barbara, California

17.1 GLOSSARY

A	area
A^{**}	modified effective Richardson constant
A_e, A_h	electron (hole) ionization parameters
B	bit rate
C_J	junction capacitance
C_P	pad capacitance
$D_e(D_h)$	diffusion coefficient for electrons (holes)
$\mathbf{E}$	electric field
$e_n(e_p)$	emission functions for electrons (holes)
F	frequency response
f	frequency
$f_{3\mathrm{dB}}$	3-dB bandwidth
G	photoconductor gain
H	transfer function
h	Plank's constant
I_d	dark current
I_{dm}	multiplied dark current
I_{du}	unmultiplied dark current
I_{ph}	photocurrent
i	current
$\langle i_{na}^2 \rangle$	amplifier noise power
J	current density

J_{DIFF}	diffusion component of current density
J_{DRIFT}	drift component of current density
$J_e(J_h)$	electron (hole) component of current density
k	ratio of electron to hole ionization coefficient
k_b	Boltzmann constant
L	absorption layer thickness
$L_e(L_h)$	diffusion length for electrons (holes)
L_s	series inductance
M	multiplication factor
$M_n(M_p)$	electron (hole) initiated multiplication factor
m	electron mass
$n(p)$	electron (hole) density
P	input optical flux
q	electron charge
R	reflectivity
R_L	load resistance
R_S	series resistance
$R_1(R_2)$	reflectivity of the surface (substrate) mirror in a resonant detector
T	temperature
t	time
$t_e,\ t_h$	transit time for electrons and holes
V_B	breakdown voltage
V_j	junction voltage
v_e, v_h	electron and hole velocities
W	thickness of the depleted region
x	position
α	absorption coefficient
α_{FC}	free carrier absorption inside the absorption layer
$\alpha_{\mathrm{FC}x}$	free carrier absorption outside the absorption layer
α_{IB}	interband absorption
α_i	electron ionization rate
α_s	scattering loss
β	propagation constant in a waveguide photodetector
β_i	hole ionization rate
Γ	confinement factor

ε	permittivity
η	quantum efficiency
κ	coupling coefficient to the waveguide of a waveguide detector
λ	wavelength
$\mu_e(\mu_h)$	mobility for electrons (holes)
ν	optical frequency
σ	charge density
σ_d	noise current spectral density
$\tau_e,\ \tau_h$	trapping time at a heterojunction for electrons (holes)
τ_{tr}	transit time
$\phi_{bc}(\phi_{bv})$	barrier height for the conduction band (valence band)
ω	angular frequency

17.2 INTRODUCTION

High-speed photodetectors are required for telecommunications systems, for high-capacity local area networks, and for instrumentation. Many different detector structures and materials are required to cover this range of applications. Silicon is one of the most commonly used detector materials for wavelengths from 0.4 to 1.0 μm, while Ge photodetectors are used at longer wavelengths up to 1.8 μm. Silicon and germanium have indirect bandgaps at these wavelengths, which result in relatively small bandwidth-efficiency products. Consequently, for high-speed applications, direct bandgap semiconductors such as III-V materials are more important and are the focus of this chapter. $Ga_{0.47}In_{0.53}As$ with a cutoff wavelength of 1.65 μm is especially useful for telecommunication photodetectors at 1.3 and 1.55 μm. GaAs has a cutoff wavelength around 0.9 μm and is ideal for visible and near infrared applications.

This chapter will focus on the physics and technology of high-speed photodetectors. The next section discusses the different structures that are possible. Later sections discuss some specific results and motivations for particular structures. The primary limitations to detector speed are discussed, followed by a description of specific photodetector systems. To supplement this chapter, the reader should refer to excellent chapters and articles written specifically about photodetectors,[1] photoconductors,[2] pin detectors,[3] avalanche photodetectors,[4] phototransistors,[5] and receivers.[6,7]

17.3 PHOTODETECTOR STRUCTURES

Many photodetector structures have been demonstrated and many more structures are possible. In this section, we classify the different possible structures and identify a few of the trade-offs. The optimum structure for a given application depends on the required bandwidth, efficiency, saturation power, linearity, ease of integration, and leakage current.

There are four common types of photodetectors: (1) photovoltaic detectors, (2) photoconductive detectors, (3) avalanche photodetectors (APD), and (4) phototransistors. Photovoltaic detectors have blocking contacts and operate under reverse bias. The blocking contact can be a reverse-biased *p-n* junction or a Schottky contact. The photoconductive detector has identical, nonblocking contacts such as two $n+$ regions in an undoped sample. The avalanche photodetector has a similar configuration to a photovoltaic detector except that it has a high field region that causes avalanching and results in gain in the detector. Improvements to the basic APD design include separate avalanche and gain regions (SAM APDs), and staircase APDs to increase the ratio of electron to hole (or hole to electron) multiplication rate. Phototransistors are three-terminal devices which have an integrated electronic gain region.

The second criterion is the contact type and configuration. The photogenerated carriers may be collected by means of (1) a vertical current collector, often a *p-n* or Schottky junction, (2) an interdigitated metal-semiconductor-metal (MSM) structure, or (3) a laterally grown or etched structure. These options are illustrated in Fig. 1*a*. PIN junctions are usually formed during the growth steps and tend to have low leakage current and high reliability.[8,9] Schottky junctions are simple to fabricate, but tend to have a large leakage current on narrow-gap semiconductors, such as InGaAs. MSM structures have the advantage of lower capacitance for a given cross-sectional area, but often have longer transit times, limited by the lithography capabilities possible in production. Experimental demonstrations with very fine lines (50 nm) have yielded high-speed devices with good quantum efficiencies. MSM detectors tend to be photoconductive detectors, but one could lower the capacitance for a given area of a PIN detector by using an interdigitated MSM structure with *p* and *n* regions under alternating metal fingers.

The third important aspect of photodetector design is the orientation of the light with respect to the wafer and the current collection region (Fig. 1*b*). Most commercial photodetectors are vertically illuminated and the device area is 10 μm in diameter or larger, which allows simple, high-yield packaging with single-mode optical fibers, or easy alignment to external bulk optics. The problem with this configuration is that the absorbing layer must be thin for a high-speed detector to keep the transit time of photogenerated carriers short. Consequently, the quantum efficiency is low, and single-pass vertically illuminated photodetectors tend to have bandwidth efficiency products around 30 GHz.[3] Bandwidth efficiency products are discussed in greater detail in Sec. 17.5. The bandwidth efficiency product can be increased by allowing two passes by reflecting the light off a metal layer or dielectric mirror.[10] Making a resonant cavity with multiple reflections at particular wavelengths should allow bandwidth efficiency products in excess of 100 GHz.[11–13] As will be seen below, essentially 100 percent quantum efficiency is possible with bandwidths up to 20 GHz, so there is no need for resonant detectors unless the required bandwidth is above 20 GHz or unless wavelength selectivity is needed as in a wavelength division multiplexed (WDM) system.

The other class of optical inputs are horizontally illuminated photodetectors (Fig. 1*c*). The simplest configuration is an edge-illuminated detector. The primary problem with an edge-illuminated detector is that the light is not guided. Diffraction of the incident light causes absorption to occur outside of the high-field region, and slow diffusion tails in the impulse response occur. A solution to this problem is the waveguide detector, where an optical waveguide confines the light to the high-field absorption region.[14–16] The waveguide efficiency product of this structure can be 100 to 200 GHz. However, it is limited by the capacitance of the structure, particularly if thin intrinsic layers are used for ultrahigh-speed devices. A solution to the capacitance limitation is a traveling wave photodetector where the incoming optical beam is velocity matched with the generated microwave signal.[17,18] The bandwidth efficiency product is then limited only by loss on the electrical transmission lines, and bandwidth efficiency products of hundreds of GHz are possible. Traveling wave detectors and, to a lesser extent, waveguide detectors have the important advantage that the volume of the light absorption can be quite large and, consequently, these detectors have much higher saturation powers.[19] Velocity matching in these structures requires quite narrow waveguides. Wu and Itoh[20] have suggested separating the parts of the optical waveguide with microwave delay lines to achieve velocity matching.

The fourth issue is the type of absorbing material (Fig. 1*d*) (1) bulk, (2) quantum well,

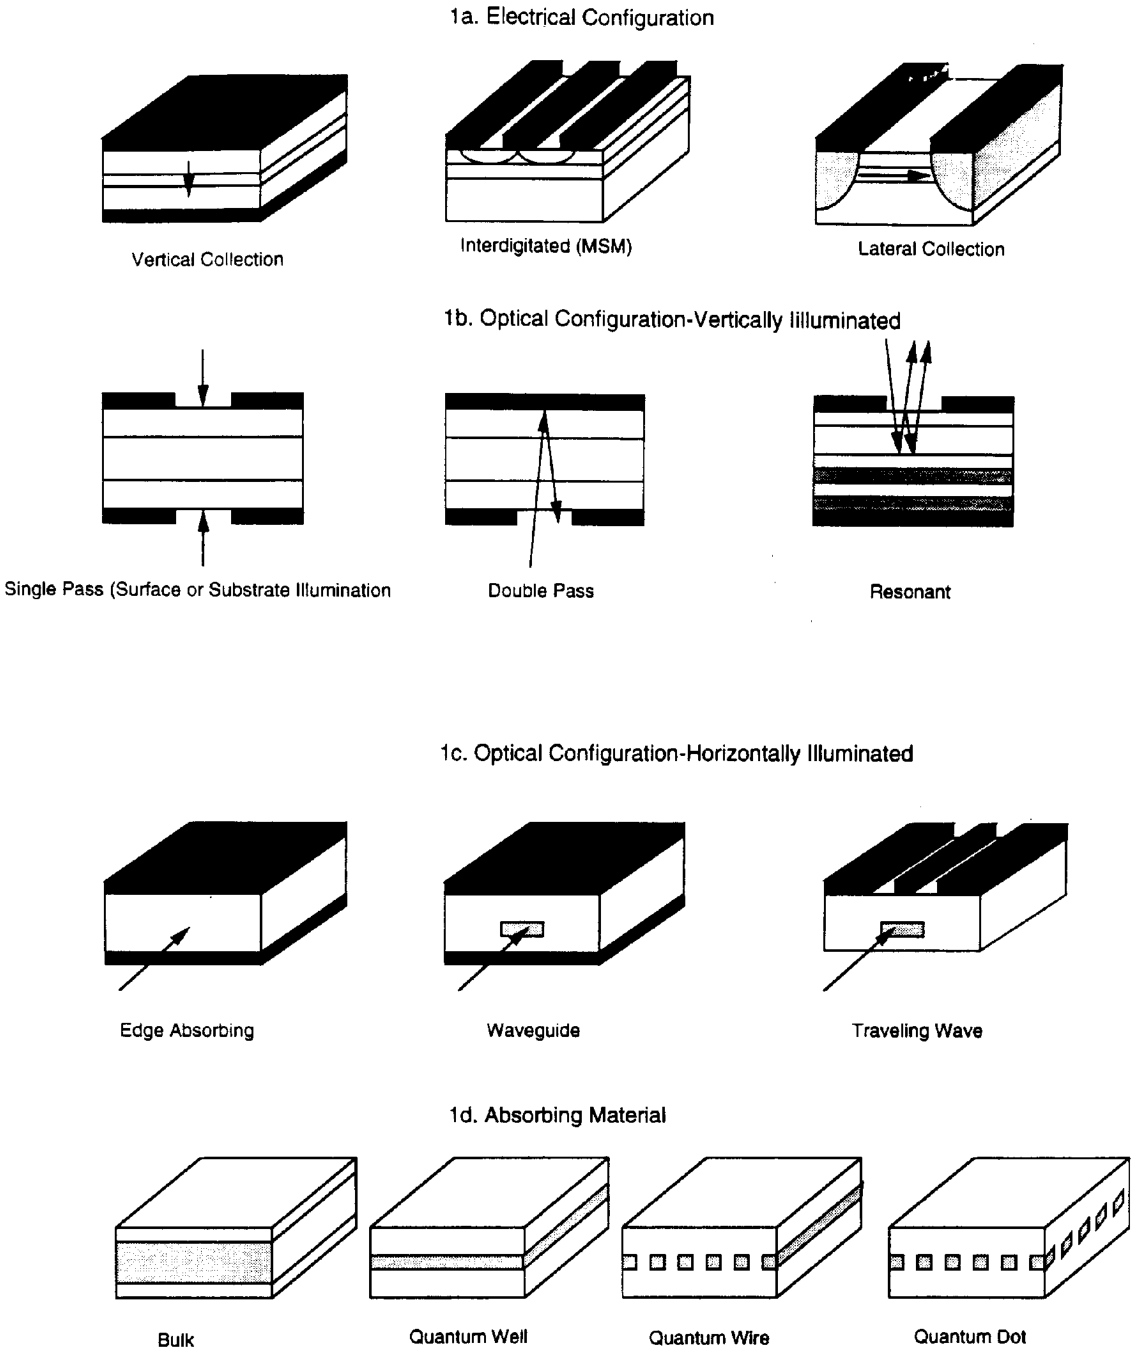

FIGURE 1 Schematic drawings of different types of photodetectors: (*a*) electrical configuration, (*b*) optical configuration-vertical illumination, (*c*) optical configuration-horizontal illumination, (*d*) absorbing material.

(3) quantum wire, (4) quantum dot, (5–7) strained quantum well, wire or dot, (8) *n*-*p*-*i*-*i* structure. The vast majority of commercial and experimental detectors use bulk material. However, quantum well detectors[21] are becoming increasingly important in photonic integrated circuits (PICs) because the absorbing quantum well material is also used in other parts of the PIC such as the laser. Quantum wire photodetectors[22] have potential advantages in terms of higher-bandwidth-efficiency products, but uniform quantum wires are rather difficult to fabricate. Quantum dot detectors have even higher peak absorption coefficients and more wavelength selectivity, but will probably have problems with slow impulse responses due to trapping of the carriers by the heterojunction. In other quantum-confined detectors, the carriers can be extracted along the quantum wire or well, and this problem can be avoided.[22]

The final classification is by means of the lifetime of the material. Conventional detectors have material lifetimes of typically 1 ns and achieve speed by using high field for rapid carrier collection. A second approach is to use low temperature (LT) grown material which has a very short lifetime, perhaps as low as 1 ps. A third approach is to damage the material by means of ion implantation. The final approach is to grow or diffuse in traps into the material such as iron[23] or gold.

If we combine these classifications, we find that 2600 types of photodetectors are possible, and additional subgroups such as superlattice APDs or SAGM APDs increase the total even further. In reality, about 100 types of detectors have been demonstrated. One of the points of this section is that improvements in one type of detector, such as adding a resonant cavity to a PIN detector, can be applied to other types of detectors, such as adding a resonant cavity to an APD. In the following section, we discuss in more detail some of the real limitations to the speed of a detector, and then apply this knowledge to a few important types of detectors.

17.4 SPEED LIMITATIONS

Generally speaking, the bandwidths of most photodetectors are limited by the following factors: (1) carrier transit time, (2) RC time constant, (3) diffusion current, (4) carrier trapping at heterojunctions, and (5) packaging. These limiting factors will be discussed in turn with specific application to *p*-*i*-*n* photodiodes.

Carrier Transit Time

In response to light absorbed in a material, the photogenerated carriers in the active region will travel across the high-field region and then be collected by the electrodes. As an example, Fig. 2*a* shows the *p*-*i*-*n* structure with a photogenerated electron-hole charge sheet of density σ. In response to the electric field, the electron will travel to the right and the hole to the left. This induces a displacement current and reduces the internal electric field (Fig. 2*b, c*), which is the cause of saturation in photodetectors. From Gauss's law the difference in the electric field at the position of electron or hole is

$$\Delta E = \frac{q\sigma}{\varepsilon} \tag{1}$$

where q is the electron charge, and ε is the permittivity. Due to the constant total voltage across the depletion region, the reduced electric field between the electron and hole will

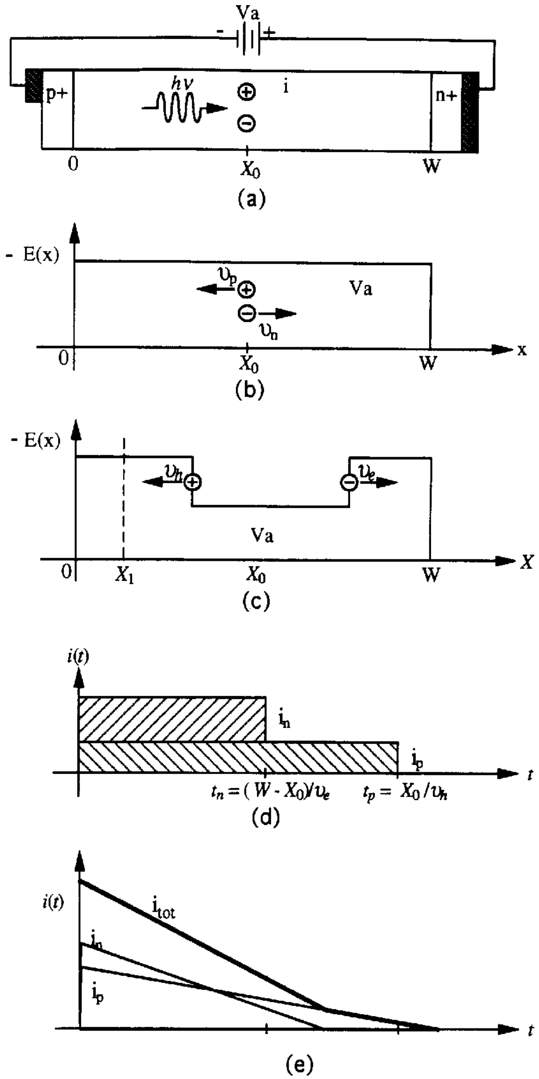

FIGURE 2 (*a*) Biased *p-i-n* structure. (*b*) Electrical field at the time when the electron-hole pairs are generated. (*c*) The perturbed electrical field due to the separated electron-hole pair. (*d*) The photocurrent due to single electron-hole pair. (*e*) The total photocurrent due to uniform illumination across the photodiode.

be compensated by the increased electric field outside. The rate of change of the electric field at the position $X = X_1$ is

$$\frac{\partial E}{\partial t} = -\frac{(v_e + v_h)\Delta E}{W} \tag{2}$$

where v_e and v_h are the saturation velocities for electrons and holes, respectively. The assumption of saturation velocities is valid at high fields. The displacement current is hence given by

$$i(t) = -\varepsilon A \frac{\partial E}{\partial t} = \frac{qAv_e\sigma}{W} + \frac{qv_h\sigma A}{W} \tag{3}$$

The current consists of two components due to the electron and hole currents. The electron current lasts for a time duration of $(W - X_0)/v_e$ and hole current of X_0/v_h. This is shown in Fig. 2*d*. Here, we note that if the fast carrier (i.e., electron) travels a longer distance, then we have a shorter pulse. The total electron and hole currents are given by

$$i_e(t) = \frac{qv_eA}{W} \int_0^W n(x, t)\, dx \tag{4}$$

$$i_h(t) = \frac{qv_hA}{W} \int_0^W p(x, t)\, dx \tag{5}$$

where $n(x, t)$ and $p(x, t)$ represent the electron and hole densities in the depletion region. The total current is the sum of Eqs. (4) and (5).

RC Time Constant

The RC time constant is determined by the equivalent circuit parameters of photodiode. For example, the intrinsic response of the *p-i-n* diode can be modeled as a current source in parallel with a junction capacitor. The diode series resistance, parasitic capacitance, and load impedance form the external circuit. Figure 3 shows the equivalent circuit of the *p-i-n* photodiode. The junction capacitance is defined by the edge of the depletion region (or space charge region). The series resistance is due to the ohmic contacts and bulk resistances. In addition, the parasitic capacitance depends on the metallization geometry. If the diode series resistance is R_S and a load resistance R_L is used to terminate the device, then the electrical 3-dB bandwidth can be approximated as

$$f_{3\text{dB}} = \frac{1}{2\pi(C_J + C_P)(R_L + R_S)} \tag{6}$$

If the photodiode is bonded by a section of gold wire, additional series inductance will be

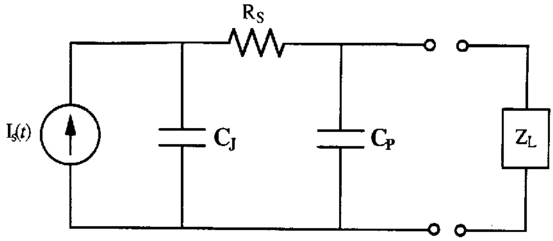

FIGURE 3 Equivalent circuit of a photodiode.

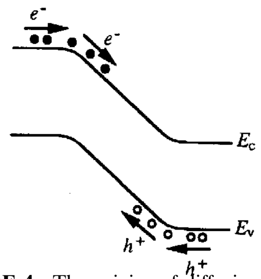

FIGURE 4 The origins of diffusion current.

included in the load impedance. The 3-dB bandwidth due to parasitics in this case is then given in Ref. 3.

Diffusion Current

Diffusion current is important in detectors in which significant absorption occurs in regions outside the high-field region. This effect is reduced to some extent by recombination in these highly doped contact layers. Those carriers within about one diffusion length of the depletion region will have a chance to diffuse into the active region. This diffusion current will contribute a slow tail to the detector impulse response (Fig. 4). The electron diffusion current at the edge of the depletion region is given by

$$J_e = qD_e \frac{\partial n}{\partial x} = qD_e \frac{\Delta n}{L_e} \tag{7a}$$

and

$$J_h = -qD_h \frac{\partial p}{\partial x} = qD_h \frac{\Delta p}{L_h} \tag{7b}$$

where $D_e(D_h)$ and $L_e(L_h)$ are the diffusion coefficient and diffusion length, respectively, for electrons (holes). The diffusion process is a relatively slow process compared with the drift process. Assuming the photocarrier density is n, with the Einstein relation and Eq. (7*a*), the electron diffusion current can be written as

$$J_{\text{DIFF}} = qn\mu_e\left(\frac{kT/q}{L_e}\right) \tag{8}$$

and the drift current term for electron can be written as

$$J_{\text{DRIF}} = qn\mu_e\mathbf{E} \tag{9}$$

where μ_e is the electron mobility and **E** is the electric field. For most devices the electric field inside the depletion region is an order of magnitude larger than $(kT/q)L_e$. For example, the hole diffusion length for GaAs is typically around 10 μm and electric field is very often over 10 kV/cm. However, the diffusion-current terms could last as long as the carrier lifetime and the charge content in the tail can be as large as the drift component due to the slow diffusion times. For high-speed detectors, the diffusion-current problem can be eliminated with a double-heterostructure design that limits the absorbing regions to the high-field intrinsic regions.[25]

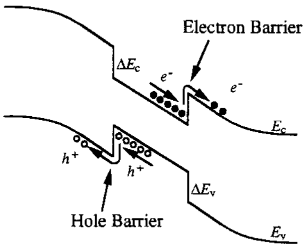

FIGURE 5 Heterostructure carrier trapping effect.

Carrier Trapping

Heterojunctions in photodetectors cause carrier trapping of electrons at conduction band discontinuities and trapping of holes at valence band discontinuities (Fig. 5). Hole trapping is a significant problem in long-wavelength photodetectors because of the large valence band discontinuity at the InP/InGaAs heterojunction. Usually, the emission rate is approximated by thermionic emission. If the interface deep-level recombination rate is significant, the total emission rate will be the sum of the two emission rates. The emission functions for electrons and holes are given by

$$e_n(t) = (1/\tau_e)\exp(-t/\tau_e)u(t) \tag{10a}$$

$$e_p(t) = (1/\tau_h)\exp(-t/\tau_h)u(t) \tag{10b}$$

where $\tau_e(\tau_h)$ represents the emission time constant for electron (hole) and $u(t)$ is the step function. The rates of thermionic emission of trapped carrier are related to the Schottky barrier height due to the bandgap discontinuity:

$$1/\tau_e = B\exp(-\phi_{be}/kT) \tag{11}$$

where B is a constant and ϕ_{bc} is the barrier height for the conduction band. The response of the carrier-trap current in time domain is often obtained by convolving an intrinsic current source with the emission function. Since the applied bias will reduce the barrier height, sufficient device bias therefore will increase the emission rate. In order to reduce the barrier height, superlattice or compositional grading is often added at the heterointerface.[25]

Packaging

The external connections to the photodetector often limit the detector performance. Another problem is that the photodiode is a high impedance load and the device has a reflection coefficient close to unity. One solution to this problem is to integrate a matching resistor with the device.[25] This can usually be added using the lower contact layer without adding any additional mask or process steps. Figure 6 shows a Smith chart plot of the impedance of a typical photodetector along with the impedance of a device with an integrated matching resistor. A good match up to 40 GHz is achieved. The disadvantage of a load resistor is the reduction in effective quantum efficiency by a factor of 2 since half of the photocurrent goes through the matching resistor. However, since the load resistance is now one-half, the RC time constant is also cut in half. Bandwidths in excess of 100 GHz have been achieved with quite large devices ($7 \times 7\ \mu\text{m}^2$) in this way. A second problem with very high speed devices is the difficulty in building external bias circuits without resonances in the millimeter range. The necessary bias capacitor and load resistor can be integrated with *p-i-n* photodetector without adding any additional mask or process steps by using a large-area *p-i-n* region as the capacitor and using the lower contact layer as the series resistor.[23] A photograph of the device is shown in Fig. 7 along with the device performance. In this case, bandwidths in excess of 100 GHz were achieved.

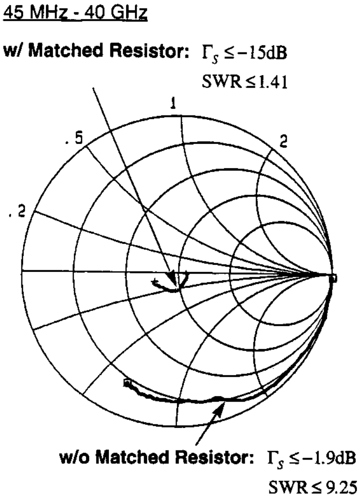

FIGURE 6 Smith chart of the impedance of typical photodiodes and photodiodes with integrated matching resistors.

Optical fiber alignment and packaging are now quite standard. Simplified alignment by means of holes etched in the substrate of back-illuminated photodiodes may allow passive alignment of optical fibers. The photodetectors must be antireflection coated to reduce the reflection to air or optical epoxy. Single dielectric layers are typically used to minimize the reflection at one wavelength. Braun et al.[26] have achieved minimum reflectivity at multiple wavelengths with one dielectric layer by using one of the semiconductor layers in a multiple antireflectivity design.

17.5 P-I-N PHOTODETECTORS

Vertically Illuminated *p-i-n* Photodiode

In order to increase the frequency response of the vertically illuminated *p-i-n* photodiode, the efficiency is always sacrificed. As the active layer thickness is reduced, the transit time decreases, and the optical absorption decreases, and there is a trade-off between the efficiency and speed. The external quantum efficiency for a surface-illuminated *p-i-n* diode is given by

$$\eta = (1 - R) \times (1 - e^{-\alpha L}) \tag{12}$$

where R is the surface reflection, α is the absorption coefficient, and L is the active layer thickness. Since the absorption coefficient is a function of wavelength $\alpha = \alpha(\lambda)$, usually α decreases as λ increases. Thus, the diode intrinsic response is wavelength-dependent. We can easily see the effect of light absorption on the transit-time-limited bandwidth by

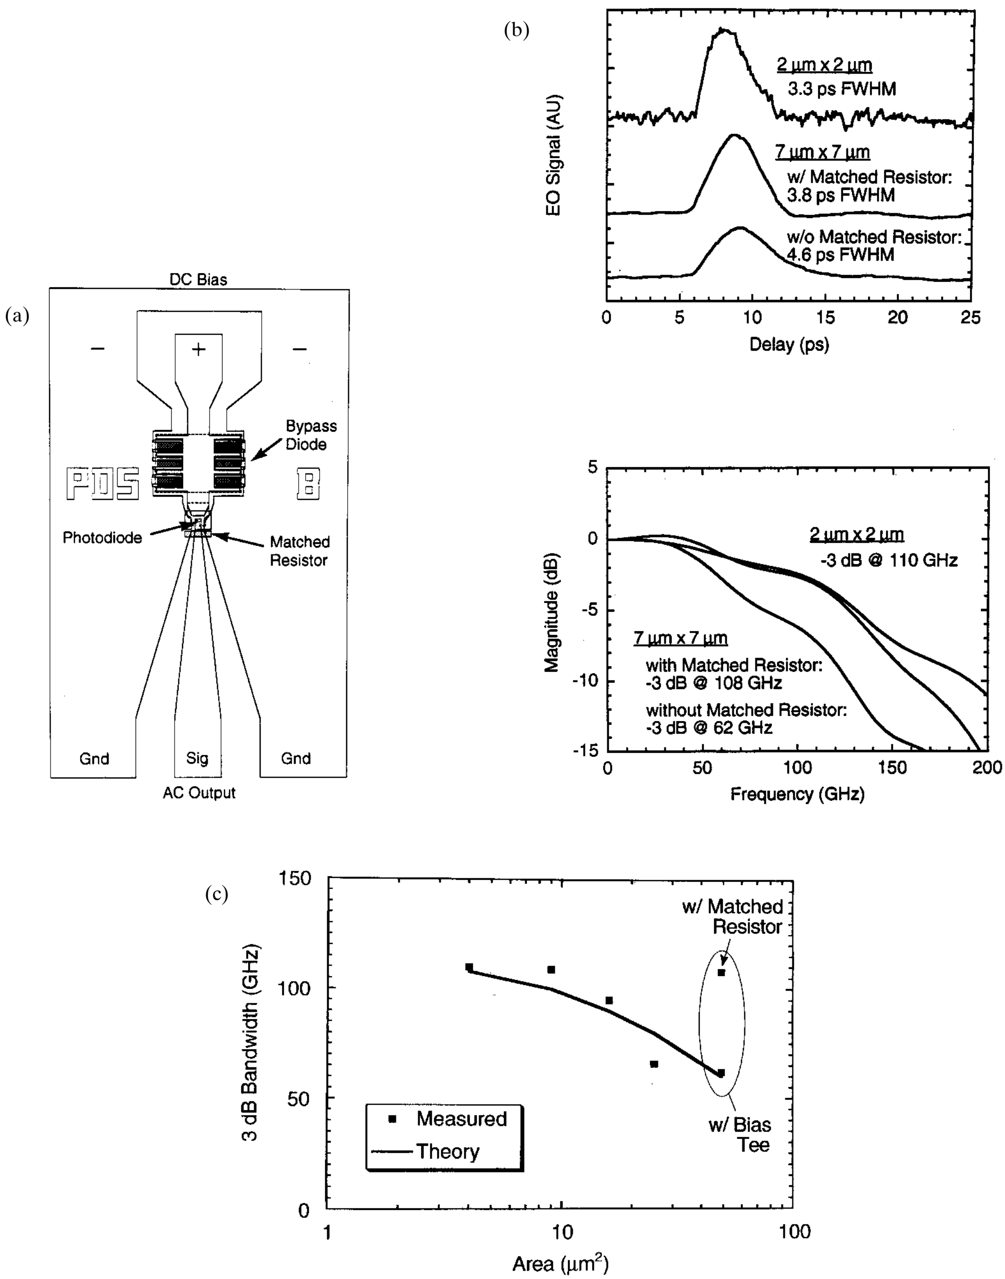

FIGURE 7 (*a*) Schematic diagram of a *p-i-n* photodiode with integrated matching resistor and bias circuit. (*b*) Impulse response of a 2-µm by 2-µm pin detector compared to 7-µm by 7-µm detectors with and without matching resistors. (*After Ref. 25.*) (*c*) Dependence of measured bandwidth on detector area and comparison to the theory presented in the text.

comparing the transit-time response[3,24] for two limiting cases for $\alpha L \rightarrow 0$ and $\alpha L \rightarrow \infty$ when $t_e = t_h = \tau_r$. The transit-time frequency response for a uniformly illuminated detector is

$$|F(\omega)_{\alpha L \rightarrow 0}| = \frac{2}{\omega \tau_{tr}} \left[1 + \frac{\sin^2 \left(\dfrac{\omega \tau_{tr}}{2} \right)}{\left(\dfrac{\omega \tau_{tr}}{2} \right)} - 2 \frac{\sin (\omega \tau_{tr})}{(\omega \tau_{tr})} \right]^{1/2} \tag{13}$$

For electron-hole pairs generated near the *p* side of the intrinsic region, electrons travel across the *i* region, and the frequency response is given by

$$|F(\omega)_{\alpha L \rightarrow \infty}| = \left| \frac{\sin \left(\dfrac{\omega \tau_{tr}}{2} \right)}{\left(\dfrac{\omega \tau_{tr}}{2} \right)} \right| \tag{14}$$
